Detection & identification of hazardous narcotics and new psychoactive substances using Fourier transform infrared spectroscopy (FTIR)

Samuel F. Williams,^a Robert Stokes,^b Pik Leung Tang^b and Ana M. Blanco-Rodriguez^b

According to the latest World Drug Report, released by the United Nations Office on Drugs and Crime (UNODC), drug use is up 30% over the past decade and there are more drugs, and more types of drugs, than ever. Herein we use Fourier Transform Infrared Spectroscopy (FTIR) for the rapid ID of narcotics in a range of concentrations – from pure forms (as it is likely to be smuggled & transported) to street forms, often mixed with conventional cutting agents. Using FTIR, 75% of “street sample” narcotics were rapidly identified, and the effects of cutting agents on identification (ID) were also investigated. The limit of detection of MDMA was assessed, with a correct ID shown from 25% w/v. Concentration was correlated with Hit Quality Index, showing the capability of FTIR use in concentration estimation.

Introduction

Consumption of illicit drugs is on the rise globally. As of the latest report from the United Nations Office on Drugs and Crime, a predicted 5.4% of the global population aged 15–64, around 269 million people, consumed an illegal drug during 2018. By 2030 an 11% increase of annual drug users is predicted, based solely on population growth. However the link between urbanisation and drug use, due to increased unemployment, poverty and crime rates in more urbanised areas, will likely mean a further increase in drug users, as more and more areas become urbanised to keep up with the demands of the ever-increasing human population.¹ Cannabis was used by around 200 million people in 2019, making it the most popular drug globally, compared to 62 million users of opioids. However, opioids accounted for an estimated loss of 18 million “healthy” years of life lost due to causing disability or premature death, making the opioid class of drugs the greatest threat to life.¹

In the UK the illicit drugs market is estimated to be worth around £9.4 billion per year and drug poisoning deaths are currently at record levels.² 4400 deaths in England and Wales were recorded due to drug misuse in 2019 according to the Office of National Statistics, increasing to 4561 deaths in 2020, 60.9% higher than a decade earlier in 2010. Opiates, such as heroin and morphine, accounted for just under half, 49.6%, of overdoses in England and Wales.^{3,4} In response to the findings that current drug misuse costs the UK £20 billion per year, the UK government has promised a 10 year plan, investing over £3

billion, targeted at breaking drugs supply chains, expanding the treatment of current addicts and improving socioeconomic conditions of society to prevent onset of addiction before it begins. The UK government has stated that by 2025 it hopes to have prevented 1000 early deaths due to drug misuse and increased capacity for treating current drug addicts by 20%.⁵

Current techniques used for narcotics identification (ID) include mass spectrometry (MS) – the current gold standard for drug analysis often combined with chromatographic techniques such as high-performance liquid chromatography, X-ray diffractometry (used to assess crystalline samples) and immunoassays (allowing for ID of metabolised drugs in urine). Whilst very powerful, these methods are generally all performed in a lab setting, potentially making them less useable for rapid analysis in field operations.^{6,7} Portable GC-MS and MS systems are available but generally at a higher price point and this again, could limit widespread deployment in community settings. Infrared, Raman and Ion Mobility Spectrometry (IMS) (used in conjunction with commercially available spectral libraries), colourimetric and microcrystalline tests are all common ID methods which can be performed at collection sites by operators without advanced laboratory training to provide sample information, although only qualitatively in the latter two methods. Infrared, and Raman all provide quantitative analysis on a vast array of narcotics at the point of care, without destroying the sample.⁸ Fast and accurate analysis of street drug samples can provide information to inform safety and operational response, and in some cases treatment options for users of narcotics. If more samples can be analysed quickly in the field, by non-scientific users, rather than sent to a lab, then costs can be reduced, and operational momentum maintained in some cases.

