# Microhydrated clusters of a pharmaceutical drug: infrared spectra and structures of amantadineH<sup>+</sup>(H<sub>2</sub>O)<sub>n</sub><sup>†</sup>

Martin Andreas Robert George  and Otto Dopfer \*

Solvation of pharmaceutical drugs has an important effect on their structure and function. Analysis of infrared photodissociation spectra of amantadineH<sup>+</sup>(H<sub>2</sub>O)<sub>n=1–4</sub> clusters in the sensitive OH, NH, and CH stretch range by quantum chemical calculations (B3LYP-D3/cc-pVTZ) provides a first impression of the interaction of this pharmaceutically active cation with water at the molecular level. The size-dependent frequency shifts reveal detailed information about the acidity of the protons of the NH<sub>3</sub><sup>+</sup> group of N-protonated amantadineH<sup>+</sup> (AmaH<sup>+</sup>) and the strength of the NH...O and OH...O hydrogen bonds (H-bonds) of the hydration network. The preferred cluster growth begins with sequential hydration of the NH<sub>3</sub><sup>+</sup> group by NH...O ionic H-bonds (*n* = 1–3), followed by the extension of the solvent network through OH...O H-bonds. However, smaller populations of cluster isomers with an H-bonded solvent network and free N–H bonds are already observed for *n* ≥ 2, indicating the subtle competition between noncooperative ion hydration and cooperative H-bonding. Interestingly, cyclic water ring structures are identified for *n* ≥ 3, each with two NH...O and two OH...O H-bonds. Despite the increasing destabilization of the N–H proton donor bonds upon gradual hydration, no proton transfer to the (H<sub>2</sub>O)<sub>n</sub> solvent cluster is observed up to *n* = 4. In addition to ammonium cluster ions, a small population of microhydrated iminium isomers is also detected, which is substantially lower for the hydrophilic H<sub>2</sub>O than for the hydrophobic Ar environment.

## 1. Introduction

1-Amantadine (1-C<sub>10</sub>H<sub>15</sub>NH<sub>2</sub>, 1-amino adamantane, Ama, Fig. 1) is the amino derivative of adamantane (C<sub>10</sub>H<sub>16</sub>, Ada) and thus belongs to the diamondoid family, a fundamental class of rigid and strain-free cycloalkanes.<sup>1,2</sup> These nm-sized H-passivated nanodiamonds are rather stable compounds<sup>3–5</sup> and offer a wide range of applications, *e.g.*, in molecular electronics, astrochemistry, materials and polymer sciences, chemical synthesis, and medical sciences.<sup>6–19</sup> Since several amines and protonated molecules have been detected in the interstellar medium and the presence of diamondoids has been suggested due to their high stability,<sup>20–26</sup> it is likely that Ama and its protonated ion are also present.<sup>7,18,19</sup> In terms of pharmaceutical applications, Ama is one of the best known commercially available diamondoids, being successfully marketed as antiviral and antiparkinsonian agents.<sup>27–30</sup> Indeed, Ama is effective in prevention and treatment of influenza A infections,<sup>31–35</sup> Parkinson,<sup>36–38</sup> multiple sclerosis,

depression, and cocaine addiction.<sup>39–43</sup> In all postulated mechanisms, the biochemically active form is N-protonated Ama, AmaH<sup>+</sup>, or its dimethylated derivative memantine.<sup>44,45</sup> The latter has been among the 100 best-selling drugs worldwide (>10<sup>9</sup> \$ in 2013).<sup>46</sup> Beside its pharmaceutical applications, Ama is an interesting diamondoid derivative because it is a suitable target for studying ionization- and protonation-induced rearrangement processes of the adamantyl cage.<sup>47,48</sup> To this end, it has been shown that the replacement of H by the electron-donating NH<sub>2</sub> group at the apical 1-position largely preserves the chemical properties of diamond-like structures, but greatly reduces the barrier to opening the C<sub>10</sub>H<sub>15</sub> cage.<sup>47,48</sup> Similarly, protonation of Ama can also lead to the formation of open-cage bicyclic iminium ions.<sup>49</sup>

Neutral Ama has been well characterized by infrared (IR), Raman and electron momentum spectroscopy as well as computational techniques.<sup>50–54</sup> It consists of a primary pyramidal NH<sub>2</sub> group attached to the adamantyl backbone, which gives the molecule the special chemical properties of a diamond-like structure.<sup>39,55</sup> In addition, the Ama...DNA interaction has been investigated by Raman spectroscopy.<sup>56</sup> Ionization of Ama into the electronic ground state of the radical cation occurs by electron ejection from the nonbonding N lone pair of the NH<sub>2</sub> group (HOMO) with a vertical ionization energy roughly

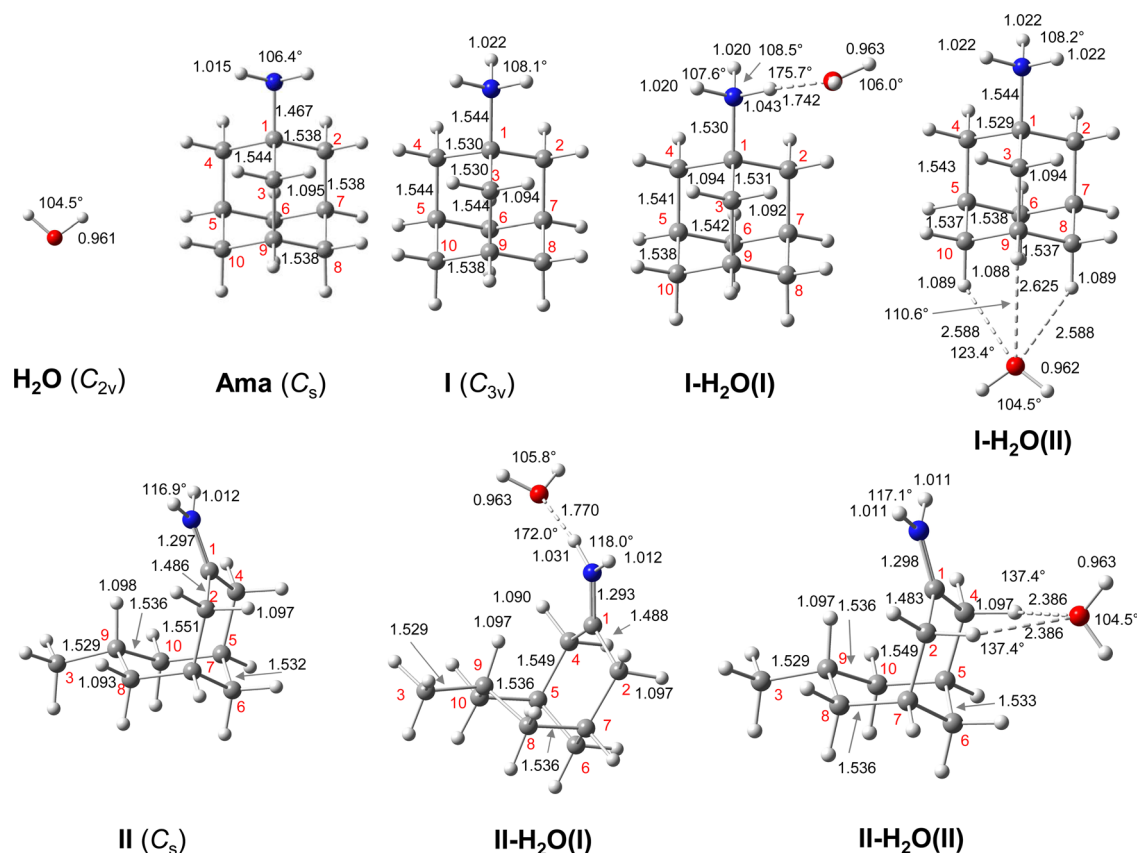

Fig. 1 Calculated equilibrium structures (in Å and degrees) of  $\text{H}_2\text{O}$ , **Ama**, **AmaH<sup>+</sup>(I,II)**, and **AmaH<sup>+</sup>(I,II)(H<sub>2</sub>O)(I,II)** in their ground electronic state (B3LYP-D3/cc-pVTZ). All bond lengths are shown in ESI† (Fig. S22).

estimated as 8.6 eV by its low-resolution electron momentum spectrum.<sup>51</sup> Recently, we have studied  $\text{Ama}^+\text{L}_n$  radical cation clusters (with  $\text{L} = \text{Ar}, \text{N}_2, \text{H}_2\text{O}$ ) generated in a supersonic electron-ionization plasma expansion with IR photodissociation (IRPD) spectroscopy and quantum chemical calculations.<sup>47,48,57</sup> These studies reveal that the adamantyl cage can open upon ionization, thus producing two distonic bicyclic iminium ions, **Ama<sup>+</sup>(II,III)**, in addition to the canonical nascent **Ama<sup>+</sup>(I)** ion with an intact  $\text{C}_{10}\text{H}_{15}$  cage. Due to the strong p/ $\pi$ -electron donating character of the  $\text{NH}_2$  group, the barriers for cage-opening are much lower than for  $\text{Ada}^+$ . Due to its higher reaction barriers, no open-cage isomers of  $\text{Ada}^+$  have yet been detected in both IR and optical spectra.<sup>19,25,58</sup> For  $\text{Ama}^+$ , the canonical cage isomer **Ama<sup>+</sup>(I)** ( $E_0 = 46 \text{ kJ mol}^{-1}$ ) is generated by vertical ionization of **Ama**, and the resulting activation of the C–C bond adjacent to the  $\text{NH}_2$  group opens the cage and forms the primary radical **Ama<sup>+</sup>(II)** ( $E_0 = 87 \text{ kJ mol}^{-1}$ ) via a conversion of one of the cyclohexane rings from a boat to a chair configuration. A subsequent 1,2 H-shift with reconversion from chair to boat forms the much more stable tertiary radical **Ama<sup>+</sup>(III)** ( $E_0 = 0 \text{ kJ mol}^{-1}$ ).

In addition to ionization, we have recently investigated protonated amantadine (**AmaH<sup>+</sup>**) by IRPD spectroscopy (Ar-tagging) and quantum chemical calculations and identified, in addition to the canonical N-protonated **AmaH<sup>+</sup>(I)** ammonium ion ( $E_0 = 0 \text{ kJ mol}^{-1}$ ), an only slightly less stable open-cage

bicyclic iminium ion (**II**) ( $E_0 = 3 \text{ kJ mol}^{-1}$ ).<sup>49</sup> This open-cage isomer **II** is probably not generated by direct protonation of **Ama** but by ionization of **Ama** followed by cage opening (by the mechanism described above) and subsequent addition of H. However, the dominant population corresponds clearly to the ammonium ion (**I**), which is the relevant structure for pharmaceutical applications in solution. Apart from our previous letter,<sup>49</sup> which provides the first spectroscopic characterization of the structure of **AmaH<sup>+</sup>**, there have been no spectroscopic studies of this fundamental bio-active molecular ion, despite its pharmaceutical importance. However, **AmaH<sup>+</sup>** has been analysed by mass spectrometry to obtain information on its fragmentation and proton affinity.<sup>59</sup> Furthermore, there are several spectrophotometric, NMR and IR studies on amantadine hydrochloride salt (**Ama-HCl**), but these are mainly concerned with analytical applications of this molecular drug.<sup>52,60–63</sup>

Herein, we analyse IRPD spectra of size-selected  $\text{AmaH}^+(\text{H}_2\text{O})_{n=1-4}$  clusters by dispersion-corrected density functional theory (DFT) calculations at the B3LYP-D3/cc-pVTZ level to characterize the initial microhydration steps of this important bio-active molecular ion. This dual approach provides direct access to the interaction potential between the ion and the solvent molecules, as demonstrated in previous studies of microhydrated cations in our laboratory.<sup>57,58,64–87</sup> Thus, the  $\text{AmaH}^+(\text{H}_2\text{O})_{n=1-4}$  data provide a first impression of the interaction of this pharmaceutically relevant ion with water solvent

molecules at the molecular level. Specifically, the IRPD spectra recorded in the informative OH, NH, and CH stretch range yield information about the potential of the ion–ligand interaction in terms of the binding site and the strength of the interaction, as well as the structure of the hydrogen-bonded (H-bonded) solvent network and the acidity of the N–H bonds of the protonated NH<sub>2</sub> group of AmaH<sup>+</sup> (and also of the iminium isomer). In previous work,<sup>57</sup> we compared microhydration of the Ama<sup>+</sup> radical cation with that of aniline<sup>+</sup> (An<sup>+</sup>),<sup>88,89</sup> aminobenzonitrile<sup>+</sup> (ABN<sup>+</sup>),<sup>75</sup> and CH<sub>3</sub>NH<sub>2</sub><sup>+</sup> (computational data)<sup>90</sup> to reveal the differences of an aromatic, aliphatic, and cycloaliphatic substituent on the acidity and intermolecular interaction of the NH protons of primary amine cations. For Ama<sup>+</sup>, the same preferential cluster growth was found as for An<sup>+</sup> and ABN<sup>+</sup> but with stronger NH···O H-bonds due to the higher acidity of the N–H bonds of Ama<sup>+</sup>. In contrast, the NH···O H-bonds of CH<sub>3</sub>NH<sub>2</sub><sup>+</sup> to H<sub>2</sub>O are much stronger than those of Ama<sup>+</sup> due to the higher positive charge on the NH<sub>2</sub><sup>+</sup> group. Therefore, a particular question to be addressed is the change in microhydration due to the additional proton attached to the NH<sub>2</sub> group of AmaH<sup>+</sup> and the resulting change in the NH···O H-bonds. Moreover, in another study on Ama<sup>+</sup>L<sub>n</sub> clusters (with L = Ar, N<sub>2</sub>, H<sub>2</sub>O), we have shown that the population of the bicyclic iminium ion Ama<sup>+</sup>(III) is significantly smaller in a H<sub>2</sub>O environment than in a nonpolar environment such as Ar or N<sub>2</sub>, due to higher rearrangement barriers between Ama<sup>+</sup>(II) and Ama<sup>+</sup>(III) (1,2 H-shift) for H<sub>2</sub>O. Since the open-cage isomer AmaH<sup>+</sup>(II) is assumed to be formed by H addition to the distonic Ama<sup>+</sup>(III) ion, the population of AmaH<sup>+</sup>(II) in a H<sub>2</sub>O environment should also be much lower, which shall be verified herein. Another important aspect is the competition between the formation of the H-bonded solvent network (which is strongly favoured by nonadditive cooperative three-body interactions) and the internal cation hydration with individual ligands bound by charge–dipole forces (which suffer from noncooperative three-body forces).<sup>64</sup> A further topic to be addressed is potential hydration-induced proton transfer from the NH<sub>3</sub><sup>+</sup> group to the solvent cluster, which becomes progressively more favourable for larger *n* due to the increasing proton affinity of (H<sub>2</sub>O)<sub>n</sub> clusters (e.g., PA = 691, 808, 862, 900, 904, and 908 kJ mol<sup>−1</sup> for *n* = 1–6)<sup>91–95</sup> approaching that of Ama (measured and computed as 949 and 957 kJ mol<sup>−1</sup>, respectively).<sup>49,91</sup>

