Engineering the sign of circularly polarized emission in achiral polymer – chiral small molecule blends as a function of blend ratio†‡

Li Wan,^{§¶} Jessica Wade,^{§^{abc}} Xuhua Wang,^{§^{abc}} Alasdair J. Campbell^{||^{ac}} and Matthew J. Fuchter^{||^{bc}}

Circularly polarized organic light-emitting diodes (CP-OLEDs) that demonstrate both state-of-the-art efficiency and strongly circularly polarized (CP) electroluminescence have proved a considerable technical challenge. Furthermore, multiple factors – from film thickness to device structure – have been shown to influence the sign of the emitted CP light, independent of the handedness (absolute stereochemistry) of the chiral emitter. Here we report CP-OLEDs using a blend of poly(9,9-dioctylfluorene-*alt*-bithiophene) (F8T2) and a chiral small molecule additive (1-aza[6]helicene, aza[6]H). We demonstrate CP-OLEDs with an impressive electroluminescence dissymmetry (g_{EL}) > 0.3 and a current efficiency of 0.53 cd A⁻¹ and brightness of 3023 cd m⁻². While at low aza[6]H loadings, F8T2 blends are consistent with previous observations of CP dissymmetric inversion as a function of film thickness/excitation mode, a higher loading of aza[6]H (~40 wt%) removes such dependencies while retaining excellent g -factors. The materials disclosed will allow for further mechanistic studies of chiral polymeric materials and provide new opportunities for chiroptical optimisation in films and devices.

Introduction

The use of chiral organic semiconductors in optoelectronic devices has attracted considerable scientific interest. One reason for this is the potential to improve the energy efficiency of organic light emitting diodes (OLEDs): the direct emission of CP luminescence from the active layers of OLEDs could significantly reduce optical losses caused by the anti-glare filters used in state-of-the-art displays.¹ A key figure of merit for CP-OLEDs is the degree of CP luminescence, which can be defined by the dissymmetry or g -factor (eqn (1)).

$$g = \frac{I_L - I_R}{\frac{1}{2}(I_L + I_R)} \quad (1)$$

In the pursuit of large g -factors and high quantum efficiencies, a wide range of CP emissive materials have been explored, including light-emitting polymers (LEPs), phosphorescent metal complexes, thermally activated delayed fluorescent (TADF) emitters and perovskites.² Although triplet-harvesting TADF and phosphorescent emitters can achieve high device efficiencies, the luminescence g -factors are generally negligible ($g \approx 10^{-2}$ – 10^{-4}).^{3–5} On the other hand, LEPs display large g -factors (e.g. $g \approx 1.0$), and the potential to optimise device performance through device engineering and molecular design. The majority of reported chiral LEPs can be categorized into two groups: (1) LEPs with chiral side chains;^{6,7} and (2) blend systems consisting of device-optimized achiral LEPs and non-emissive chiral small molecule additives.^{8–11} Our previous studies have demonstrated that such LEPs have very large intrinsic chiroptical activity without the need for polymer alignment, partly due to the formation of chiral polymer phases with large inter-chain excitonic coupling.^{8,10,12}

To date, much of our work on achiral LEPs with chiral additives has concerned the use of poly(9,9-dioctylfluorene-*alt*-benzothiadiazole) (F8BT) blended with 1-aza[6]helicene (hereafter, aza[6]H). Through rigorous studies of this key blend system, we have discovered a number of interesting trends with respect to the sign of the emitted CP light relative to the handedness/absolute stereochemistry of the chiral active layer. These include luminescence dissymmetry factors that depend on film thickness,¹³ device architecture,⁸ and whether the CP emission is photo- or electro-luminescence. However, one parameter that has not been well

explored is the influence of the LEP and chiral small molecule additive blend ratio and the effect that such a ratio has on chiroptical activity and device performance.