Fourier Transform Infrared spectroscopy (FTIR) is used to identify the chemical fingerprint of samples based on the absorption of infrared by chemical bond vibration, and as such is applicable for use in ID of unknown samples. Previous studies have shown the capability of FTIR in profiling illicit drugs such as cocaine, and as part of the UK government's strategy of breaking the supply lines in illegal drug networks, further investments have been made in 2021 to equip the London Metropolitan Police with FTIR spectrometers to aid in ID of seized samples suspected of containing controlled and illegal substances.^{9–11}

In this study we aimed to investigate the utility of FTIR methods in an “out-of-lab” based setting in counter-narcotics operations by analysing 184 illicit narcotic samples previously seized by UK law enforcement and cross-checked by laboratory techniques. Samples studied here included common class A drugs, with the addition of new psychoactive substances (NPS) & pharmaceuticals. Due to availability during measurement collection, there are some omissions in the sample pool, including fentanyl & synthetic cannabinoids, and thus samples may not fully represent current UK drug use trends. Several spectroscopic analysis techniques that could be easily deployed in field operations were assessed to determine the performance of attenuated total reflectance (ATR)-FTIR in rapid ID of suspected illicit drugs, as would be used by law enforcement in counter-narcotics investigations. Spectroscopic libraries are expensive to purchase – particularly as they often incur a significant cost to the device. As such we investigated the utility of focussed and broad-based commercially available libraries in the analysis of street drug samples.

Methods

Instrumentation

The Agilent 4500 and 5500 portable FTIR spectrometers (Agilent Technologies, Santa Clara, USA) supplied by Agilent Technologies (Oxford, United Kingdom) were used to collect all spectra from samples during this study. Both spectrometers were fitted with a diamond 1-bounce attenuated total reflectance (ATR) accessory and a triglycine sulphate (DTGS) detector. Each spectrum was compiled of 64 sample scans (scan time ~ 15 seconds), with 128 background scans collected between each sample, at a resolution of 4 cm⁻¹, with HappGenzel apodization, a zero fill factor set to 2 and Mertz phase correction. All spectrometers were operated using Microlab PC software (Agilent Technologies, Santa Clara, USA).

Sample source

Narcotics and NPS used for library creation were obtained as chemical standards and used as purchased (Cayman Chemical or Sigma Aldrich). 184 “Street samples”, split into 56 substance types, were supplied by TICTAC (TICTAC Communications, University College London, UK) and measured without purification. Samples were previously analysed by TICTAC *via* liquid chromatography-mass spectrometry (LCMS) to identify the active

ingredient to categorise the sample. Samples were crushed, where necessary, and mixed before being measured in triplicate.

Library sources and sample analysis

A spectroscopic library containing 549 spectra, compiled by Agilent Technologies, was used for street sample ID through the Microlab Lite software (Agilent Technologies, Santa Clara, USA). Similarity library matching algorithm was based on scalar dot product. Results are given as a hit quality index from 0–1, with a closer match resulting in a higher index. The compound ID was defined by being the top library match and a hit quality index (HQI) exceeding 0.75, and was then compared to LC-MS results. Sample purity and physical state, as well as processing actions such as normalisation, baseline inclusion and wave-number region choice all can impact final index. To compare ID success between the initial library and an expanded spectral database, a commercial ATR-FTIR library (ST Japan, Germany) library was compiled of 10 119 spectra, with contents selected for analysis of white powders, explosives, traditional drugs, cutting agents, minerals and solvents.

Results & discussion

Street narcotics

Illicit drugs are manufactured and supplied to consumers through county lines networks in many different forms; powders delivered in small plastic bags, wrapped in filter papers as “bombs” or pressed into tablets to be consumed orally. Drugs seized by law enforcement are commonly found to contain “cutting agents” alongside the active ingredient, in which the drug will be sold as. These cutting agents are often legal to obtain, and have the purpose of reducing the amount of active ingredients in sold samples, increasing profits and also adding or replicating effects of the compounds when consumed.¹² Caffeine is amongst the most popular cutting agents, used in a variety of drug types providing beneficial side effects such as reducing fatigue.^{13,14} Cutting agents can also be used to mimic side effects of the active ingredient. Benzocaine is a compound commonly found in illicit drugs sold as cocaine due to its use for local anaesthetics in a number of settings including dentistry, which mimics the numbing effects of cocaine when ingesting through the nose, causing consumers to believe there is more of the psychoactive ingredient in the sample than is actually present.^{9,15,16} Table 1 shows the various narcotic samples analysed during this study, with narcotic forms categorised by the form sampled in *i.e.*, powder, tablet, or crystal. Samples were stored in the packaging law enforcement seized them in, often polyethylene resealable bags, capsules or wrapped in other materials such as filter paper, depending on method of intended consumption.