## 2. Experimental and computational techniques

The IRPD spectra of mass-selected AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>n</sub> clusters (*n* = 1–4) shown in Fig. 2 are recorded in a tandem quadrupole mass spectrometer coupled to an electron ionization (EI) source.<sup>64,96</sup> The clusters are produced in a pulsed supersonic plasma expansion by electron and/or chemical ionization of Ama followed by three-body hydration reactions. The expansion gas is generated by passing a carrier gas mixture (9 bar) composed of Ar and 5% H<sub>2</sub>/He in the ratio 10:1 through a reservoir containing solid Ama (Sigma-Aldrich, >97%) heated to 80 °C. The filaments of the EI

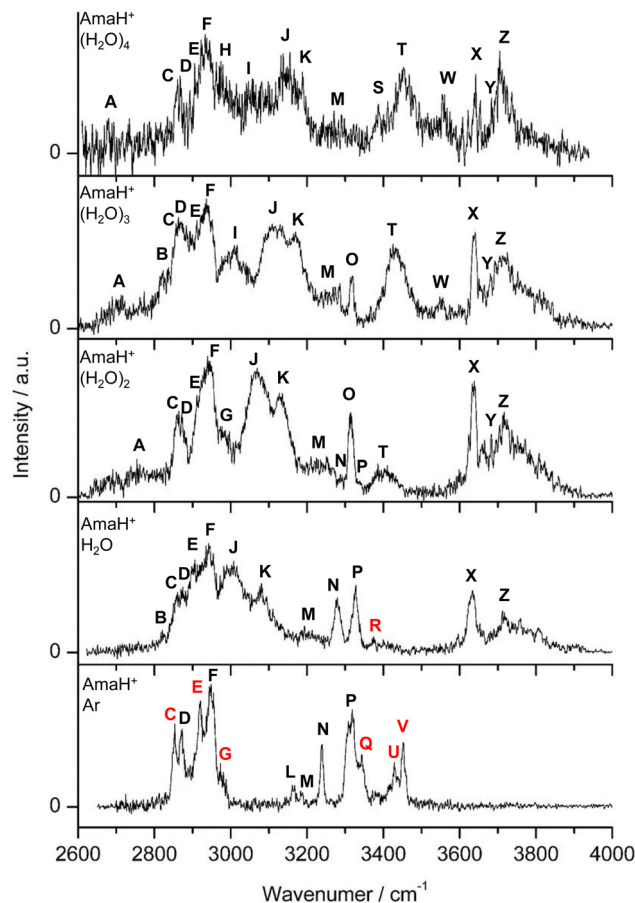

Fig. 2 IRPD spectra of AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>n=1–4</sub> in the 2600–4000 cm<sup>−1</sup> range recorded in the H<sub>2</sub>O loss channel are compared to the IRPD spectrum of AmaH<sup>+</sup>Ar.<sup>49</sup> The position, widths, and assignments of the transitions observed (A–Z) are listed in Table 1. The bands that can only be assigned to the iminium isomers are highlighted in red.

source are powered by a 220 V offset voltage, which sets an upper limit on the kinetic energy of the electrons hitting the molecules in the expansion. To produce hydrated AmaH<sup>+</sup> clusters, distilled water is added to the gas line just in front of the sample reservoir. One possible production route for AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>n</sub> involves ionization of H<sub>2</sub> (eqn (1)) followed by exothermic proton transfer reactions (eqn (2) and (3)) to generate AmaH<sup>+</sup> and three-body collisions to form AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>n</sub> clusters (eqn (4)).<sup>97,98</sup>

Instead of protonation of with H<sub>3</sub><sup>+</sup>, protonation may occur by proton transfer from (H<sub>2</sub>O)<sub>n</sub>H<sup>+</sup> clusters generated by EI of abundant neutral (H<sub>2</sub>O)<sub>n+1</sub> clusters:

As suggested earlier,<sup>49</sup> there is an alternative production route for AmaH<sup>+</sup>, in which Ama<sup>+</sup> is formed first (eqn (7)) which then reacts in an endothermic reaction with H<sub>2</sub> to form AmaH<sup>+</sup> (eqn (8)):

This alternative production route, in which Ama<sup>+</sup> is formed as an intermediate, can lead to cage opening and the formation of two bicyclic distonic iminium ions **Ama<sup>+</sup>(II,III)**, in addition to canonical cage structure **Ama<sup>+</sup>(I)**.<sup>47</sup> Unlike **Ama<sup>+</sup>(I)**, which is preferentially hydrogenated at the NH<sub>2</sub> group (eqn (8)) leading to the formation of an ammonium cation **AmaH<sup>+</sup>(I)**, **Ama<sup>+</sup>(II)** and **Ama<sup>+</sup>(III)** are hydrogenated at their radical centers, leading to the formation of iminium cations **AmaH<sup>+</sup>(II–IV)**,<sup>99</sup> which have recently been detected by IRPD.<sup>49</sup> The produced AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>n</sub> parent clusters of interest are mass-selected by the first quadrupole and irradiated in the adjacent octupole by an IR laser pulse emitted from a tunable optical parametric oscillator pumped by a Q-switched nanosecond Nd:YAG laser, with pulse energies of 2–5 mJ, a repetition rate of 10 Hz, and a bandwidth of <4 cm<sup>−1</sup>. Calibration of the IR laser frequency accurate to <1 cm<sup>−1</sup> is accomplished by a wavemeter. Resonant vibrational excitation upon single-photon absorption leads to evaporation of a single H<sub>2</sub>O ligand. The resulting AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>n−1</sub> fragment ions are selected by the second quadrupole and monitored by a Daly detector as a function of the laser frequency to obtain the IRPD spectra of AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>n</sub>. All IRPD spectra are normalized for frequency-dependent variations in the photon flux measured with a pyroelectric detector.

Quantum chemical calculations are performed at the B3LYP-D3/cc-pVTZ level of theory for Ama, Ama<sup>+</sup>, AmaH<sup>+</sup>, and AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>n</sub> hydrates to determine their structural, energetic, and spectroscopic properties.<sup>100</sup> As shown for the related Ama<sup>+</sup>L<sub>n</sub> and AmaH<sup>+</sup>Ar clusters, this computational approach reproduces the experimental IR spectra and binding energies with satisfactory accuracy and is an efficient compromise between accuracy and computing time.<sup>47–49,57</sup> Relative energies and equilibrium binding energies (*E<sub>e</sub>*, *D<sub>e</sub>*) are corrected for harmonic zero-point vibrational energies to yield *E<sub>0</sub>* and *D<sub>0</sub>*. Gibbs free energies (*G*) are evaluated at 298.15 K. Harmonic vibrational frequencies are scaled by factors of 0.9618, 0.9491, and 0.9630 for CH, NH, and OH stretch frequencies, respectively.<sup>47,48,57</sup> The frequencies in the fingerprint range required for the determination of the overtones and combination bands are scaled with a factor of 0.9732.<sup>47</sup> Computed IR stick spectra are convoluted with Gaussian line profiles (fwhm = 10 cm<sup>−1</sup>) to facilitate convenient comparison with the measured IRPD spectra. Natural bond orbital (NBO) analysis is employed to evaluate the charge distribution and charge transfer in AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>n</sub> as well as the second-order perturbation energies (*E*<sup>(2)</sup>) of donor–acceptor orbital interactions involved in the H-bonds.<sup>101,102</sup> Cartesian coordinates and energies of all relevant structures are available in ESI.†

## 3. Experimental results

### 3.1 Mass spectra

Typical mass spectra of the ion source show dehydrogenated, ionized, and protonated Ama (*m/z* 150–152) as well as their clusters with Ar and H<sub>2</sub>O (Fig. S1, ESI†). In addition, the typical fragment ions of Ama<sup>+</sup> (*F*<sup>+</sup> at *m/z* 57, 94, 108, 135) are detected, consistent with the standard EI mass spectrum of Ama and previous mass spectra, confirming the identity of *m/z* 151 and 152 as Ama<sup>+</sup> and AmaH<sup>+</sup>.<sup>47–49,52</sup> To confirm the chemical composition of the generated AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>n</sub> clusters, collision-induced dissociation (CID) experiments are performed, revealing mainly dissociation of H<sub>2</sub>O molecules and ruling out significant isobaric mass contamination (Fig. S2 and S3, ESI†).

### 3.2 Overview of IRPD spectra

The IRPD spectra of AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>n=1–4</sub> are compared in Fig. 2 to the previously recorded AmaH<sup>+</sup>Ar spectrum,<sup>49</sup> and the observed bands and their vibrational assignments are listed in Table 1. The investigated spectral range (2600–4000 cm<sup>−1</sup>) covers aliphatic CH stretch modes (**B–G**, ν<sub>CH<sub>n</sub></sub>, 2800–3000 cm<sup>−1</sup>), and H-bonded (**A**, **H–K**, ν<sub>NH<sub>3</sub></sub><sup>b</sup>, 2600–3200 cm<sup>−1</sup>) and free NH stretch modes (**N–P**, ν<sub>NH<sub>3</sub></sub><sup>f/a/s</sup>, 3200–3400 cm<sup>−1</sup>) of the NH<sub>3</sub><sup>+</sup> ammonium group of AmaH<sup>+</sup>, NH stretch modes of the NH<sub>2</sub><sup>+</sup> amino group of AmaH<sup>+</sup> (**Q**, **R**, **V**, ν<sub>NH<sub>2</sub></sub>, 3300–3500 cm<sup>−1</sup>), bound (**S**, **T**, **W**, ν<sub>OH<sub>2</sub></sub><sup>b</sup>, 3300–3600 cm<sup>−1</sup>) and free (**X–Z**, ν<sub>OH<sub>2</sub></sub><sup>f/a/s</sup>, 3600–3900 cm<sup>−1</sup>) OH stretch modes of the H<sub>2</sub>O ligands, and combination bands and overtones of the OH, NH, and CH bending fundamentals (**L**, **M**, **U**, 3100–3500 cm<sup>−1</sup>). The IRPD spectra show a clear and distinct dependence on the cluster size *n* and therefore provide detailed information about the hydration motifs, both in terms of the H<sub>2</sub>O binding sites and the structures of the hydration network.

### 3.3 IRPD of AmaH<sup>+</sup>Ar

The bands in the AmaH<sup>+</sup>Ar spectrum have been assigned in detail previously.<sup>49</sup> Ar-tagging has little impact on the frequencies of bare AmaH<sup>+</sup>, and bands marked in black/red are attributed to the ammonium/iminium isomers. Briefly, bands **N** and **P** are attributed to the low-frequency NH stretch modes of the ammonium isomer (**I**), while bands **Q** and **V** arise from higher-frequency NH stretch modes of the iminium isomer (**II**). Although the AmaH<sup>+</sup>Ar spectrum is strongly dominated by the ammonium isomer formed by simple protonation of Ama at the NH<sub>2</sub> group, ~20–25% of the AmaH<sup>+</sup> population is attributed to iminium isomers.

### 3.4 IRPD of AmaH<sup>+</sup>H<sub>2</sub>O

The IRPD spectrum of AmaH<sup>+</sup>H<sub>2</sub>O shows the distinct free NH stretch signatures of the NH<sub>3</sub><sup>+</sup> ammonium group by observing the intense bands **N** and **P** at 3279 and 3328 cm<sup>−1</sup> with widths of 17 and 20 cm<sup>−1</sup>, respectively. These are close to those of AmaH<sup>+</sup>Ar (ν<sub>NH<sub>3</sub></sub><sup>s</sup> = 3238 cm<sup>−1</sup> (**N**), ν<sub>NH<sub>3</sub></sub><sup>a</sup> = 3317 cm<sup>−1</sup> (**P**)). On the other hand, the intense signatures of the NH<sub>2</sub><sup>+</sup> amino group of the iminium isomers (**Q**, **V**) observed for AmaH<sup>+</sup>Ar are barely discernible or absent for AmaH<sup>+</sup>H<sub>2</sub>O, with the possible

<sup>a</sup> Ref. 49. <sup>b</sup> Stretching ( $\nu$ ), bending ( $\beta$ ). <sup>c</sup> FR = Fermi resonance with  $\nu_{\text{NH}_3}^b$ .

exception of the very weak band **R** at  $3373\text{ cm}^{-1}$ . Hence, the  $\text{AmaH}^+\text{H}_2\text{O}$  spectrum is concluded to be predominantly produced by ammonium isomers, while the population of iminium isomers is close to or below the detection limit ( $<10\%$ ). A further major difference between the  $\text{AmaH}^+\text{Ar}$  and  $\text{AmaH}^+\text{H}_2\text{O}$  spectra is the appearance of the intense and broad bands **J** and **K** at  $3007$  and  $3080\text{ cm}^{-1}$  with widths of  $24$  and  $23\text{ cm}^{-1}$  for  $\text{L} = \text{H}_2\text{O}$ , respectively. These are indicative of a strongly redshifted bonded NH stretch mode, arising from the predominant presence of an H-bonded  $\text{AmaH}^+\text{H}_2\text{O}$  isomer with a strong  $\text{NH}\cdots\text{O}$  ionic H-bond between  $\text{H}_2\text{O}$  (acceptor) and the acidic  $\text{NH}_3^+$  group (donor). This H-bond is strongly stabilized by the large electrostatic charge-dipole forces between the  $\text{AmaH}^+$  cation and the  $\text{H}_2\text{O}$  dipole which dominate the long-range part of the intermolecular attraction. The strong  $\text{NH}\cdots\text{O}$  H-bond causes a large redshift of the bonded  $\nu_{\text{NH}_3}^b$  mode down to the spectral range  $2800\text{--}3200\text{ cm}^{-1}$ , where it couples strongly with NH, OH and CH bend overtones (via anharmonic Fermi resonance (FR)) or with CH stretch fundamentals (via local mode mixing). These interactions result in a broad vibrational multi-band pattern in the IR spectrum. Similar complex patterns arising from  $\text{NH}\cdots\text{O}$  ionic H-bonds have been observed previously for a variety of related hydrated aromatic cations such as acetanilide, hydroxyindole, pyrrole, and formanilide.<sup>77,78,81,82,103</sup> All IRPD spectra of  $\text{AmaH}^+(\text{H}_2\text{O})_{n=1-4}$

show an almost identical  $\text{CH}_n$  stretch pattern of the  $\text{AmaH}^+$  cage to that observed for  $\text{AmaH}^+\text{Ar}$  (**C–F**). However, because of the redshifted  $\nu_{\text{NH}_3}^b$  mode and the associated strong couplings, their relative integrated intensities are strongly enhanced (when compared to the free NH stretch bands). The  $\text{CH}_n$  stretch pattern consists of one intense doublet **C** and **D** at  $\sim 2860$  and  $\sim 2870\text{ cm}^{-1}$  with a total width of  $\sim 45\text{ cm}^{-1}$  and a more intense and broader doublet **E** and **F** at  $\sim 2910$  and  $\sim 2940\text{ cm}^{-1}$  with a total width of  $\sim 60\text{ cm}^{-1}$ . When compared to the  $\text{AmaH}^+\text{Ar}$  spectrum, bands **C** are slightly blueshifted by  $\sim 7\text{ cm}^{-1}$  while bands **E** are redshifted by  $\sim 12\text{ cm}^{-1}$ . The distinct blueshifts of the doublet **C/D** from Ar to  $\text{H}_2\text{O}$  may arise from the assignment to different isomers (iminium for Ar and ammonium for  $\text{H}_2\text{O}$ ). With increasing  $n$ , only bands **D** and **F** show notable redshifts from  $2874$  ( $n = 1$ ) to  $2867\text{ cm}^{-1}$  ( $n = 4$ ) and from  $2943$  ( $n = 1$ ) to  $2933\text{ cm}^{-1}$  ( $n = 4$ ), respectively. However, in the  $\text{AmaH}^+\text{H}_2\text{O}$  spectrum an additional weak band **B** is observed at  $2821\text{ cm}^{-1}$  in the CH stretch range. As expected, the  $\text{AmaH}^+\text{H}_2\text{O}$  spectrum reveals two bands in the OH stretch range, which are absent for  $\text{AmaH}^+\text{Ar}$ . Bands **X** and **Z** at  $3633$  and  $3717\text{ cm}^{-1}$  are readily assigned to the free symmetric ( $\nu_{\text{OH}_2}^s$ ) and antisymmetric ( $\nu_{\text{OH}_2}^a$ ) OH stretch modes of the  $\text{H}_2\text{O}$  acceptor in the  $\text{NH}\cdots\text{O}$  ionic H-bond. Their modest redshifts of  $24$  and  $39\text{ cm}^{-1}$  from the transitions of bare  $\text{H}_2\text{O}$