In this study, we focus on an alternative polymer: poly(9,9-dioctylfluorene-*alt*-bithiophene) (F8T2, Fig. 1a), an archetypal semiconducting polymer that has been extensively studied as the (non-chiral) active layer in OLEDs,¹⁴ organic field-effect transistors,¹⁵ and organic solar cells.¹⁶ In separate work, it has been demonstrated that, in enantiopure chiral solvents, F8T2 can form helical π - π aggregates which exhibit circular dichroism (CD) and CP photoluminescence (CP PL) ($|g_{abs}| \approx 0.1$, $|g_{PL}| \approx 0.065$).^{17,18} Here we show that F8T2:aza[6]H blends can be used as the active layer in CP-OLEDs and allow for the observation of fascinating dependencies in the g_{PL} and g_{EL} data on blend ratio. In contrast to the polymeric systems we have previously studied, F8T2:[P]/[M]-aza[6]H blends can tolerate a much higher aza[6]H loading, due to the similar HOMO levels of the two materials (~ 5.4 eV).¹⁹ Enabled by this potential for increased aza[6]H loading, we find that the sign of CP luminescence depends not only on active layer thickness, but also on the wt% of aza[6]H. These intriguing results further highlight the fascinating chiroptical phenomena at play in achiral LEP – chiral additive blends and expands the repertoire of polymers compatible with this approach for effective polymer CP-OLEDs.

Results and discussion

The optical absorption and CD spectra of F8T2:10 wt% aza[6]H blends have previously been reported by our group (Fig. 1b and Fig. S25 in Ref¹⁰). Reflectance corrected F8T2:10 wt% aza[6]H

thin films exhibit a large thickness independent g_{abs} of ~ 1.3 ,¹⁰ which we have recently exploited as the active layers of CP photodetectors.²⁰ Here, we focus on the luminescence, and measure the CP emission of F8T2:aza[6]H for the first time. Thin film and device fabrication and all other experimental procedures are described in the Experimental Details and the ESI† (Fig. S1, ESI†).

Following our previously optimized annealing process,¹⁰ the handedness of the CP PL of F8T2:10 wt% aza[6]H is found to invert as film thickness is increased (Fig. 1c–e). For example, for F8T2:[M], left-handed (LH) CP PL is observed in thin (72 nm) films, whilst right-handed (RH) CP PL is observed when film thickness > 100 nm (Fig. 1c and d). [P]- and [M]-aza[6]H blended F8T2 films exhibit a maximal g_{PL} ($\lambda = 546$ nm) = +0.62 and –0.52 for 100 nm thick films, respectively. Similar to the PL, we also observe an inversion of g_{EL} with increasing active layer thickness (Fig. 1f–h) in CP-OLEDs (ITO/PEDOT:PSS/TFB/F8T2:aza[6]H/Ca/Al). Together with our previous data,^{11,13} the inversion of g_{PL} and g_{EL} as a function of film thickness has now been robustly observed in two polymeric systems, with crossover points at ~ 120 nm (F8BT¹³) and ~ 80 nm (F8T2), respectively (Fig. S2, ESI†). It should also be highlighted that, for the range of active layers considered (60–140 nm), the g_{EL} and g_{PL} of F8T2:10 wt% aza[6]H are of opposite signs. This fascinating chiroptical phenomenon was also apparent in our inverted F8BT:10 wt% aza[6]H devices,⁷ and may be due to the complex processes involved with electronically generated excitons in chiral LEP phases. The consistency of this experimental observation in two different polymers suggests a more fundamental origin, which requires further investigation.

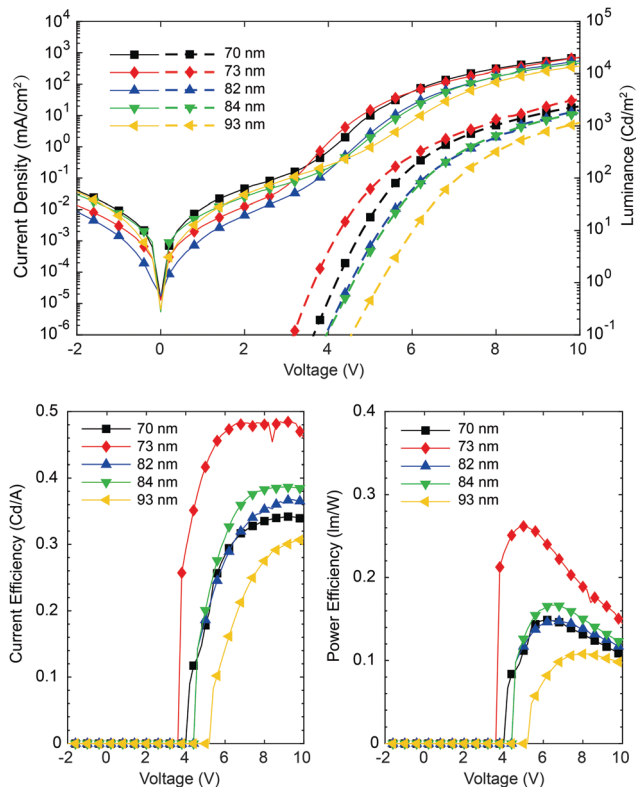

Fig. 2 J - V - L , CE and PE curves of F8T2:aza[6]H devices with increasing active layer thickness.