Sample ID

Fig. 1 shows the results of the library matching of collected spectra of samples previously identified using liquid chromatography (LC)-MS. Part A shows prior to any analysis, in 63% of all samples the active ingredients were correctly identified as

Table 1 Compound categories – with drug form categorised in key. The 184 street samples analysed during this study were formed of 56 discrete drug types

0-Acetylpsilocin (4-AC-DMT) (Powder)	4-Methylmethcathinone HCl (Powder)	Ethcathinone (Ethylpropion) (Powder)	N-Ethlnorpentadron (Powder)
2C-B (Powder, Tablet)	5-MeO-PYR-T (Powder)	Ethylon (Powder)	NEP (Powder)
2C-B-FLY (Tablet)	5F-ADB (5F-MDMB-PINACA) (Powder)	Fluxotine (Tablet)	NM-2201 (Powder)
3-Chloromethcathinone (3-CMC) (Powder)	5F-NNEI (5F-MN-24) (Powder)	Heroin (Crystal, Powder)	NOOPEPT (Powder)
4-Chloro-alpha-pyrrolidinopropiophenone (Powder)	ADB-FUBINACA (Powder)	Ketamine (Powder, Crystal)	Norephedrine (Powder)
4-Chloroethcathinone (Powder)	Alpha-PHP (PV7) (Powder)	Lorazepam (Tablet)	Olanzapine (Tablet)
4-Fluoro-alpha-PVP (FPVP) (Powder)	AMB-FUBINACA (FUB-AMB) (Powder)	Lynlor (Tablet)	Pentylone (Powder)
4-Fluoro-alpha-pyrrolidinooctanophenone (4F-PV9) (Powder)	Amphetamine (Crystal, Powder)	MDMA (Crystal, Powder, Tablet)	PV-10 (Alpha-PNP) (Powder)
4-Fluoro-pyrrolidinohexanophenone (Crystal)	Beta-Ethylmethcathinone (Powder)	MDPHP (Powder)	Suboxone (Tablet)
4-HO-MET (Powder)	Cocaine (Powder)	Mephedrone (Powder)	Tetrahydrocannabinol (Delta 9-THC) (Tablet)
4-Methyl-N-Ethylpentadron (4-MEAP) (Powder)	Codeine (Tablet)	Methylon (Powder)	Tryptamine (Powder)
4-Methyl-N,N-dimethylcathinone (Powder)	Diazepam (Tablet)	Metizolam (Tablet)	U-48800 (Powder)
4-Methyl-N,N-dimethylcathinone (4-Methyl-N,N-DMC) (Crystal)	Dibutylone (BK-DMBDB) (Crystal)	Mirtazapine (Tablet)	Z-PB-22F (5-Fluoro NPB-22) (Powder)
4-Methyl-pentadron (4-MPD)	Elvanse Adult (Tablet)	Morphine (Zomorph & Morphgesic) (Powder)	Zopiclone (Tablet)

Sample Form Key:

Powder	Tablet	Crystal	Multiple Forms
--------	--------	---------	----------------

the top HQI result, matching LC-MS results, with 21.2% of samples incorrectly identified as compounds which are chemically related and share many of the same functional groups as

**Fig. 1** Breakdown of the FTIR matching performance based on the HQI attained before (A) and after residual analysis (B). Samples were previously identified via LC-MS.

the actual active ingredient present. 16.3% of samples were incorrectly identified with no significant chemical relationship. Residual analysis in MicroLab subtracts a selected spectrum in the library from the sample spectrum, leaving a resultant spectrum that is then matched with remaining spectra in the library. In Fig. 1B, after secondary residual analysis, it was observed that that ~10% of those previously identified as chemically related compounds, were correctly identified as the active ingredient.