( $\nu_{\text{OH}_2}^{\text{s/a}} = 3657/3756 \text{ cm}^{-1}$ ) and the strong IR enhancement of  $\nu_{\text{OH}_2}^{\text{s}}$  are typical for cation- $\text{H}_2\text{O}$  clusters.<sup>57,64,71,83,84,104</sup> Interestingly, band **Z** is rather broad with a total width of  $137 \text{ cm}^{-1}$  and several additional features at  $3711$ ,  $3759$ , and  $3805 \text{ cm}^{-1}$ , which may arise from Q-branches of hindered internal  $\text{H}_2\text{O}$  rotation, as has been reported previously for  $\text{Ada}^+\text{H}_2\text{O}$ . However, the spacings between these bands are not regular for  $\text{AmaH}^+\text{H}_2\text{O}$  and not associated directly with rotational constants of bare  $\text{H}_2\text{O}$ , indicating that this motion is more complicated than in  $\text{Ada}^+\text{H}_2\text{O}$ . Finally, the weak band **M** of  $\text{AmaH}^+\text{H}_2\text{O}$  at  $3193 \text{ cm}^{-1}$  has a slightly higher frequency than the  $\beta_{\text{NH}_3}$  overtone observed for  $\text{AmaH}^+\text{Ar}$  ( $2\beta_{\text{NH}_3} = 3185 \text{ cm}^{-1}$  (**M**)), consistent with the stronger  $\text{NH} \cdots \text{O}$  H-bond providing a larger retarding force by  $\text{H}_2\text{O}$  for this mode.

### 3.5 IRPD of $\text{AmaH}^+(\text{H}_2\text{O})_2$

The  $\text{AmaH}^+(\text{H}_2\text{O})_2$  spectrum shows significant changes compared to  $n = 1$ , except for the CH stretch bands (**C–F**). Significantly, instead of two intense free NH stretch bands (**N**, **P**), only one free NH stretch band **O** at  $3315 \text{ cm}^{-1}$  dominates that spectral range, indicating the predominant presence of a  $n = 2$  isomer, in which two  $\text{H}_2\text{O}$  molecules bind separately to the  $\text{NH}_3^+$  group *via* individual  $\text{NH} \cdots \text{O}$  H-bonds while one N–H bond remains free (interior ion solvation motif). Band **O** occurs roughly midway between **N** and **P**, as expected for the change from two coupled free NH stretch oscillators to a single uncoupled one. The resulting bound NH stretch bands **J** and **K** are blueshifted by  $62$  and  $47 \text{ cm}^{-1}$  to  $3069$  and  $3127 \text{ cm}^{-1}$  compared to  $n = 1$ , respectively, and gain significantly in IR intensity. Because interior ion solvation is slightly noncooperative (due to enhanced delocalization of the positive charge), the  $\text{NH} \cdots \text{O}$  H-bonds in  $n = 2$  are somewhat weaker than in  $n = 1$ , resulting in stronger N–H donor bonds and smaller redshifts in the bonded NH stretch modes. As a result, the CH stretch band **G** observed in  $\text{AmaH}^+\text{Ar}$  ( $\nu_{\text{CH}_2} = 3756 \text{ cm}^{-1}$ ) is for  $n = 2$  no longer obscured and detected at  $2977 \text{ cm}^{-1}$  in the shoulder of band **F**. The free OH stretch bands **X** and **Z** remain at nearly the same frequencies of  $3638$  and  $3716 \text{ cm}^{-1}$  and are again attributed to  $\nu_{\text{OH}_2}^{\text{s}}$  and  $\nu_{\text{OH}_2}^{\text{a}}$  of the individual uncoupled  $\text{H}_2\text{O}$  ligands, respectively. The observed increase in relative IR intensity of both bands is attributed to the larger number of ligands. Interestingly, the number of sub-peaks of band **Z** increased even further at  $n = 2$ , with additional reproducible peaks at  $3683$ ,  $3705$ ,  $3737$ , and  $3772 \text{ cm}^{-1}$ , but again no simple internal rotation pattern with equidistant lines can be recognized.

Significantly, the OH stretch range provides clear evidence for the minor presence of a second isomer, in which a H-bonded  $(\text{H}_2\text{O})_2$  dimer with an  $\text{OH} \cdots \text{O}$  H bond is attached to one of the NH proton donors of the  $\text{NH}_3^+$  group (H-bonded solvent network motif). The broader band **T** at  $3403 \text{ cm}^{-1}$  with a width of  $39 \text{ cm}^{-1}$  is observed in the spectral range of bound OH stretch modes ( $\nu_{\text{OH}_2}^{\text{b}}$ ). Compared to bare  $(\text{H}_2\text{O})_2$  ( $3601 \text{ cm}^{-1}$ ),<sup>105</sup> the  $\nu_{\text{OH}_2}^{\text{b}}$  frequency is drastically reduced, which is due to the large cooperativity of the H-bonded network

resulting from the strong polarization forces induced by the nearby positive charge of  $\text{AmaH}^+$ . The associated free OH stretch mode  $\nu_{\text{OH}_2}^{\text{f}}$  of the  $\text{H}_2\text{O}$  donor can be identified at  $3683 \text{ cm}^{-1}$  (**Y**), which is also redshifted compared to bare  $(\text{H}_2\text{O})_2$  ( $3735 \text{ cm}^{-1}$ ).<sup>105</sup> The two free NH stretch bands of this isomer are expected close to bands **N** and **P** of  $n = 1$ . The signal in the  $n = 2$  spectrum in this range is rather small (but visible), indicating that the population of this isomer is relatively small compared to the predominant interior ion solvation isomer.

Finally, band **M** gains width and intensity and shifts somewhat to the blue by  $37 \text{ cm}^{-1}$  to  $3230 \text{ cm}^{-1}$  due to further retarding forces of the  $\text{H}_2\text{O}$  ligands on the  $\beta_{\text{NH}_3}$  mode. In addition, a broad but weak band **A** is observed at  $2754 \text{ cm}^{-1}$ , while the weak band **B** disappears. However, the true intensity of band **A** is difficult to estimate because the laser intensity decreases rapidly in the lower frequency range.

### 3.6 IRPD of $\text{AmaH}^+(\text{H}_2\text{O})_3$

In the  $n = 3$  spectrum, bands **J** and **K** are further blueshifted to  $3118$  and  $3170 \text{ cm}^{-1}$  compared to  $n = 2$  and an additional band **I** appears at  $3009 \text{ cm}^{-1}$  with a width of  $39 \text{ cm}^{-1}$ . All three bands are attributed to the  $\nu_{\text{NH}_3}^{\text{b}}$  modes of an isomer, in which all NH bonds are singly hydrated by  $\text{H}_2\text{O}$  ligands. The slightly blueshifted peak **O** ( $3317 \text{ cm}^{-1}$ ) is still visible but weak, indicative of a minor isomer with a single free NH bond of the  $\text{NH}_3^+$  group. The associated band **T**, attributed to  $\nu_{\text{OH}_2}^{\text{b}}$  of a  $(\text{H}_2\text{O})_2$  dimer unit, is also blueshifted to  $3432 \text{ cm}^{-1}$  and gains intensity, indicating the abundance increase of isomeric structures with  $(\text{H}_2\text{O})_2$  binding to the  $\text{NH}_3^+$  group. Moreover, an additional weak band **W** appears at  $3552 \text{ cm}^{-1}$  with a width of  $11 \text{ cm}^{-1}$  in the weakly H-bonded OH stretch range, which can be attributed to a  $\nu_{\text{OH}_2}^{\text{b-ring}}$  mode of a  $(\text{H}_2\text{O})_3$  water ring structure attached to the  $\text{NH}_3^+$  group. Compared to bare cyclic  $(\text{H}_2\text{O})_3$  ( $3533 \text{ cm}^{-1}$ ),<sup>105</sup> the frequency is slightly blueshifted by  $19 \text{ cm}^{-1}$ . The bands **X** ( $3639 \text{ cm}^{-1}$ ), **Y** ( $3680 \text{ cm}^{-1}$ ), **Z** ( $3712 \text{ cm}^{-1}$ ) associated with the free OH stretch modes have almost the same frequencies as for  $n = 2$ , although band **Z** broadens to  $42 \text{ cm}^{-1}$ . The broad band **M** assigned to  $2\beta_{\text{NH}_3}$  is probably composed of several sharper transitions and shifted further to the blue by  $38 \text{ cm}^{-1}$  to  $3268 \text{ cm}^{-1}$  due to increased retarding forces. Transition **A** gains slightly in intensity and redshifts down to  $2712 \text{ cm}^{-1}$ .

### 3.7 IRPD of $\text{AmaH}^+(\text{H}_2\text{O})_4$

The  $n = 4$  spectrum exhibits a somewhat poorer signal-to-noise ratio due to the reduced abundance of  $\text{AmaH}^+(\text{H}_2\text{O})_4$  clusters produced in the ion source. Nonetheless, at least 16 peaks can still be identified. As mentioned above, the four CH stretch bands (**C–F**) have almost the same positions as in the  $n = 1$ – $3$  spectra, although bands **D** and **E** are narrower with widths of  $4$  and  $3 \text{ cm}^{-1}$ , respectively. Bands **I**, **J**, and **K** attributed to the  $\nu_{\text{NH}_3}^{\text{b}}$  modes are again slightly blueshifted to  $3058$ ,  $3144$ , and  $3188 \text{ cm}^{-1}$ , respectively, and an additional band **H** appears at  $2974 \text{ cm}^{-1}$  with a width of  $18 \text{ cm}^{-1}$ . In addition, band **O** disappears, indicating that at this cluster size all N–H bonds

of the  $\text{NH}_3^+$  group are fully solvated and that isomers with a free N–H bond are below the detection limit. The bands **T** and **W** at 3452 and 3554  $\text{cm}^{-1}$  associated with  $\nu_{\text{OH}_2}^{\text{b}}$  modes are also blueshifted. Band **W** exhibits increased intensity, indicating an increasing abundance of isomers with cyclic water ring structures bound to the  $\text{NH}_3^+$  group. Moreover, an additional band **S** is observed at 3387  $\text{cm}^{-1}$  with a width of 13  $\text{cm}^{-1}$  in the range of  $\nu_{\text{OH}_2}^{\text{b}}$  modes. The free OH stretch bands **X–Z** are hardly shifted, with frequencies of 3642, 3683, and 3705  $\text{cm}^{-1}$ . The broad band **M** remains almost at the same frequency at 3271  $\text{cm}^{-1}$ , although it is more difficult to analyze because of the lower signal. Band **A** is again further redshifted by 32  $\text{cm}^{-1}$  down to 2680  $\text{cm}^{-1}$ .

In summary, the IRPD spectra of  $\text{AmaH}^+(\text{H}_2\text{O})_n$  with  $n = 1\text{--}4$  can be interpreted with a predominant sequential cluster growth in which the three NH protons of the  $\text{NH}_3^+$  group of the predominant N-protonated ammonium isomer of  $\text{AmaH}^+$  are gradually solvated with  $\text{H}_2\text{O}$  molecules. This view is justified by the observation of the multi-band pattern **F**, **J**, and **K**, which is typical for  $\text{NH}\cdots\text{O}$  ionic H-bonds, as well as by the progressive disappearance of the free N–H stretch bands (**N**, **P**, **O**). As the number of  $\text{H}_2\text{O}$  ligands increases, the presence of solvent network isomers also increases, as evidenced by the increased intensity of bands **T** and **W**. The population of open-cage iminium isomers is very low, because the signal strength in the range of the characteristic iminium NH stretch transitions of the  $\text{NH}_2^+$  group (**Q**, **R**, **V**) is very low.