The J - V - L , current efficient (CE) and power efficiency (PE) of F8T2:10 wt% aza[6]H CP OLEDs with various active layer thickness are shown in Fig. 2. This thickness range covers the crossover points of g_{PL} and g_{EL} (Fig. 1c and f, see absorption and CD spectra for this range in Fig. 4a and c). Due to the known low PLQE of F8T2,^{14,19} the turn-on voltage V_{on} ranged from 3.5 V to 5.4 V (at 1.0 cd m⁻²) and brightness from 1120 cd m⁻² to 3200 cd m⁻² (at 10 V). We observed the best device performance with the thickness of 73 nm in terms of the efficiency (CE = 0.48 cd A⁻¹) and luminance (3200 cd m⁻²).

Upon further evaluation of the F8T2:aza[6]H blends, it became apparent that F8T2 allowed for increased aza[6]H loading than F8BT or PFO. Previously, we found that increasing the wt% of aza[6]H > 10% in F8BT:aza[6]H blends resulted in a dramatic decrease of brightness, which renders it challenging to reliably measure g_{EL} .^{11,13} Given the similar HOMO levels of F8T2 and aza[6]H (~5.4 eV), a wider range of blend ratios can be studied without aza[6]H acting as a hole trap. We therefore conducted a more extensive inspection of the impact on the relative wt% of the blend components (LEP, aza[6]H) on the chiroptical properties for the first time. The wt% aza[6]H was varied from 10 wt% to 40 wt% (Fig. 4). We note that ratios higher than 40 wt% were not possible due to the formation of crystalline aza[6]H domains, resulting in poor morphology and device operation. As shown in Fig. 4b and Fig. S3 (ESI[†]), the electronic transitions of aza[6]H ($\lambda = 350$ nm) become visible in the UV-Vis spectra of high wt% blends. For aza[6]H > 20 wt%, polymer emission in the PL spectrum (Fig. S4, ESI[†]) is also blue-shifted, which we suggest is caused by disruption of

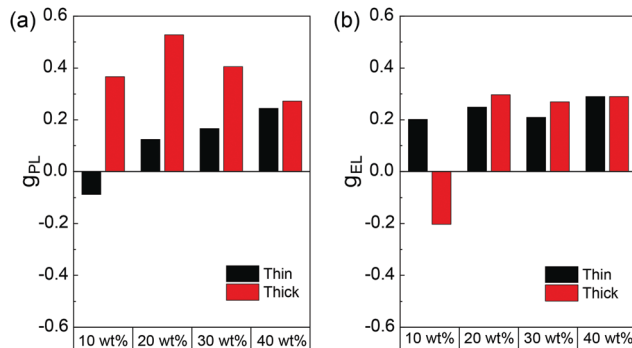

Fig. 3 (a) g_{PL} and (b) g_{EL} of thin (~60 nm) and thick (~100 nm) F8T2:[P]-aza[6]H films and devices.

polymer chain packing by excess aza[6]H. This, in turn, reduces the effective conjugation length and results in higher energy emission.^{21,22} Importantly, the dissymmetry inversion as a function of active layer thickness is no longer observed at the maximum aza[6]H loading (40 wt%): g_{PL} and g_{EL} have the same sign ($g \sim 0.3$, Fig. 3). Furthermore, the ellipticity and strength of the Cotton bands of the lowest energy electronic transition decreases as aza[6]H loading is increased (Fig. 4d). To rigorously assess the thickness dependence of CP EL it is essential to combine optical modelling with device engineering (e.g. modifying the electrode reflectivity, tuning the position of the recombination zone), as has been previously demonstrated.^{13,23,24}

The device efficiency of F8T2:[P]-aza[6]H CP OLEDs with thin active layers (60 nm, Fig. 5) increases with aza[6]H wt%. In fact,