In both the examples in Fig. 2 the correct active ingredient was identified with a HQI score given out of a maximum score of 1. Due to the high HQI scores in these examples, the difference

Fig. 2 Positive ID of cocaine (A) and MDMA (B) street samples through library matching.

in HQI score between the first and second result, as well as the visual overlay between the current sample and the library “hit” there is a high degree of certainty that the active ingredient was correctly identified. The analysis of one of the samples making up the 10% which were correctly identified after residual analysis is shown in Fig. 3. In part A, in the top four matches are legal substances which are likely incorporated into the sample as cutting agents, as previously discussed, and are thus masking the signal from any illicit materials. The residual function allows positive ID by removing a single signal from the spectrum contributed by the selected library match. In the example in Fig. 3A, lactose is identified as the predominant material in the sample, but after removal of lactose peaks from the signal codeine was successfully identified as the predominant active ingredient, with the sample also likely containing chloroquine diphosphate – often observed as a common adulterant,

Fig. 3 Incorrect ID of codeine street sample (A), followed by successful ID after secondary residual analysis (B).

Fig. 4 Comparison of Hit Quality Index of spectra collected from narcotics (where a minimum of 10 samples of specific narcotic were analysed), matching to a library containing 549 sample spectra. SD = Standard Deviation, N = amount of samples.

particularly in heroin samples (Fig. 3B). Fig. 4 depicts the performance of the method through the generated HQI in samples categorised by the active ingredient. It can be observed that active ingredient detection (HQI) is greater in some varieties of narcotics, such as cocaine, ketamine, NEP, morphine and 2-CB compared to amphetamine and heroin. It is possible that in the cases of low HQI the active ingredient is masked by a cutting agent that was not included in the library used for matching compounds. Heroin, for example, is commonly cut with starch, which was not present in the library.¹⁷ However, a low HQI did not necessarily mean that a correct match cannot be identified, as 50% of heroin samples with an initial HQI between 0.3–0.65 were correctly identified after subtraction of the first match and analysis of the residual spectrum. Further expansion of the library used to include more cutting agents would further increase detection performance in this regard.

Enhancing sample ID performance

The use of expandable libraries means that ID of unknown samples can be improved over time. Use of multiple libraries at once increases the amount of library spectra matched to that of the unknown sample. Use of the commercial library containing 10 119 spectra was assessed to increase positive sample ID rate by 3.24%, shown in Fig. 5. Fig. 4 shows the mean HQI for Heroin samples in this study was 0.58, meaning that some difficulty

Fig. 5 Breakdown of the FTIR matching performance based on the HQI attained before and after residual analysis, after addition of S.T. Japan Europe GmbH library.

Fig. 6 Mean \pm SD Hit Quality Index of Heroin samples using original library containing 549 spectra, before and after addition of 4 new spectra, when matching samples to a heroin–caffeine–paracetamol spectrum (A), compared to match against the Heroin standard (used in Fig. 4) after residual analysis to remove peaks contributed by paracetamol and caffeine (B).

may be encountered when attempting to correctly identify seized Heroin samples encountered in the field. Fig. 6 shows the difference in HQI of Heroin samples prior to and after adding 4 new spectra to the library used for sample ID. Due to Heroin frequently found to be cut with common over-the-counter painkillers and stimulants, the spectra for paracetamol, aspirin & caffeine were added to the library, as well as a computationally produced heroin–caffeine–paracetamol mix spectrum.¹⁸

When matching the unknown samples to the heroin–caffeine–paracetamol mix spectrum, as this mixed spectrum is contributed to equally by the three drugs, the increase in HQI may be caused by content of caffeine or paracetamol present in the samples, rather than the active ingredient. To combat this, the residual was used to remove the contributing caffeine and paracetamol signals from the sample. Fig. 6B shows that HQI of

Heroin was still improved when matching to the Heroin standard T242 which was previously used in Fig. 4, due to the removal of signal from common adulterants.

Principal component analysis

Another method for ID of the illicit active ingredient in samples is to use principal component analysis (PCA), which assesses the spectral variance, displayed as principal component factors, between sample types. The PCA model for ID of narcotics samples is shown in Fig. 7.