## 4. Computational results and assignments

### 4.1 Ama, $\text{Ama}^+$ , $\text{AmaH}^+$

To determine the  $\text{AmaH}^+(\text{H}_2\text{O})_{n=1-4}$  structures responsible for the recorded IRPD spectra, it is required to first consider the relevant monomer isomers of **Ama**,  $\text{Ama}^+(\text{I–III})$ , and  $\text{AmaH}^+(\text{I–IV})$ , which have been recently studied in detail by the same computational and spectroscopic approach.<sup>47–49</sup> Their structures and NBO charge distributions are shown in ESI† (Fig. S4, ESI†), and we briefly review the information relevant for the present work. Neutral **Ama** ( $^1\text{A}_1$ ,  $C_s$ ), with its  $\text{NH}_2$  group attached to the adamantyl cage ( $\text{C}_{10}\text{H}_{15}$ ) in pyramidal configuration ( $\text{sp}^3$  hybridisation of N), has short N–H bonds leading to relatively high NH stretch frequencies ( $\nu_{\text{NH}_2}^{\text{a/s}} = 3285/3359 \text{ cm}^{-1}$ ) with rather low IR intensity ( $I^{\text{a/s}} = 3/0.2 \text{ km mol}^{-1}$ ). The structure and IR spectrum calculated for Ama agree well with previous experimental and computational data.<sup>51–54</sup>

The energetically favourable protonation site of Ama is the basic  $\text{NH}_2$  group with a calculated proton affinity of  $\text{PA} = 957 \text{ kJ mol}^{-1}$ , which is in good agreement with the accepted experimental value ( $\text{PA} = 949 \text{ kJ mol}^{-1}$ ).<sup>91</sup> The resulting ammonium ion (**I**,  $C_{2v}$ ,  $^1\text{A}_1$ ) is the global minimum on the ground state potential ( $E_0 = 0 \text{ kJ mol}^{-1}$ ). N-protonation leads to a drastic elongation of the N–H bonds by 7 mÅ to 1.022 Å, resulting in massive redshift of the  $\nu_{\text{NH}_2/3}^{\text{s/a}}$  modes of  $\sim 70/60 \text{ cm}^{-1}$  ( $\nu_{\text{NH}_3}^{\text{s}} = 3214 \text{ cm}^{-1}$ ,  $\nu_{\text{NH}_3}^{\text{a}} = 3301 \text{ cm}^{-1}$ ) and a

drastic increase in their IR intensities (by a factor of  $\sim 10/500$ ) due to the increased charge on the NH protons ( $q_{\text{H}} = 0.429 e$ ). The  $\text{NH}_2$  angles increase slightly to  $108.1^\circ$ , while preserving the pyramidal configuration. Due to the higher positive charge of the  $\text{NH}_3^+$  group ( $q_{\text{NH}_3} = 0.605 e$ ) and its electron-withdrawing character, the neighbouring C–N bond is elongated by 77 mÅ to 1.544 Å and the adjacent C–C bonds contract compared to Ama ( $r_{\text{C1C2}} = 1.530 \text{ vs. } 1.538 \text{ Å}$ ,  $r_{\text{C1C3}} = 1.530 \text{ vs. } 1.544 \text{ Å}$ ), while the C–C bonds parallel to the  $C_3$  symmetry axis are slightly stretched ( $r_{\text{C4C5}} = 1.544 \text{ vs. } 1.538 \text{ Å}$ ). Most C–H bonds contract ( $\Delta r_{\text{CH}} = 2 \text{ mÅ}$ ), resulting in small blueshifts of the  $\nu_{\text{CH}}$  modes ( $\nu_{\text{CH}} = 2890 \text{ vs. } 2899 \text{ cm}^{-1}$ ,  $\nu_{\text{CH}} = 2917 \text{ vs. } 2956 \text{ cm}^{-1}$ , Table S1, ESI†).

Although protonation of **Ama** at a C atom is energetically very unfavourable (as it would lead to a nonclassical fivefold coordinated C atom), at least one isomer with an iminium group ( $\text{NH}_2^+$ ) instead of an ammonium group ( $\text{NH}_3^+$ ) has been identified by Ar-tagging IRPD,  $\text{AmaH}^+(\text{II})$ , which must therefore also be taken into account when studying microhydration of  $\text{AmaH}^+$ .<sup>49</sup> This open-cage isomer **II** is likely formed by addition of an H radical to the open-cage  $\text{Ama}^+$  radical cation isomer,  $\text{Ama}^+(\text{III})$ ,<sup>49</sup> which is formed by EI of **Ama** in addition to the canonical  $\text{Ama}^+(\text{I})$  cage isomer.<sup>47,48</sup>  $\text{AmaH}^+(\text{II})$  ( $^1\text{A}'$ ,  $C_s$ ,  $E_0 = 3.0 \text{ kJ mol}^{-1}$ ) has also an open-cage structure with a C=N double bond (1.297 Å), but with a C9H group instead of the  $\text{CR}_3^\bullet$  radical centre and a much wider open cage ( $\theta_{\text{C1C9C3}} = 155.3^\circ \text{ vs. } 106.1^\circ$ ,  $r_{\text{C1}\cdots\text{C3}} = 4.47 \text{ vs. } 3.35 \text{ Å}$ , Fig. 1). The C9–H bond is oriented toward the nearly planar  $\text{CNH}_2^+$  group ( $r_{\text{C9H}\cdots\text{C1}} = 2.450 \text{ Å}$ ) and the C–C bonds at the C9 atom are drastically stretched compared to  $\text{Ama}^+(\text{III})$  ( $r_{\text{C3C9}} = 1.482 \text{ vs. } 1.529 \text{ Å}$ ,  $r_{\text{C9C8}} = 1.492 \text{ vs. } 1.536 \text{ Å}$ ). The newly formed C9–H bond ( $r_{\text{C9H}} = 1.098 \text{ Å}$ ) is the longest C–H bond ( $r_{\text{CH}} = 1.090\text{--}1.098 \text{ Å}$ ) and its intense  $\nu_{\text{CH}}$  mode ( $\nu_{\text{CH}} = 2848 \text{ cm}^{-1}$ ) is therefore significantly redshifted from the other  $\nu_{\text{CH}_n}$  modes. The N–H bonds are much shorter compared to those of the  $\text{NH}_3^+$  group of  $\text{AmaH}^+(\text{I})$  ( $r_{\text{NH}} = 1.012 \text{ vs. } 1.022 \text{ Å}$ ), resulting in  $\nu_{\text{NH}_2}$  modes at  $\nu_{\text{NH}_2}^{\text{s/a}} = 3358/3433 \text{ cm}^{-1}$  well separated (by 100  $\text{cm}^{-1}$ ) from those of the  $\text{NH}_3^+$  group. Although the positive charge of the  $\text{NH}_2^+$  group ( $q_{\text{NH}_2} = 0.210 e$ ) is much lower than that of the  $\text{NH}_3^+$  group of  $\text{Ama}^+(\text{I})$  ( $q_{\text{NH}_3} = 0.604 e$ ), the  $\text{NH}_2^+$  group is still very attractive for hydration, because of similar positive charges of the protons ( $q_{\text{H}} = 0.419 \text{ vs. } 0.427 e$ ). However, the high positive charge of the adjacent C1 atom ( $q_{\text{C1}} = 0.538 e$ ) also influences the attachment of  $\text{H}_2\text{O}$  ligands. In addition to isomer **II**, two further open-cage structures,  $\text{AmaH}^+(\text{III})$  and  $\text{AmaH}^+(\text{IV})$ , are calculated (Fig. S4, ESI†), which differ structurally only slightly from isomer **II**.<sup>49</sup> Both isomers show similar solvation behaviour as **II** with nearly identical IR spectra and can thus experimentally not be distinguished (Fig. S5, ESI†). For this reason, these structures and their hydrated clusters will not be discussed in detail here. This procedure may be justified by their much higher relative energy ( $E_0 > 27 \text{ kJ mol}^{-1}$ ). For completeness, the structures, IR spectra, and energies of all considered  $\text{AmaH}^+(\text{I–IV})(\text{H}_2\text{O})_{n=1-4}$  isomers are available in ESI† (Fig. S6–S25 and Tables S2–S6), along with their NBO charge distribution (Fig. S26–S29, ESI†).

In our previous work, we provide a detailed vibrational and isomer-specific assignment of the bands C–G, L, M, N, P, Q, U, and V of the AmaH<sup>+</sup>Ar spectrum.<sup>49</sup> Briefly, the influence of Ar ligands is negligible justifying a direct assignment of the AmaH<sup>+</sup>Ar bands to the ammonium (AmaH<sup>+</sup>(I)) and iminium (AmaH<sup>+</sup>(II)) isomers. Most of the intense bands are readily assigned to the most stable AmaH<sup>+</sup>(I) isomer (Table S7, ESI†). Bands N (3238 cm<sup>−1</sup>) and P (3317 cm<sup>−1</sup>) are attributed to  $\nu_{\text{NH}_3}^{\text{a/s}}$  of the NH<sub>3</sub><sup>+</sup> group (3214 and 3301 cm<sup>−1</sup>), bands D (2872 cm<sup>−1</sup>) and F (2949 cm<sup>−1</sup>) to the convoluted peaks of the  $\nu_{\text{CH}_n}$  modes (2899 and 2956 cm<sup>−1</sup>), and the small peaks M (3185 cm<sup>−1</sup>) and L (3164 cm<sup>−1</sup>) to  $2\beta_{\text{NH}_3}$  overtones (3222 cm<sup>−1</sup>). On the other hand, the bands Q, U, and V cannot be explained by AmaH<sup>+</sup>(I) but arise from the iminium isomer AmaH<sup>+</sup>(II). Specifically, bands Q (3344 cm<sup>−1</sup>) and V (3451 cm<sup>−1</sup>) agree well with  $\nu_{\text{NH}_2}^{\text{a/s}}$  of the NH<sub>2</sub><sup>+</sup> group of AmaH<sup>+</sup>(II) (3331 and 3435 cm<sup>−1</sup>), while band U (3428 cm<sup>−1</sup>) is assigned to  $2\beta_{\text{NH}_2}$  (3328 cm<sup>−1</sup>). Finally, bands C (2853 cm<sup>−1</sup>), E (2921 cm<sup>−1</sup>), F (2949 cm<sup>−1</sup>), and G (2973 cm<sup>−1</sup>) are attributed to the convoluted peaks of the  $\nu_{\text{CH}_n}$  modes of AmaH<sup>+</sup>(II) (2848, 2913, 2952, 2977 cm<sup>−1</sup>). The population ratio for AmaH<sup>+</sup>(I) and AmaH<sup>+</sup>(II) is estimated as 4:1 or 3:1 from computed and measured relative band intensities.

## 4.2 AmaH<sup>+</sup>H<sub>2</sub>O

Starting from the AmaH<sup>+</sup> isomers I–IV (Fig. S4 and Table S2, ESI†),<sup>49</sup> stable AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>n</sub> structures are constructed by adding H<sub>2</sub>O ligands to the acidic N–H bonds or to the less positively charged adamantyl cage (C<sub>10</sub>H<sub>15</sub>). All obtained monohydrated structures exhibit a favorable charge–dipole configuration, with the electronegative O atom of H<sub>2</sub>O directed toward AmaH<sup>+</sup>. Two I–H<sub>2</sub>O and four II–H<sub>2</sub>O structures are found (Table S3 and Fig. S6, S7, ESI†). The two most stable isomers in each case are compared to Ama, AmaH<sup>+</sup>(I), and AmaH<sup>+</sup>(II) in Fig. 1, while their computed IR spectra are compared with the experimental IRPD spectrum in Fig. 3. The position and widths of the transitions observed in the IRPD spectrum of AmaH<sup>+</sup>H<sub>2</sub>O are listed in Table 2, along with their vibrational and isomer assignment. In the most stable isomers I–H<sub>2</sub>O(I) and II–H<sub>2</sub>O(II), H<sub>2</sub>O forms a strong NH<sup>+</sup>⋯O ionic H-bond to the NH<sub>2</sub><sup>+</sup> or NH<sub>3</sub><sup>+</sup> group, while in the others it is bound to the adamantyl cage by weaker charge–dipole forces, resulting in much higher relative energies ( $E_0 > 30$  kJ mol<sup>−1</sup>).

In the I–H<sub>2</sub>O(I) global minimum, H<sub>2</sub>O forms a strong and nearly linear NH<sup>+</sup>⋯O H-bond (175.7°) to the NH<sub>3</sub><sup>+</sup> group with a bond length of 1.742 Å and a high binding energy of 70.9 kJ mol<sup>−1</sup>. Upon hydration, the N–H donor bond stretches drastically by 21 mÅ to 1.043 Å and the NH<sub>2</sub> angle increases slightly to 108.5°, resulting in a massive redshift of the  $\nu_{\text{NH}_3}^{\text{b}}$  mode by 380 cm<sup>−1</sup> to 2921 cm<sup>−1</sup>, associated with a huge increase (by a factor of 13) in IR intensity ( $I = 682$  km mol<sup>−1</sup>). These structural and spectroscopic effects are typical for NH<sup>+</sup>⋯O ionic H-bonds in RNH<sub>3</sub><sup>+</sup>–H<sub>2</sub>O dimers.<sup>79,106,107</sup> The two remaining free N–H bonds contract slightly by 2 mÅ to 1.020 Å, resulting in modest  $\nu_{\text{NH}_3}^{\text{s/a}}$  blueshifts of 44/11 cm<sup>−1</sup> to 3258/3312 cm<sup>−1</sup>, respectively. The

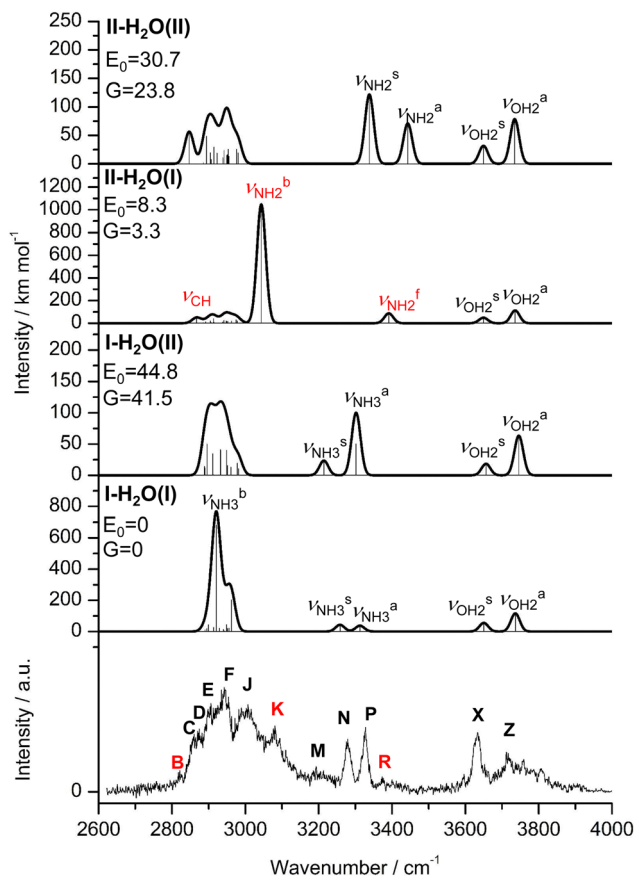

Fig. 3 IRPD spectrum of AmaH<sup>+</sup>H<sub>2</sub>O compared to linear IR absorption spectra of AmaH<sup>+</sup>(I,II)(H<sub>2</sub>O)(I,II) calculated at the B3LYP-D3/cc-pVTZ level. The positions of the transition observed in the IRPD spectrum of AmaH<sup>+</sup>H<sub>2</sub>O and their vibrational assignment are listed in Table 2. Differences in relative energy ( $E_0$ ,  $G$ ) are given in kJ mol<sup>−1</sup>. Note the different IR intensity scale for the computed IR spectra. The bands that can only be assigned to the iminium isomer II–H<sub>2</sub>O(II) are highlighted in red.