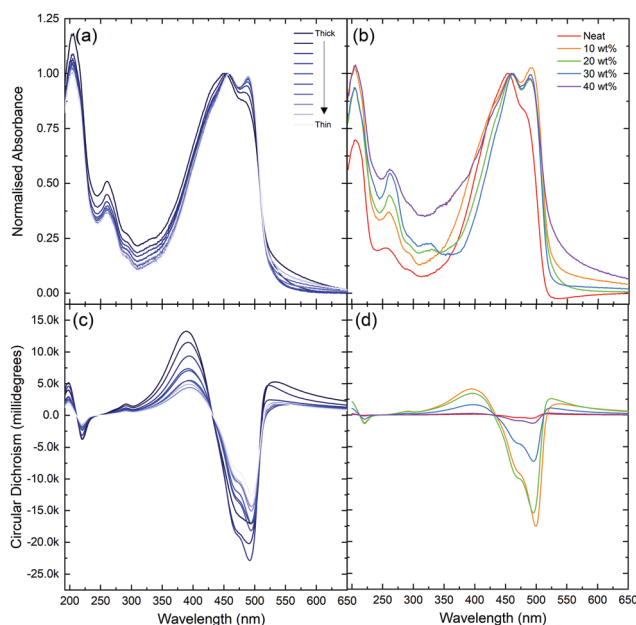

Fig. 4 (a and b) Absorption and (c and d) circular dichroism spectra for (a and d) F8T2:10 wt% [M]-aza[6]H blends as a function of film thickness and (b and d) 100 nm thick F8T2:[M]-aza[6]H blends as a function of aza[6]H loading ratio.

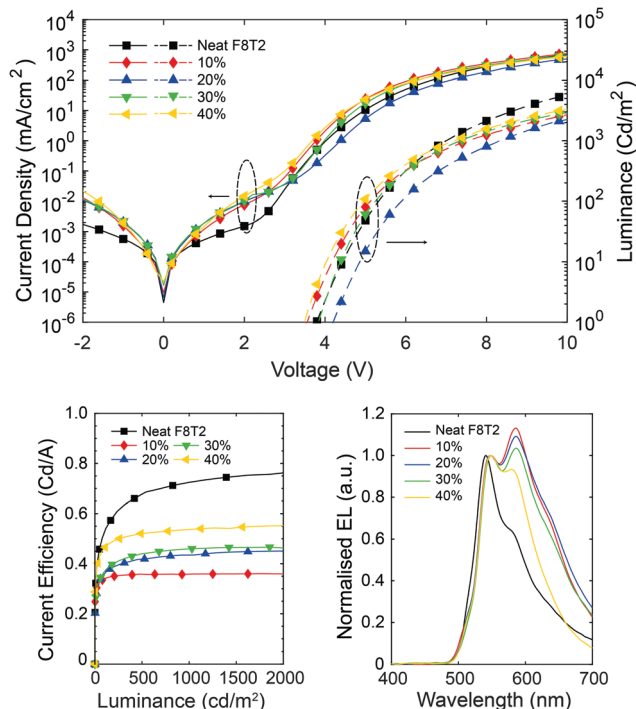

Fig. 5 J - V - L , efficiency curves and EL of F8T2:[*P*]-aza[6]H 60 nm devices with increasing blending ratios of [*P*]-aza[6]H.

the 40 wt% aza[6]H device exhibits the best device performance ($CE = 0.53 \text{ cd A}^{-1}$, $L = 3020 \text{ cd m}^{-2}$ at 10 V) of any aza[6]H blend devices considered here. This impressive device performance indicates that by carefully considering the energy levels of both the achiral polymer and chiral small molecule additive, CP OLEDs with both high g_{EL} and improved device performance can be realized.

Taken together, this study further confirms that multiple factors influence the sign of the emitted CP light for these materials, independent of the handedness (absolute stereochemistry) of the chiral (polymer) emitter. As described by Duong and co-workers, the coupling of excited states in conjugated LEPs results in degenerate S_1 states that give rise to CP PL.¹⁸ This implies that in the majority of cases, the sign of CP PL should be consistent with the sign of the CD. However, our previously reported CP-OLEDs,^{8,9,13} and this work, indicate that film thickness, device architecture and active layer composition also influence the CP emission. The oppositely handed g_{PL} and g_{EL} in F8T2:10 wt% aza[6]H blends also indicate that the mechanisms that underpin the strong CP EL in LEPs are not the same as those that can be used to rationalize the CP PL.