The results of sample ID using the PCA model above are listed in Table 2. The PCA model shows that different amphetamine samples have a clear split, located in two separate clusters, seen in Fig. 8. Where sample groups cluster closely together, their spectral differences are smaller. Although most samples within the same sample group cluster together, the amphetamine samples suspected of containing caffeine as an adulterant, based on their library match, were plotted in the lower-right cluster, separating from amphetamine samples without caffeine.

ID of samples using the PCA model above is possible in 45% of the sample groups assessed here. Difficulty in ID could be caused by the purity of the samples, as according to the United States Drug Enforcement Administration (DEA), the purity of amphetamine, cocaine, ketamine and MDMA seized by law enforcement ranged from 49.5–96.1% in 2020. Whereas, opioids such as heroin have been found to be, on average, 37.6% pure.^{19,20} This expected difference in purity helps to

Fig. 7 Principal component analysis (PCA) of narcotics spectra, grouped by drug type. Clusters depict more similar spectra after assessing variance using principal component factors 1 and 2.

Fig. 8 Principal component analysis (PCA) of narcotics spectra, grouped by drug type, after addition of "amphetamine (+caffeine)" group. Clusters depict more similar spectra after assessing variance using principal component factors 1 and 2.

Table 2 Results of active ingredient ID using PCA model seen in Fig. 7

Sample group	Drug type	Correct ID (%)	Total samples	Validation samples
2-CB	Psychedelic	100	9	3
4-Chloroethcathinone	Stimulant	0	7	2
Amphetamine	Stimulant	75	12	4
Cocaine	Stimulant	100	13	4
Heroin	Opioid	0	10	3
Ketamine	Dissociative	75	15	4
MDMA	Empathogen	83.3	36	12
Mephedrone	Empathogen	0	6	2
Morphine	Opioid	0	10	3
NEP	Stimulant	0	10	3
Tryptamine	Psychedelic	0	3	1

Fig. 9 The relationship between Hit Quality Index and percentage of active ingredient (MDMA) present in the street sample.

explain the clustering pattern, as when using Table 2, the clusters are not formed of samples of the same drug type. The less pure samples will be impacted more greatly by the adulterants present, as seen with amphetamine. This can create difficulty in ID of samples, as it becomes difficult to ascertain to what extent the clustering pattern is caused by the adulterants, rather than the active ingredient. This highlights the need for increased reporting of cutting agents and diluents as well as a degree of hierarchical supervision and intense model training to enhance analysis and ID ability of such models when assessing street drug samples.

Concentration studies

To expand on the performance analysis of simple ID of unknown street samples, 19 samples of MDMA were scanned. The batches of these 19 samples had previously been

quantified so that the percentage mass of psychoactive ingredient MDMA making up each pill was known. The HQI of MDMA in each sample is plotted against the known mass concentration in Fig. 9, showing that the limit of detection (LOD) of MDMA was 4.4%. However, for purposes of identifying unknown suspect illicit drugs, successful ID of MDMA was only possible in excess of 22.7% of total mass, this measure previously being defined as the limit of ID (LOI).²¹ This suggests that there is potential for ATR-FTIR to be used to first identify and then quantitatively estimate the concentrations of active ingredient present in unknown narcotic samples, provided the minimum threshold of mass concentration is met.

Cutting agents

The ID of cutting agents or adulterants alongside the active ingredient in narcotic samples is not as widely reported as it might be. Many substances such as caffeine are usually omitted by labs when identifying suspected controlled substances, which hampers the collection of information that could be beneficial for law enforcement and treatment of users.¹⁸ Two examples are shown below in Fig. 10 & 11 where an adulterant is identified in samples of cocaine and heroin respectively. Again, the top "hit" was selected and the contributing signal removed through residual analysis in each case to remove need for user judgement.