C–N bond is shortened by 14 mÅ to 1.530 Å compared to I, while the other C–C and C–H bonds change only slightly ( $\Delta r_{\text{CC}} < 3$  mÅ,  $\Delta r_{\text{CH}} < 2$  mÅ). The NBO analysis reveals a partial charge transfer of 42 me from AmaH<sup>+</sup> to H<sub>2</sub>O and  $E^{(2)} = 75.2$  kJ mol<sup>−1</sup> for the donor–acceptor interaction between the lone pairs of O and the antibonding  $\sigma^*$  orbital of the N–H donor bond involved in the NH<sup>+</sup>⋯O ionic H-bond (Fig. S26, ESI†). As a result, the O–H bonds slightly elongate by 2 mÅ to 0.963 Å and the OH<sub>2</sub> bond angle opens from 104.5° to 106.0°, leading to a rise in IR intensity of the  $\nu_{\text{OH}_2}$  modes (by a factor of 18/3) and a redshift of their frequencies by 12/23 cm<sup>−1</sup> down to  $\nu_{\text{OH}_2}^{\text{s/a}} = 3650/3736$  cm<sup>−1</sup>, respectively.

In the high-energy I–H<sub>2</sub>O(II) isomer ( $E_0 = 44.8$  kJ mol<sup>−1</sup>), H<sub>2</sub>O binds with a low binding energy of 26.1 kJ mol<sup>−1</sup> to CH<sub>(2)</sub> groups opposite to the NH<sub>3</sub><sup>+</sup> group of the adamantyl cage of I via three weak CH<sup>+</sup>⋯O contacts based mostly on charge–dipole forces. Due to the weak and strongly nonlinear CH<sup>+</sup>⋯O contacts with intermolecular distances greater than 2.5 Å, the charge transfer from I to H<sub>2</sub>O ( $\Delta q = 6$  me) and the impact of hydration on the monomer structure are negligible, except for the slight contractions of the involved C–H bonds ( $\Delta r_{\text{CH}} = 2$  mÅ). As a

**Table 2** Computed vibrational frequencies (in  $\text{cm}^{-1}$ , B3LYP-D3/cc-pVTZ) of **I-H<sub>2</sub>O(I)**, **II-H<sub>2</sub>O(I)**, and **H<sub>2</sub>O** compared to experimental values of AmaH<sup>+</sup>H<sub>2</sub>O (Fig. 3).<sup>a</sup> The experimental values (peak maxima) are given with width (fwhm in parenthesis) and are assigned to the most dominant vibrations

result, the IR spectrum of **I-H<sub>2</sub>O(II)** is essentially a combination of the spectra of **I** and bare **H<sub>2</sub>O**.

The most stable iminium monohydrate **II-H<sub>2</sub>O(I)** is 8.3  $\text{kJ mol}^{-1}$  above the most stable ammonium hydrate **I-H<sub>2</sub>O(I)**. Thus, monohydration increases the ammonium-iminium gap by 5  $\text{kJ mol}^{-1}$  because the  $\text{NH}_2^+$  group is less acidic than the  $\text{NH}_3^+$  group leading to weaker  $\text{NH} \cdots \text{O}$  H-bonds. In **II-H<sub>2</sub>O(I)**, **H<sub>2</sub>O** binds to  $\text{NH}_2^+$  group *via* a strong and nearly linear  $\text{NH} \cdots \text{O}$  H-bond ( $172.0^\circ$ ) with a binding energy of 65.6  $\text{kJ mol}^{-1}$ . As a result, the  $\text{NH} \cdots \text{O}$  H-bond (1.770 Å) is slightly longer and the N-H bond (1.031 Å) is less elongated compared to **I-H<sub>2</sub>O(I)** ( $\Delta r_{\text{NH}} = 19$  vs. 21 mÅ), resulting in a less pronounced redshift of the  $\nu_{\text{NH}_2}^b$  mode to 3044  $\text{cm}^{-1}$  (287 vs. 380  $\text{cm}^{-1}$ ) and a slightly smaller increase in IR intensity (factor 7). However, the absolute IR activity of the  $\nu_{\text{NH}_2}^b$  mode is significantly higher than that of the  $\nu_{\text{NH}_3}^b$  mode ( $I = 1047$  vs. 682  $\text{km mol}^{-1}$ ). The charge transfer to **H<sub>2</sub>O** and orbital interaction energy are slightly smaller than in **I-H<sub>2</sub>O(I)** ( $\Delta q = 39$  vs. 42 me,  $E^{(2)} = 68.3$  vs. 75.2  $\text{kJ mol}^{-1}$ , Fig. S26, ESI†). The  $\text{NH}_2$  bond angle increases slightly by  $1.1^\circ$  to  $118.0^\circ$  and the length of the free N-H bond remains at 1.012 Å, resulting in  $\nu_{\text{NH}_2}^f$  at 3391  $\text{cm}^{-1}$ . The  $\text{OH}_2$  bond angle opens slightly from  $104.5^\circ$  to  $105.8^\circ$  and the O-H bonds are slightly

stretched, leading to the same redshifts in  $\nu_{\text{OH}_2}$  as for **I-H<sub>2</sub>O(I)**,  $\nu_{\text{OH}_2}^{s/a} = 3649/3736 \text{ cm}^{-1}$ ). Upon hydration, the C=N double bond of **II** is slightly shortened by 4 mÅ to 1.293 Å and the adjacent C-C bonds are somewhat elongated ( $r_{\text{C1C2/C4}} = 1.488/1.489$  vs. 1.486 Å). The  $\theta_{\text{C1C9C3}}$  angle opens slightly from  $155.3^\circ$  to  $155.7^\circ$  and the C9-H bond contracts slightly, leading to a small blueshift of the associated  $\nu_{\text{CH}}$  mode closer to the range of the other  $\nu_{\text{CH(2)}}$  modes ( $\nu_{\text{CH}} = 2867$  vs. 2848  $\text{cm}^{-1}$ ). Most of the other C-C and C-H bonds do not change significantly.

In the second iminium monohydrate, **II-H<sub>2</sub>O(II)** at  $E_0 = 30.7 \text{ kJ mol}^{-1}$ , **H<sub>2</sub>O** binds to the adamantyl cage *via* weak  $\text{CH} \cdots \text{O}$  contacts, which are substantially shorter (2.39 Å) and stronger (43.2  $\text{kJ mol}^{-1}$ ) than for **I-H<sub>2</sub>O(II)**. The reason is probably the high positive charge on C1 ( $q_{\text{C1}} = 0.556 e$ ), to which **H<sub>2</sub>O** is attracted at a distance of 3.27 Å. Nevertheless, charge transfer to **H<sub>2</sub>O** is again quite small ( $\Delta q = 9$  me) and the effects on monomer structure and IR spectrum of **II** are negligible. The structures and IR spectra of the less favourable iminium isomers **II-H<sub>2</sub>O(III,IV)** are very similar to those of **II-H<sub>2</sub>O(II)** (Fig. S7, ESI†) and not discussed because of their relatively high energies ( $E_0 > 43 \text{ kJ mol}^{-1}$ ).

The IRPD spectrum of AmaH<sup>+</sup>H<sub>2</sub>O is compared in Fig. 3 to linear IR absorption spectra calculated for the four considered **I/II-H<sub>2</sub>O(I,II)** isomers. At first glance, most bands of the IRPD spectrum can readily be assigned to the most stable **I-H<sub>2</sub>O(I)** isomer (Table 2). The typical signature of a  $\text{NH} \cdots \text{O}$  ionic H-bond is observed as a broad multi-band pattern (**F**, **J**, **K**) that can be associated with the redshifted  $\nu_{\text{NH}_3}^b$  mode of **I-H<sub>2</sub>O(I)** and its coupled modes (FR and/or local mode mixing).<sup>77,78,81,82,103</sup> Thus, an assignment of the intense bands **F**, **J**, and **K** to specific modes of **I-H<sub>2</sub>O(I)** is not trivial. Since bands **C-F** were already observed in the AmaH<sup>+</sup>Ar spectrum and assigned to  $\nu_{\text{CH(2)}}$  modes, they are again attributed to  $\nu_{\text{CH(2)}}$  modes here, while band **J** at 3007  $\text{cm}^{-1}$  is mostly associated with the  $\nu_{\text{NH}_3}^b$  mode predicted at 2921  $\text{cm}^{-1}$ . Band **K** at 3080  $\text{cm}^{-1}$  is then explained by a FR. Bands **N** and **P** (3279 and 3328  $\text{cm}^{-1}$ ) are unambiguously assigned to the two remaining free  $\nu_{\text{NH}_3}^f$  modes of **I-H<sub>2</sub>O(I)** predicted at  $\nu_{\text{NH}_3}^{s/a} = 3258/3312 \text{ cm}^{-1}$  with deviations of 21/16  $\text{cm}^{-1}$ , respectively. Moreover, bands **X** and **Z** observed at 3633 and 3717  $\text{cm}^{-1}$  agree well with the free  $\nu_{\text{OH}_2}^{s/a}$  modes of **I-H<sub>2</sub>O(I)** computed at 3650/3736  $\text{cm}^{-1}$ . As for AmaH<sup>+</sup>Ar,<sup>49</sup> band **M** at 3193  $\text{cm}^{-1}$  is attributed to the  $2\beta_{\text{NH}_3}$  overtone of **I-H<sub>2</sub>O(I)** estimated at 3198  $\text{cm}^{-1}$ , which is slightly blueshifted by  $\text{Ar} \rightarrow \text{H}_2\text{O}$  substitution consistent with the larger retarding force arising from the stronger H-bond to **H<sub>2</sub>O**. Hence, with the exception of the weak bands **B** and **R**, the IRPD spectrum of AmaH<sup>+</sup>H<sub>2</sub>O can be fully explained by the **I-H<sub>2</sub>O(I)** global minimum. As bands **B** and **R** are weak, they may also be attributed to overtone or combination bands, or in the case of band **B** even to a CH stretch fundamental of **I-H<sub>2</sub>O(I)**, although the latter assignment gives a large discrepancy between calculation and experiment (69  $\text{cm}^{-1}$ ). Thus, in an alternative and strongly favoured second scenario, these bands are assigned to transitions of a minor population of the **II-H<sub>2</sub>O(I)** iminium isomer, whose monomer structure was also detected in the AmaH<sup>+</sup>Ar spectrum.<sup>49</sup>

Specifically, band **R** at  $3373\text{ cm}^{-1}$  is associated with the  $\nu_{\text{NH}_2}^f$  mode (predicted at  $3391\text{ cm}^{-1}$ ) of **II-H<sub>2</sub>O(I)** and then the redshifted  $\nu_{\text{NH}_2}^b$  mode (predicted at  $3044\text{ cm}^{-1}$ ) is overlapping with band **K** at  $3080\text{ cm}^{-1}$  with deviations of 18 and  $36\text{ cm}^{-1}$ , respectively. Moreover, band **B** at  $2821\text{ cm}^{-1}$  arises from the intense and low-frequency  $\nu_{\text{CH}}$  mode of the long C9-H bond of **II-H<sub>2</sub>O(I)** predicted at  $2867\text{ cm}^{-1}$ . Following this second scenario, the relative population of **II-H<sub>2</sub>O(I)** can roughly be estimated as  $<10\%$  of **I-H<sub>2</sub>O(I)** by considering the computed and observed integrated peak intensities of the isolated peaks **N**, **P**, and **R**. The two much less stable isomers **I-H<sub>2</sub>O(II)** and **I-H<sub>2</sub>O(III)** can be excluded as noticeable carrier of the IRPD spectrum, because their free  $\nu_{\text{NH}_2/3}$  modes are not observed and have a predicted IR intensity ratio in large disagreement with experiment. In summary, the IRPD spectrum clearly shows the predominant presence of **I-H<sub>2</sub>O(I)** and (at most) only a small population of **II-H<sub>2</sub>O(I)**. In both dimers, H<sub>2</sub>O binds to the  $\text{AmaH}^+$  isomers *via* strong ionic  $\text{NH}\cdots\text{O}$  H-bonds, while there is no spectroscopic evidence for isomers with H<sub>2</sub>O attached to the adamantyl cage.

### 4.3 $\text{AmaH}^+(\text{H}_2\text{O})_2$

For the  $\text{AmaH}^+(\text{H}_2\text{O})_2$  dihydrate, seven isomers are considered for both **I** and **II** (Fig. S10, S11 and Table S4, ESI†). In the

following, only **I-(H<sub>2</sub>O)<sub>2</sub>(I-III)** and **II-(H<sub>2</sub>O)<sub>2</sub>(I,II)** are discussed, because the other isomers have an energy difference of  $>30\text{ kJ mol}^{-1}$  to the global minimum and are not necessary for explaining the IRPD spectrum. These most stable structures are shown in Fig. 4, while their computed IR spectra are compared in Fig. 5 with the IRPD spectrum.

In the **I-(H<sub>2</sub>O)<sub>2</sub>(I)** global minimum ( $C_s$ ), both H<sub>2</sub>O molecules are symmetrically bound to the  $\text{NH}_3^+$  group *via* equivalent  $\text{N-H}\cdots\text{O}$  H-bonds ( $1.794\text{ \AA}$ ,  $173.5^\circ$ ) and a total binding energy of  $133.1\text{ kJ mol}^{-1}$ , yielding  $66.6\text{ kJ mol}^{-1}$  per H-bond. This binding motif corresponds to interior ion solvation. The  $\text{NH}_2$  angles decrease slightly to  $108.0^\circ$ , while the N-H donor bonds are stretched from  $1.022$  to  $1.036\text{ \AA}$ . Compared to **I-H<sub>2</sub>O(I)**, the H-bonds are somewhat weaker and the resulting perturbation of the monomer properties are correspondingly smaller, because of the noncooperative effect typical for internal ion solvation. As a result, the  $\nu_{\text{NH}_3}^b$  modes are less redshifted to  $3007$  and  $3033\text{ cm}^{-1}$  ( $\Delta\nu_{\text{NH}_3}^b = 306/268$  vs.  $380\text{ cm}^{-1}$ ). The single remaining free N-H bond contracts slightly by  $3\text{ m\AA}$  to  $1.019\text{ \AA}$ , resulting in a blueshift of  $\nu_{\text{NH}_3}^f$  by  $83\text{ cm}^{-1}$  to  $3297\text{ cm}^{-1}$ . Due to the two H<sub>2</sub>O ligands, the C-N bond contracts even more by  $22\text{ m\AA}$  to  $1.522\text{ \AA}$  compared to **I**, while the other C-C bonds and C-H bonds change only slightly ( $\Delta r_{\text{CC}} < 3\text{ m\AA}$ ,  $\Delta r_{\text{CH}} < 2\text{ m\AA}$ ).