We further show that CP dissymmetry inversion, as a function of active layer thickness, is no longer observed at increased aza[6]H loadings. We attribute this outcome to an increase in the proportion of aza[6]H in the blend, which has a significant effect on polymer structure and packing. Ultimately, it is the structural change of the chiral polymeric phase that determines such chiroptical behaviour,^{8,10,12} which are impacted by aza[6]H loading. Despite the effect on polymer morphology, very respectable levels of g_{PL} and g_{EL} are still achieved (~ 0.3) at high aza[6]H loadings.

Conclusions

Chiral emitters based on LEPs continue to achieve luminescence dissymmetries orders of magnitudes greater than other systems (e.g. $g \approx 1.0$). In particular, achiral LEP – chiral small molecule additive blends have presented a simple approach to generate strong CP luminescence of tunable handedness with impressive device performances and many interesting chiroptical phenomena have already been reported. In this study, we have expanded the number of polymers suited to such an approach, through the use of the LEP F8T2. F8T2 blends with low aza[6]H loading further confirm previous observations that highly dissymmetric CP luminescence can be achieved, where the sign of the CP light is thickness dependent and dependent on whether the excitons are optically or electronically generated within the active layer. The same is not true for high wt% aza[6]H blends however, where the overall handedness of the emitted light depends solely on the absolute stereochemistry of the active layer (i.e. F8T2:40 wt% [*P*]-aza[6]H thin films $g_{\text{EL}} \sim +0.3$, thick films $g_{\text{EL}} \sim +0.3$). It is evident that further experimental (for example, evaluating how excited state populations are impacted by drift currents through chiral polymer phases) and theoretical work is required to fully understand and optimize these chiral LEP systems and the CP handedness dependencies and such studies are ongoing in our group.

Materials and methods

Materials

1-Aza[6]helicene was prepared as previously reported and separated using preparative chiral HPLC. F8T2 was provided by Sumitomo Chemical Co., Ltd and used without further purification.

Solution preparation and thin film deposition

F8T2 was dissolved with a variety of mixing ratios of aza[6]helicene (0, 10 wt%, 20 wt%, 30 wt% and 40 wt%) in toluene (15 mg mL^{-1}). Thin films of various thickness are controlled by spin speed (1200–5000 rpm) and deposited on fused silica substrates. All annealed samples were annealed for 10 min under a nitrogen atmosphere (glovebox, $<0.1 \text{ ppm H}_2\text{O}$, $<0.1 \text{ ppm O}_2$). The film thicknesses of all films were measured using a Dektak 150 surface profiler.

OLED fabrication and characterization

Prepatterned ITO substrates (Thin Film Devices Inc) were rinsed in an ultrasonic bath with acetone, isopropyl alcohol (IPA) and Hellmanex III (Hellma GmbH) and deionized water before deposition of poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) (H.C. Starck GmbH) (55 nm). Then, aza[6]helicene blended F8T2 with varying thickness was spin-coated (1200–5000 rpm) onto PEDOT:PSS. Afterwards, a 25 nm Ca layer capped by a 100 nm Al layer was thermally evaporated onto the organic layer under vacuum level of 1×10^{-7} mbar. J - V - L characterization (pixel area = 0.045 cm^2) was performed using a Keithley 2400 and Konica

Minolta LS-110 Luminance Meter *via* a computer controlled Labview program. EL spectra were measured using an Ocean Optics USB 2000 charge-coupled device spectrophotometer.

Photophysical and morphology characterisation

Absorption and PL spectra of the blends at various thickness and blending ratios were measured by a Cary 300 UV-Vis spectrometer (Agilent Technologies) and a FluoroMax-3 (Horiba Jobin Yvon), respectively. Left-handed and right-handed CP PL spectra were acquired using a linear polarizer and quarter-wave plate prior to a FluoroMax-3 spectrometer. The background introduced by the polarizer, the quarter-wave plate and the silica substrates were corrected by using the CP PL results from a blank sample. The dissymmetry factor g in the CP PL spectra was calculated from the equation $g = 2(I_L - I_R)/(I_L + I_R)$, $|g| \leq 2$. I_L and I_R are the left-handed and right-handed emission intensities respectively. A similar method was used to analyse the CP EL spectra. EL spectra from the OLED was recorded using an Ocean Optics USB 2000 charge-coupled spectrophotometer.