The adulterant is identified by residual analysis, removing the signal contributed by the active ingredient, to leave signal contributed by any other substances found in the sample. Using

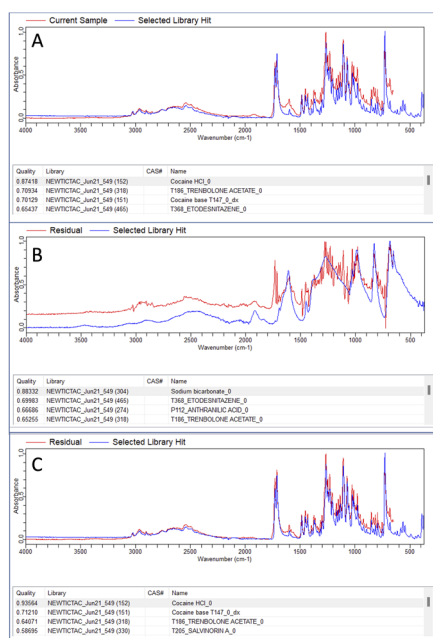

Fig. 10 Process of ID of adulterant present in a cocaine sample and using this information to improve HQI of the active ingredient, shown through initial result (A), and use of residual analysis to remove cocaine (B) or sodium bicarbonate (C) contributing peaks to find adulterants and improve match results.

Fig. 11 Process of ID of adulterant present in a heroin sample and using this information to improve HQI of the active ingredient, shown through initial incorrect match of etodesnitazene (A), and use of residual analysis to remove; etodesnitazene (B) and then paracetamol and caffeine (C) contributing peaks from the original spectrum to find adulterants and improve match results.

this information to remove the adulterant signal from our original sample then improved HQI of the active ingredient, with cocaine HQI increasing from 0.87 to 0.94. After removal of the paracetamol–caffeine signal from the heroin sample it was observed that the active ingredient heroin, which was not previously listed inside the top four HQI matches, now matches third with a HQI of 0.77233, making the likelihood of positive rapid ID of the controlled substance more likely.

Rapid ID of adulterants shown here could be hugely important in the safety of law enforcement working in the field as well as current users. Adulterants such as fentanyl, a potent synthetic opioid, often found in heroin in the US is beginning to become more common in the UK, with NHS trusts first receiving information on the treatment of suspected fentanyl overdoses on the central alert system in 2017.²² Some fentanyl variants have a lethal dose of ~2 mg, whilst an even more powerful variant, carfentanil, has a lethal dose around 100× less than this, and may be absorbed through the skin or inhaled.²³ The use and study of such substances is clearly hugely dangerous, and thus improving rapid ID of active ingredients as well as cutting agents or adulterants such as fentanyl could be important in preventing loss of life.

Hyphenated techniques such as GC-FTIR are effective in separating compounds found in a single sample, allowing for efficient psychoactive ingredient(s) ID, without impact from cutting agents, even at trace levels within the assessed sample.⁶⁷ However, two-step analytical techniques with front-end sample separation such as GC-FTIR can require more advanced sample preparation prior to analysis. As this study was focussed on rapid ID of psychoactive samples by law enforcement at the scene of sample collection, such techniques were not within scope of this work.

Conclusions

In his study we have investigated the ability of FTIR in rapid ID of a large range of illicit psychoactive substances. Spectral library matching was effective in identifying 75% of samples of varying degrees of purity effectively. The benefit of “location specific” intelligence on cutting agents has a significant effect on the matching hit quality index, especially when combined with larger libraries. This study highlights the value of this in local law enforcement agencies. Where sample concentration by mass percentage has been confirmed, through external analysis of MDMA tablets, we have shown an LOD of 4.4% and LOI of >22.7% mass concentration. Through the link of concentration to HQI, there is potential for FTIR to quantitatively estimate purity of such samples.

We have also assessed the use of principal component analysis in ID of street narcotic samples. Although there was success in just 46% of our sample groups, the results appear to be skewed by adulterants present. This highlights the need for further reporting of adulterants to gain insight into common mixtures of controlled and non-controlled substances and aid in ID of potentially dangerous diluents or additives, for the protection of law enforcement and current drug users. Taken as a whole, we have demonstrated the utility of, fast, easy to use

and cost effective FTIR spectroscopic techniques for accurate ID of street narcotics samples in a field setting. This has the potential to enable law enforcement organizations to perform analysis in the field improving operational efficiency and, in some cases, reducing the need to send samples to a lab.