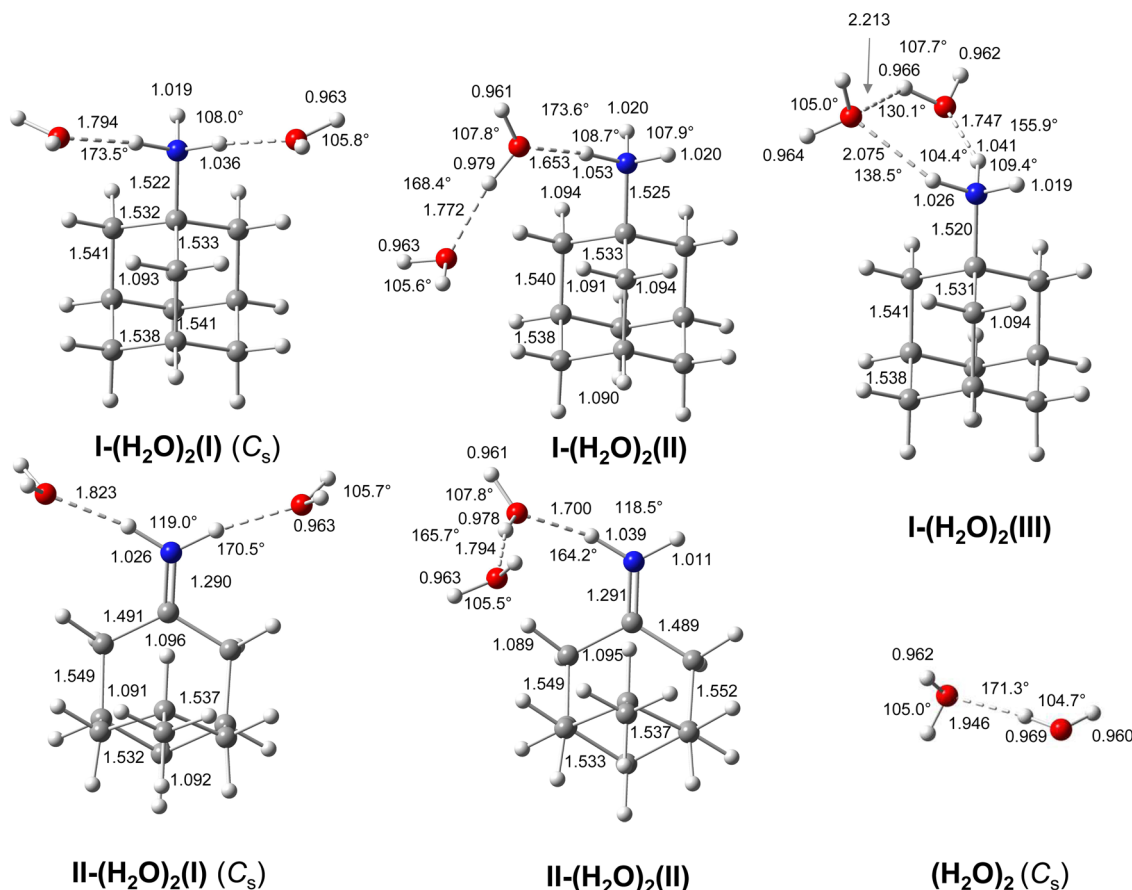

Fig. 4 Calculated equilibrium structures (in Å and degrees) of  $(\text{H}_2\text{O})_2$ ,  $\text{AmaH}^+(\text{I})(\text{H}_2\text{O})_2(\text{I-III})$  and  $\text{AmaH}^+(\text{II})(\text{H}_2\text{O})_2(\text{I,II})$  in their ground electronic state (B3LYP-D3/cc-pVTZ). All bond lengths are shown in ESI† (Fig. S23).

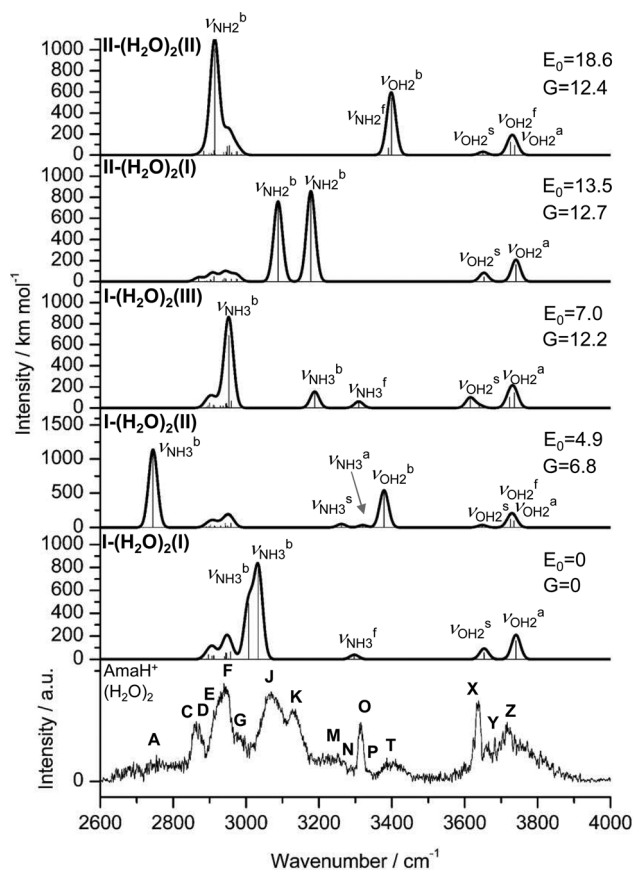

Fig. 5 IRPD spectrum of  $\text{AmaH}^+(\text{H}_2\text{O})_2$  compared to linear IR absorption spectra of  $\text{AmaH}^+(\text{I})(\text{H}_2\text{O})_2(\text{I-III})$  and  $\text{AmaH}^+(\text{II})(\text{H}_2\text{O})_2(\text{I,II})$  calculated at the B3LYP-D3/cc-pVTZ level. The positions of the transition observed in the IRPD spectrum of  $\text{AmaH}^+(\text{H}_2\text{O})_2$  and their vibrational assignment are listed in Table S8 (ESI†). Differences in relative energy ( $E_0$ , G) are given in  $\text{kJ mol}^{-1}$ . Note the different IR intensity scale for the computed IR spectra.

The NBO analysis yields a total charge transfer from  $\text{AmaH}^+$  to the  $\text{H}_2\text{O}$  ligands of 70 me and  $E^{(2)} = 60.8 \text{ kJ mol}^{-1}$  per H-bond (Fig. S27, ESI†). As a result, the O–H bonds are slightly elongated by 2 mÅ to 0.963 Å and the  $\text{OH}_2$  bond angle opens from 104.5° to 105.8°, leading to a redshift of their coupled free OH stretch modes to  $\nu_{\text{OH}_2}^s = 3653/4 \text{ cm}^{-1}$  and  $\nu_{\text{OH}_2}^a = 3740/1 \text{ cm}^{-1}$ , respectively, along with an increase in IR intensity.

In the only slightly less stable isomer  $\text{I}-(\text{H}_2\text{O})_2(\text{II})$  with  $E_0 = 4.9 \text{ kJ mol}^{-1}$ , a H-bonded  $(\text{H}_2\text{O})_2$  dimer is attached to the  $\text{NH}_3^+$  group via a single  $\text{NH} \cdots \text{O}$  ionic H-bond ( $D_0 = 128.5 \text{ kJ mol}^{-1}$ ). This binding motif corresponds to formation of a H-bonded solvent network. The  $(\text{H}_2\text{O})_2$  dimer is oriented toward the adamantyl cage, because of weak  $\text{CH} \cdots \text{O}$  contacts. Due to the larger proton affinity of  $(\text{H}_2\text{O})_2$  compared to  $\text{H}_2\text{O}$  (808 vs. 691  $\text{kJ mol}^{-1}$ ),<sup>91,92</sup> the  $\text{NH} \cdots \text{O}$  H-bond is much stronger and shorter than in  $\text{I-H}_2\text{O}(\text{I})$  (1.653 vs. 1.742 Å). The affected N–H bond is drastically stretched by 31 mÅ to 1.053 Å due to the cooperative effects of the water solvent network, while the two remaining N–H bonds are slightly shortened to 1.020 Å. As a result, the  $\nu_{\text{NH}_3}^b$  mode is strongly redshifted by 556  $\text{cm}^{-1}$  down to 2745  $\text{cm}^{-1}$  while  $\nu_{\text{NH}_3}^s$  and  $\nu_{\text{NH}_3}^a$  are slightly blueshifted to 3262 and 3320  $\text{cm}^{-1}$ , respectively. The total charge transfer is increased from 42 to 59 me and  $E^{(2)}$  increases from 75.2

to 107.9  $\text{kJ mol}^{-1}$  compared to  $\text{I-H}_2\text{O}(\text{I})$  (Fig. S27, ESI†). The affected  $\text{NH}_2$  angle increases to 108.7°, while the other  $\text{NH}_2$  angle decreases slightly to 107.9°. The C–N bond is shortened by 19 mÅ to 1.525 Å, while the other C–C bonds and C–H bonds are hardly affected by  $(\text{H}_2\text{O})_2$  dimer attachment ( $\Delta r_{\text{CC}} < 4 \text{ mÅ}$ ,  $\Delta r_{\text{CH}} < 3 \text{ mÅ}$ ). However, the C–H bonds pointing toward  $(\text{H}_2\text{O})_2$  are shortened due to the weak  $\text{CH} \cdots \text{O}$  contacts, while the other C–H bonds maintain their length. The  $\text{OH} \cdots \text{O}$  H-bond in  $\text{I}-(\text{H}_2\text{O})_2(\text{II})$  is much stronger and shorter than in bare  $(\text{H}_2\text{O})_2$  (1.772 vs. 1.946 Å), because of the strong cooperativity of the nonadditive three-body polarization forces caused by the  $\text{AmaH}^+$  charge. In addition, the binding energy of the terminal  $\text{H}_2\text{O}$  is much higher compared to bare  $(\text{H}_2\text{O})_2$  ( $D_0 = 57.4$  vs. 19.7  $\text{kJ mol}^{-1}$ ) as is the  $E^{(2)}$  energy of the  $\text{OH} \cdots \text{H}$  H-bond ( $E^{(2)} = 62.0$  vs. 34.0  $\text{kJ mol}^{-1}$ ). The O–H donor bond is stretched by 18 mÅ to 0.979 Å and the remaining free O–H bond is slightly shortened to 0.961 Å compared to  $\text{I-H}_2\text{O}(\text{I})$ . As a result,  $\nu_{\text{OH}_2}^b$  is strongly redshifted down to 3379  $\text{cm}^{-1}$ , consistent with a large increase in its IR intensity (factor  $\sim 13$ ), while  $\nu_{\text{OH}_2}^f$  is slightly blueshifted to 3725  $\text{cm}^{-1}$  and modes of the terminal  $\text{H}_2\text{O}$  at 3648 and 3735  $\text{cm}^{-1}$  nearly do not change.

In  $\text{I}-(\text{H}_2\text{O})_2(\text{III})$  at  $E_0 = 7.0 \text{ kJ mol}^{-1}$ , the two nonequivalent  $\text{H}_2\text{O}$  ligands are attached to an N–H bond via  $\text{NH} \cdots \text{O}$  H-bonds of different strength and connected to each other by a strongly bent and thus weak neutral  $\text{OH} \cdots \text{O}$  H-bond. This binding motif corresponds to the formation of a cyclic H-bonded solvent network. The stronger and more linear  $\text{NH} \cdots \text{O}$  H-bond has a bond length of 1.747 Å and a bond angle of 155.9°, while the weaker less linear one has 2.075 Å and 138.5°. The corresponding N–H bonds are stretched by 19 and 4 mÅ to 1.041 and 1.026 Å, respectively, resulting in redshifts of the corresponding  $\nu_{\text{NH}_3}^b$  modes to 2953 and 3188  $\text{cm}^{-1}$ . The total charge transfer to the  $\text{H}_2\text{O}$  ligands is 56 me (35 and 21 me) and the  $E^{(2)}$  energies are 70.2 and 18.6  $\text{kJ mol}^{-1}$  (Fig. S27, ESI†) for the strong and weak  $\text{NH} \cdots \text{O}$  H-bond, respectively. The rather weak  $\text{OH} \cdots \text{O}$  H-bond is strongly nonlinear (130.1°) and much longer (2.213 Å) than in bare  $(\text{H}_2\text{O})_2$ , as also indicated by the low  $E^{(2)}$  energy of 7.4  $\text{kJ mol}^{-1}$ . The involved O–H donor bond is only slightly more elongated by 5 mÅ to 0.966 Å than the other free O–H bonds with 0.962 and 0.964 Å. As a result, the strongly coupled  $\nu_{\text{OH}_2}$  modes are slightly redshifted to  $\nu_{\text{OH}_2}^s = 3615 \text{ cm}^{-1}$  and  $\nu_{\text{OH}_2}^a = 3640 \text{ cm}^{-1}$  and to  $\nu_{\text{OH}_2}^b = 3723 \text{ cm}^{-1}$  and  $\nu_{\text{OH}_2}^f = 3736 \text{ cm}^{-1}$  for the first and second  $\text{H}_2\text{O}$  molecule. The effects on the adamantyl cage are again negligible, except for the contraction of the C–N bond from 1.544 Å to 1.520 Å.

The most stable dihydrated iminium isomer,  $\text{II}-(\text{H}_2\text{O})_2(\text{I})$ , lies 13.5  $\text{kJ mol}^{-1}$  above the global minimum,  $\text{I}-(\text{H}_2\text{O})_2(\text{I})$ , and has also  $C_s$  symmetry because both  $\text{H}_2\text{O}$  ligands are symmetrically bound to the  $\text{NH}_2^+$  group via separate  $\text{NH} \cdots \text{O}$  H-bonds (1.823 Å, 170.5°) with a total binding energy of 122.7  $\text{kJ mol}^{-1}$ . As the  $\text{NH}_2^+$  group is less acidic than the  $\text{NH}_3^+$  group, dihydration increases the energy gap between ammonium and iminium isomers further. The total charge transfer of 64 me and  $E^{(2)}$  energy per H-bond (55.3  $\text{kJ mol}^{-1}$ ) are correspondingly smaller than in  $\text{I}-(\text{H}_2\text{O})_2(\text{I})$  (Fig. S27, ESI†). The N–H bonds elongate by 14 mÅ to 1.026 Å, resulting in  $\nu_{\text{NH}_2}^b$  redshifts to 3088

and 3178 cm<sup>-1</sup>, along with an increase in IR intensity. The NH<sub>2</sub> angle increases by 2.1° to 119.0°. The OH<sub>2</sub> bond angle rises to 105.7° and the O–H bonds slightly elongate to 0.963 Å, resulting in small redshifts to  $\nu_{\text{OH}_2}^{\text{s}} = 3652/3653 \text{ cm}^{-1}$  and  $\nu_{\text{OH}_2}^{\text{a}} = 3740/3741 \text{ cm}^{-1}$ . H<sub>2</sub>O attachment slightly shortens the C=N double bond by 7 mÅ to 1.290 Å, while the adjacent C–C bonds are stretched by 5 mÅ to 1.491 Å. However, the effect of the H<sub>2</sub>O attachment on the adamantyl cage is again negligible ( $\Delta r_{\text{CH}} < 1 \text{ mÅ}$ ,  $\Delta r_{\text{CC}} < 5 \text{ mÅ}$ ).

In **II**-(H<sub>2</sub>O)<sub>2</sub>(**II**) at  $E_0 = 18.6 \text{ kJ mol}^{-1}$ , a H-bonded (H<sub>2</sub>O)<sub>2</sub> dimer is attached to the NH<sub>2</sub><sup>+</sup> group of **II** via a NH $\cdots$ O ionic H-bond ( $D_0 = 117.6 \text{ kJ mol}^{-1}$ , 1.700 Å, 164.2°,  $\Delta q = 56 \text{ me}$ ,  $E^{(2)} = 89.8 \text{ kJ mol}^{-1}$ ). The N–H donor bond is drastically stretched by 27 mÅ to 1.039 Å due to the cooperative effect of the H-bonded solvent network, while the free N–H bond slightly contracts by 1 mÅ to 1.011 Å. As a result,  $\nu_{\text{NH}_2}^{\text{b}}$  is strongly redshifted by 521 cm<sup>-1</sup> to 2914 cm<sup>-1</sup>, while  $\nu_{\text{NH}_2}^{\text{f}}$  is slightly blueshifted to 3399 cm<sup>-1</sup>, associated with an increase in IR intensities by a factor of 13 and 4, respectively. The OH $\cdots$ O H-bond of the attached (H<sub>2</sub>O)<sub>2</sub> is longer and less linear than in **I**-(H<sub>2</sub>O)<sub>2</sub>(**II**) (1.794 vs. 1.772 Å, 165.7° vs. 168.4°). The involved O–H donor bond is stretched by 17 mÅ to 0.978 Å and the remaining free O–H bond slightly shortens to 0.961 Å compared to **II**-H<sub>2</sub>O(**I**). As a result,  $\nu_{\text{OH}_2}^{\text{b}}$  is redshifted to 3399 cm<sup>-1</sup>, accompanied with an increase in intensity (factor  $\sim 5$ ) and  $\nu_{\text{OH}_2}^{\text{f}}$  is slightly blueshifted to 3725 cm<sup>-1</sup>, while  $\nu_{\text{OH}_2}^{\text{s/a}}$  of the terminal water remain at  $\nu_{\text{OH}_2}^{\text{s}} = 3650$  and  $\nu_{\text{OH}_2}^{\text{a}} = 3738 \text{ cm}^{-1}$ . The C=N double bond is slightly shortened by 6 mÅ to 1.291 Å, while the other C–C and C–H bonds are hardly affected ( $\Delta r_{\text{CC}} < 3 \text{ mÅ}$ ,  $\Delta r_{\text{CH}} < 3 \text{ mÅ}$ ).

Comparison of the measured IRPD spectrum of AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>2</sub> with the IR spectra computed for **I**-(H<sub>2</sub>O)<sub>2</sub>(**I–III**) and **II**-(H<sub>2</sub>O)<sub>2</sub>(**I,II**) in Fig. 5 (Table S8, ESI†) clearly shows the signature of the **I**-(H<sub>2</sub>O)<sub>2</sub>(**I**) global minimum. The isolated band **O** at 3315 cm<sup>-1</sup> is a clear-cut sign of a single free NH stretch oscillator of an ammonium ion and agrees well with the predicted frequency ( $\nu_{\text{NH}_3}^{\text{f}} = 3297 \text{ cm}^{-1}$ ). Similar to AmaH<sup>+</sup>H<sub>2</sub>O, a specific assignment of the two  $\nu_{\text{NH}_3}^{\text{b}}$  modes is difficult due to the FR. Tentatively, the broad band **J** (3069 cm<sup>-1</sup>) is predominantly assigned to the two  $\nu_{\text{NH}_3}^{\text{b}}$  modes of **I**-(H<sub>2</sub>O)<sub>2</sub>(**I**) computed at 3007 and 3033 cm<sup>-1</sup> with deviations of 62 and 36 cm<sup>-1</sup>, respectively. As for  $n = 1$ , band **K** (3127 cm<sup>-1</sup>) is associated with a FR. The corresponding  $\nu_{\text{OH}_2}$  modes ( $\nu_{\text{OH}_2}^{\text{s}} = 3653/4 \text{ cm}^{-1}$ ,  $\nu_{\text{OH}_2}^{\text{a}} = 3740/1 \text{ cm}^{-1}$ ) are attributed to bands **X** and **Z** at 3638 and 3716 cm<sup>-1</sup>. Band **M** at 3230 cm<sup>-1</sup> with a large width is again assigned to  $2\nu_{\text{NH}_3}$  (3293 cm<sup>-1</sup>) and may also have contributions  $2\nu_{\text{OH}_2}$  (3200 and 3208 cm<sup>-1</sup>). As for  $n = 1$ , bands **C–F** can arise from  $\nu_{\text{CH}_{(2)}}$  of all present isomers, due to the small influence of hydration on the adamantyl cage. However, bands **A** and **T** at 2754 and 3403 cm<sup>-1</sup> are not explainable by **I**-(H<sub>2</sub>O)<sub>2</sub>(**I**) and can, according to Fig. 5, only be attributed to **I**-(H<sub>2</sub>O)<sub>2</sub>(**II**). This isomer with an attached (H<sub>2</sub>O)<sub>2</sub> has a strongly redshifted  $\nu_{\text{NH}_3}^{\text{b}}$  mode at 2745 cm<sup>-1</sup> and a redshifted  $\nu_{\text{OH}_2}^{\text{b}}$  mode at 3379 cm<sup>-1</sup> which both agree well with the observed bands **A** and **T**, with minor deviations

of 9 and 24 cm<sup>-1</sup>, respectively. Band **A** is rather broad as expected for a strongly redshifted proton donor band and its experimental intensity may largely be underestimated by the low laser intensity in this spectral range. Moreover, band **Y** (3683 cm<sup>-1</sup>) can be assigned to  $\nu_{\text{OH}_2}^{\text{f}}$  at 3725 cm<sup>-1</sup> of **I**-(H<sub>2</sub>O)<sub>2</sub>(**II**) and the two free  $\nu_{\text{NH}_3}^{\text{s/a}}$  modes at 3262 and 3320 cm<sup>-1</sup> are probably weakly present at **N** and **P** at 3288 and 3331 cm<sup>-1</sup>. Thus, the IRPD spectrum of AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>2</sub> can be fully explained by the major contribution of the most stable **I**-(H<sub>2</sub>O)<sub>2</sub>(**I**) isomer and a minor contribution of the next stable **I**-(H<sub>2</sub>O)<sub>2</sub>(**II**) isomer, whereby the population of the latter is estimated to be of the order of 20% from the observed and computed IR intensities of the free NH stretch modes. There is no need to invoke other higher-energy isomer isomers, although their minor presence cannot be ruled out completely. In particular, weak signal near 3600 cm<sup>-1</sup> may indicate a small population of the cyclic **I**-(H<sub>2</sub>O)<sub>2</sub>(**III**) isomer. A significant population of dihydrated iminium isomers, **II**-(H<sub>2</sub>O)<sub>2</sub>, is not expected based on their high relative energy and their small population for  $n = 1$ . As the energy difference between iminium and ammonium isomers increases with  $n$  ( $3.0 < 8.3 < 13.5 < 21.5 \text{ kJ mol}^{-1}$  for  $n = 0\text{--}3$ ), we do not consider herein hydrated iminium isomers in detail for  $n \geq 3$  but focus only on **I**-(H<sub>2</sub>O) <sub>$n$</sub>  clusters.

#### 4.4 AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>3</sub>

For trihydrated **I**, we find nine isomers (Fig. S14, S15 and Table S5, ESI†) but discuss in more detail only the structures and IR spectra of the four most stable isomers, **I**-(H<sub>2</sub>O)<sub>3</sub>(**I–IV**) in Fig. 6 and 7, because the other isomers are higher in energy ( $E_0 > 12 \text{ kJ mol}^{-1}$ ) and not necessary to explain the IRPD spectrum. In addition, for brevity we keep the discussion on the structures and IR spectra for the  $n = 3$  and also  $n = 4$  isomers shorter than for  $n = 0\text{--}2$  and refer to ESI† for more details. In general, the structural, energetic, vibrational, and charge transfer trends, arising from cooperativity of the formation of H-bonded networks and noncooperativity of interior ion solvation discussed for  $n = 1\text{--}2$  are also apparent for  $n = 3$  and 4. The main change for the larger clusters with  $n \geq 3$  is that entropic effects have a decisive role on their relative energies. Hence, we discuss also free energies, which favor isomers with flexible hydration structures (e.g., single ligands) over rigid ones (e.g., cyclic rings or longer solvent chains interacting with the adamantyl cage). For example, while the energetic order for the four isomers in Fig. 6 is **I–IV**, with  $E_0 = 0, 2.5, 4.4$ , and  $11.9 \text{ kJ mol}^{-1}$ , their free energies vary as  $G_0 = 0, -8.8, -1.2$ , and  $12.8 \text{ kJ mol}^{-1}$ , i.e., **II** and **III** become more stable than **I** at elevated temperature due to entropy. This temperature effect may become an issue as cooling in the supersonic plasma expansion may be incomplete and not equilibrated (the effective temperature is difficult to estimate) and kinetic trapping may occur during the expansion.

In the most stable **I**-(H<sub>2</sub>O)<sub>3</sub>(**I**) with  $C_s$  symmetry ( $E_0/G = 0/0$ ) and a total binding energy of  $190.4 \text{ kJ mol}^{-1}$ , the three H<sub>2</sub>O ligands and the NH<sub>3</sub><sup>+</sup> group form a cyclic eight-membered ring with two equivalent O–H $\cdots$ O H-bonds (1.932 Å, 162.1°) and two equivalent but stronger N–H $\cdots$ O ionic H-bonds (1.765 Å, 161.5°). Two H<sub>2</sub>O ligands act as single-donor single-acceptor,

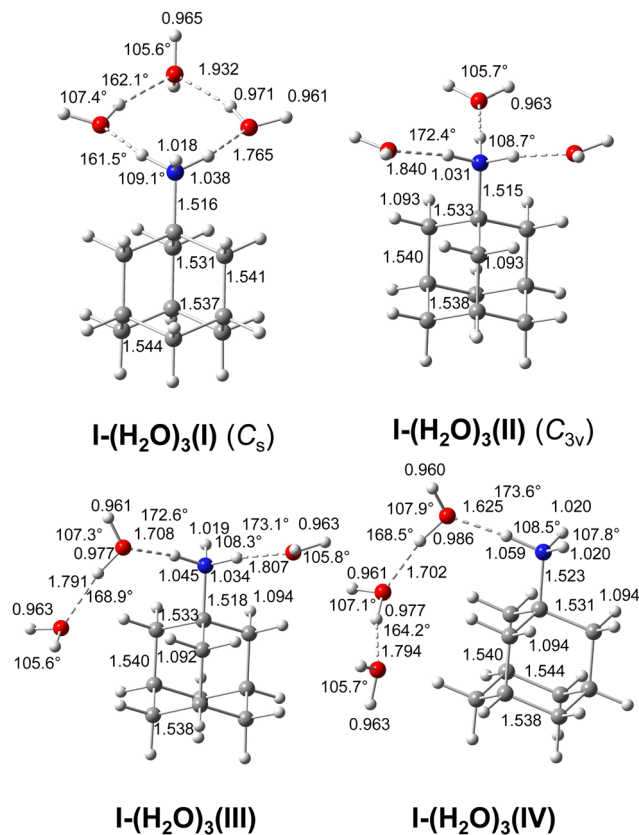

Fig. 6 Calculated equilibrium structures (in Å and degrees) of **AmaH<sup>+</sup>(I)(H<sub>2</sub>O)<sub>3</sub>(I–IV)** in their ground electronic state (B3LYP-D3/cc-pVTZ). All bond lengths are shown in ESI† (Fig. S24).

while the terminal H<sub>2</sub>O molecule closing the ring acts as a double-acceptor ligand. To close the ring, the two H<sub>2</sub>O ligands involved in the NH<sub>3</sub>···O H-bonds have to rotate into the ring plane but due to cooperativity of the formed ring, they are stronger and shorter than in **I-(H<sub>2</sub>O)<sub>2</sub>(I)**. Due to higher strain and resulting larger nonlinearity as compared to **I-(H<sub>2</sub>O)<sub>2</sub>(II)** with a (H<sub>2</sub>O)<sub>2</sub> chain, the OH···O H-bonds are weaker and longer. Compared to cyclic **I-(H<sub>2</sub>O)<sub>2</sub>(III)** with a cyclic six-membered ring, the addition of one ligand into the ring decreases strain and thus the OH···O H-bonds are stronger and more linear. The strengths of the H-bonds correlate with the charge transfer and  $E^{(2)}$  energies and have direct impact on the perturbation of the intramolecular O–H and N–H donor bonds and resulting frequency shifts. The IR spectrum of **I-(H<sub>2</sub>O)<sub>3</sub>(I)** is characterized by two intense and moderately redshifted bound OH stretch bands at  $\nu_{\text{OH}_2}^b = 3509/3533 \text{ cm}^{-1}$ , two intense and strongly redshifted bound NH stretch bands at  $\nu_{\text{NH}_3}^b = 2982/2984 \text{ cm}^{-1}$ , and a weaker and nearly unshifted free NH stretch band at  $\nu_{\text{NH}_3}^f = 3307 \text{ cm}^{-1}$ .

The second most stable **I-(H<sub>2</sub>O)<sub>3</sub>(II)** isomer on the potential energy surface ( $E_0/G = 2.5/-8.8 \text{ kJ mol}^{-1}$ ) becomes the global minimum on the free energy surface. It has three single H<sub>2</sub>O ligands attached to the NH<sub>3</sub><sup>+</sup> group *via* three equivalent NH···O ionic H-bonds (1.840 Å, 172.4°), leading to a structure with (near)  $C_{3v}$  symmetry and a total binding energy of  $D_0 =$

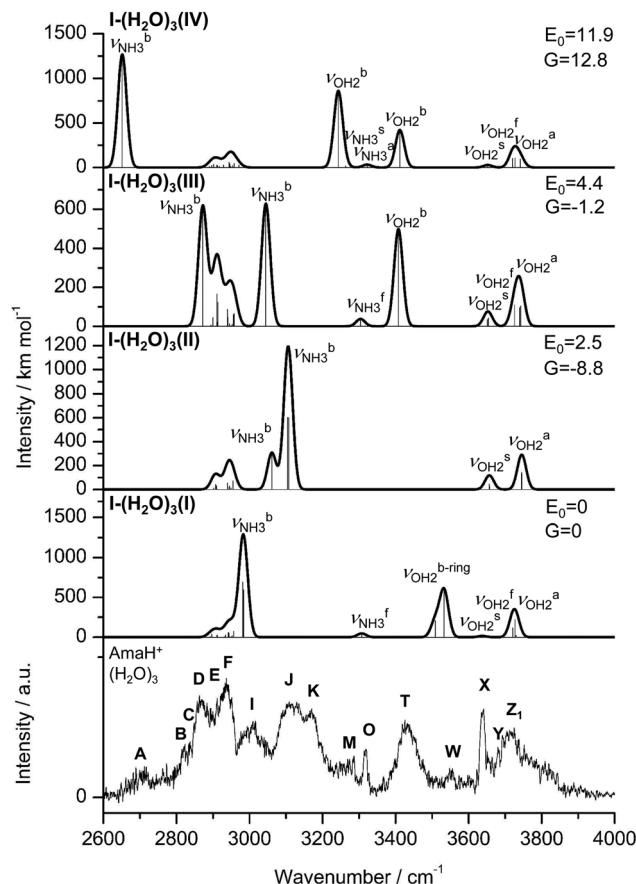

Fig. 7 IRPD spectrum of **AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>3</sub>** compared to linear IR absorption spectra of **AmaH<sup>+</sup>(I)(H<sub>2</sub>O)<sub>3</sub>(I–IV)** calculated at the B3LYP-D3/cc-pVTZ level. The positions of the transition observed in the IRPD spectrum of **AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>3</sub>** and their vibrational assignment are listed in Table S9 (ESI†). Differences in relative energy ( $E_0$ ,  $G$ ) are given in  $\text{kJ mol}^{-1}$ . Note the different IR intensity scale for the computed IR spectra.

187.9  $\text{kJ mol}^{-1}$ . Due to noncooperativity of interior ion solvation, the three H-bonds of the fully solvated NH<sub>3</sub><sup>+</sup> group are weaker than those of the corresponding  $n = 2$  and 1 isomers ( $1.742 < 1.794 < 1.840 \text{ Å}$  for  $n = 1-3$ ), as also seen in the corresponding  $E^{(2)}$  energies ( $75.2 > 60.8 > 50.3 \text{ kJ mol}^{-1}$ ) and the smaller redshifts in  $\nu_{\text{NH}_3}^b$ . Due to its high symmetry, the IR spectrum of this isomer is rather simple and characterized by three intense redshifted  $\nu_{\text{NH}_3}^b$  bands near  $3100 \text{ cm}^{-1}$  (two of which are degenerate in  $C_{3v}$ ), two free OH stretch bands ( $\nu_{\text{OH}_2}^{s/a}$ ), and missing free NH and bound OH stretch bands ( $\nu_{\text{NH}_3}^f, \nu_{\text{OH}_2}^b$ ).

In the **I-(H<sub>2</sub>O)<sub>3</sub>(III)** isomer ( $E_0/G = 4.4/-1.2 \text{ kJ mol}^{-1}$ ) with a total binding energy of  $D_0 = 186.0 \text{ kJ mol}^{-1}$ , two N–H bonds of the NH<sub>3</sub><sup>+</sup> group are solvated by a single H<sub>2</sub>O ligand and a (H<sub>2</sub>O)<sub>2</sub> dimer. The NH···O H-bond to H<sub>2</sub>O (1.807 Å, 173.1°) is weaker than that to (H<sub>2</sub>O)<sub>2</sub> (1.708 Å, 172.6°), as also indicated by the lower  $E^{(2)}$  energy (57.6 and 88.0  $\text{kJ mol}^{-1}$ ) and the smaller redshift in the bound NH stretch mode ( $\nu_{\text{NH}_3}^b = 3045 \text{ and } 2872 \text{ cm}^{-1}$ ). Overall, attachment of the single H<sub>2</sub>O ligand slightly weakens the NH···O

and OH...O H-bonds of the (H<sub>2</sub>O)<sub>2</sub> ligand *via* noncooperativity. The convoluted IR spectrum of this isomer is characterized by two strongly redshifted and intense  $\nu_{\text{NH}_3}^{\text{b}}$  bands, one weak free  $\nu_{\text{NH}_3}^{\text{f}}$  band, one intense and strongly redshifted  $\nu_{\text{OH}}^{\text{b}}$  band, and two free OH stretch bands.

In the **I**-(H<sub>2</sub>O)<sub>3</sub>(**III**) isomer ( $E_0/G = 12.8/11.9$  kJ mol<sup>-1</sup>), a linear H-bonded (H<sub>2</sub>O)<sub>3</sub> trimer chain forms a rather strong and nearly linear NH...O H-bond to the NH<sub>3</sub><sup>+</sup> group (1.625 Å, 173.6°,  $E^{(2)} = 123.5$  kJ mol<sup>-1</sup>) supported by weaker CH...O contacts, resulting in a total binding energy of  $D_0 = 178.5$  kJ mol<sup>-1</sup>. As the PA of (H<sub>2</sub>O)<sub>n</sub> clusters increases with *n*, the NH...O H-bond is stronger and shorter than those of the related isomers of *n* = 1 (isomer **I**) and 2 (isomer **II**) (1.742 > 1.700 > 1.625 Å for *n* = 1–3), resulting in a larger redshift in the bound NH stretch mode ( $\nu_{\text{NH}_3}^{\text{b}} = 2921 > 2745 > 2652$  cm<sup>-1</sup>) and increase in IR intensity ( $I = 682 < 1139 < 1268$  km mol<sup>-1</sup>), arising from the stronger elongation of the N–H donor bond ( $r_{\text{NH}} = 1.031 > 1.053 > 1.059$  Å). The stronger NH...O H-bond is also visible in the increasing charge transfer to solvent ( $\Delta q = 42 < 59 < 75$  me) and the corresponding orbital interaction energy ( $E^{(2)} = 75.2 < 107.9 < 123.5$  kJ mol<sup>-1</sup>). Due to closer proximity to the positive charge, the first O–H...O H-bond (1.702 Å, 168.5°,  $E^{(2)} = 82.7$  kJ mol<sup>-1</sup>) is much shorter and more linear than the second one (1.794 Å, 164.2°,  $E^{(2)} = 55.6$  kJ mol<sup>-1</sup>), resulting in correspondingly larger and smaller redshifts in their  $\nu_{\text{OH}_2}^{\text{b}}$  mode (3243 vs. 3412 cm<sup>-1</sup>). The convoluted IR spectrum of this isomer is characterized by one very strongly redshifted and intense  $\nu_{\text{NH}_3}^{\text{b}}$  band, two weak and coupled free  $\nu_{\text{NH}_3}^{\text{s/a}}$  bands, two intense, strongly redshifted, and well-separated  $\nu_{\text{OH}}^{\text{b}}$  bands, and two free OH stretch bands.

Comparison of the IRPD spectrum of AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>3</sub> to the IR spectra calculated for **I**-(H<sub>2</sub>O)<sub>3</sub>(**I–IV**) in Fig. 7 (Table S9, ESI†) suggests the presence of at least three isomers based on the observation of the four redshifted NH<sub>3</sub> bands (**A**, **I**, **J**, **K**). The global minimum **I**-(H<sub>2</sub>O)<sub>3</sub>(**I**) is identified by band **W** at 3552 cm<sup>-1</sup> assigned to  $\nu_{\text{OH}_2}^{\text{b-ring}}$  modes (3509/3533 cm<sup>-1</sup>) and band **O** at 3317 cm<sup>-1</sup> assigned to  $\nu_{\text{NH}_3}^{\text{f}}$  at 3307 cm<sup>-1</sup>. However,  $\nu_{\text{OH}_2}^{\text{b-ring}}$  modes could be also assigned to band **T** at 3432 cm<sup>-1</sup>. Moreover, its  $\nu_{\text{NH}_3}^{\text{b}}$  modes (2982/2984 cm<sup>-1</sup>) agree well with band **I** at 3009 cm<sup>-1</sup>, with only minor deviations of 25/27 cm<sup>-1</sup>. Band **M** (3268 cm<sup>-1</sup>) can be assigned to  $2\nu_{\text{OH}_2}$  (3237 cm<sup>-1</sup>) and/or  $2\nu_{\text{NH}_3}$  (3244 cm<sup>-1</sup>). The calculated  $\nu_{\text{OH}_2}^{\text{s/a}}$  modes at 3637 and 3721 cm<sup>-1</sup> agree with the observed OH<sub>2</sub> bands **X** and **Z** at 3639 and 3712 cm<sup>-1</sup>. Due to negligible influence of hydration on the adamantyl cage, bands **C–F** are consistent with the  $\nu_{\text{CH}_{(2)}}$  modes of **I**-(H<sub>2</sub>O)<sub>3</sub>(**I**) but also all other isomers. Indeed, the observed bands **A**, **B**, **J**, **K**, and **T** imply the presence of further isomers. Bands **J** and **K** (at 3118 and 3170 cm<sup>-1</sup>) can be assigned to three redshifted  $\nu_{\text{NH}_3}^{\text{b}}$  modes of the fully solvated NH<sub>3</sub><sup>+</sup> group of **I**-(H<sub>2</sub>O)<sub>3</sub>(**II**), with again relatively large deviations of 57 and 65 cm<sup>-1</sup>. However, the experimental blueshifts of **J** ( $\Delta\nu_{\text{NH}_3}^{\text{b}} = 49$  cm<sup>-1</sup>) and **K** ( $\Delta\nu_{\text{NH}_3}^{\text{b}} = 43$  cm<sup>-1</sup>) agree well with the predicted ones ( $\Delta\nu_{\text{NH}_3}^{\text{b}} = 54/72$  cm<sup>-1</sup>) upon further solvation of the NH<sub>3</sub><sup>+</sup> group of **I**-(H<sub>2</sub>O)<sub>2</sub>(**I**). The broad transition **T**

(3432 cm<sup>-1</sup>) can only be attributed to redshifted  $\nu_{\text{OH}_2}^{\text{b}}$  modes of isomers with an attached (H<sub>2</sub>O)<sub>2,3</sub> cluster and is therefore assigned to  $\nu_{\text{OH}_2}^{\text{b}}$  of **I**-(H<sub>2</sub>O)<sub>3</sub>(**III**) (3408 cm<sup>-1</sup>) and/or  $\nu_{\text{OH}_2}^{\text{b}}$  of **I**-(H<sub>2</sub>O)<sub>3</sub>(**IV**) (3412 cm<sup>-1</sup>). Moreover, band **O** (3317 cm<sup>-1</sup>) contains  $\nu_{\text{NH}_3}^{\text{f}}$  ( $\nu_{\text{NH}_3}^{\text{f}} = 3304$  cm<sup>-1</sup>) and band **J** (3118 cm<sup>-1</sup>) the redshifted  $\nu_{\text{NH}_3}^{\text{b}}$  mode of **I**-(H<sub>2</sub>O)<sub>3</sub>(**III**) ( $\nu_{\text{NH}_3}^{\text{b}} = 3045$  cm<sup>-1</sup>) associated with the H-bond to a single H<sub>2</sub>O. The further redshifted  $\nu_{\text{NH}_3}^{\text{b}}$  mode **I**-(H<sub>2</sub>O)<sub>3</sub>(**III**) ( $\nu_{\text{NH}_3}^{\text{b}} = 2872$  cm<sup>-1</sup>) associated with the H-bond to (H<sub>2</sub>O)<sub>2</sub> agrees well with band **B** (2823 cm<sup>-1</sup>), even though the intensity in the IRPD spectrum is too low (possibly for reasons of low laser intensity). Furthermore,  $\nu_{\text{NH}_3}^{\text{a}}$  (3263 cm<sup>-1</sup>) and  $\nu_{\text{NH}_3}^{\text{s}}$  (3322 cm<sup>-1</sup>) of **I**-(H<sub>2</sub>O)<sub>3</sub>(**IV**) can also be attributed to **M** (3268 cm<sup>-1</sup>) and **O** (3317 cm<sup>-1</sup>), with minor deviations of 11 and 5 cm<sup>-1</sup>. Its strongly redshifted  $\nu_{\text{NH}_3}^{\text{b}}$  mode (2652 cm<sup>-1</sup>) due to the attached (H<sub>2</sub>O)<sub>3</sub> is also observed with band **A** at 2712 cm<sup>-1</sup>, with a deviation of 60 cm<sup>-1</sup>. Assuming that only isomers **I**-(H<sub>2</sub>O)<sub>3</sub>(**I–IV**) are detected and bands **A**, **B**, **K**, and **W** can each be assigned to only one isomer, the relative populations of **I–IV** can be roughly estimated from the calculated and observed peak intensities (peak area) as 1:4:4:1, respectively.

#### 4.5 AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>4</sub>

As the number of H<sub>2</sub>O ligands increases, the number of possible low-energy isomers grows drastically. In total, we identified ten low-energy AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>4</sub> isomers for each monomer (**I–IV**) (Fig. S18–S21 and Table S6, ESI†). Due to the large number of observed peaks in the AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>4</sub> spectrum, almost no isomer can be excluded by spectroscopy. Hence, we discuss herein only the most stable isomers **I**-(H<sub>2</sub>O)<sub>4</sub>(**I–VI**) of monomer **I** (Fig. 8 and Fig. S26, ESI†), which are sufficient to explain the IRPD spectrum (Fig. 9). Isomers **I–III** and **V** are derived by hydrating the most stable cyclic **I**-(H<sub>2</sub>O)<sub>3</sub>(**I**) trihydrated cluster at different positions of the eight-membered solvation ring or the third N–H bond of the NH<sub>3</sub><sup>+</sup> unit, while **IV** is obtained by starting the second hydration shell of the **I**-(H<sub>2</sub>O)<sub>3</sub>(**II**) isomer with a fully hydrated NH<sub>3</sub><sup>+</sup> group and **VI** by hydrating **I**-(H<sub>2</sub>O)<sub>3</sub>(**II**) to form a C<sub>s</sub> symmetric structure with two N–H...O H-bonds to two (H<sub>2</sub>O)<sub>2</sub> units. Isomers **II** and **IV** have a fully hydrated NH<sub>3</sub><sup>+</sup> group, while **I**, **III**, and **VI** have one free NH group, illustrating the strong competition between interior ion solvation and the formation of a H-bonded solvent network. As with *n* = 3, the energetic order of these isomers **I–VI** of *n* = 4 ( $E_0 = 0, 0.6, 1.7, 4.9, 7.1, 7.2$  kJ mol<sup>-1</sup>) change drastically with inclusion of entropy ( $G = 0, -7.0, -2.9, -13.2, 3.0, -7.7$  kJ mol<sup>-1</sup>), so that the energetically most stable isomer **I** becomes the fifth stable at room temperature, while the energetically forth stable isomer **IV** becomes the global minimum on the free energy surface (Table S6, ESI†). Indeed, **IV** has only one OH...O H-bond, leading to a flexible and thus entropically favoured structure, while the other low-energy isomers have larger constrain due to two (**II**, **VI**) or three OH...O H-bonds (**I**, **III**, **V**). As with *n* = 3, we refer for a detailed discussion on the structures and IR spectra for the *n* = 4 isomers to ESI.† In general, the structural, energetic, vibrational, and charge transfer trends, arising from cooperativity of the formation of

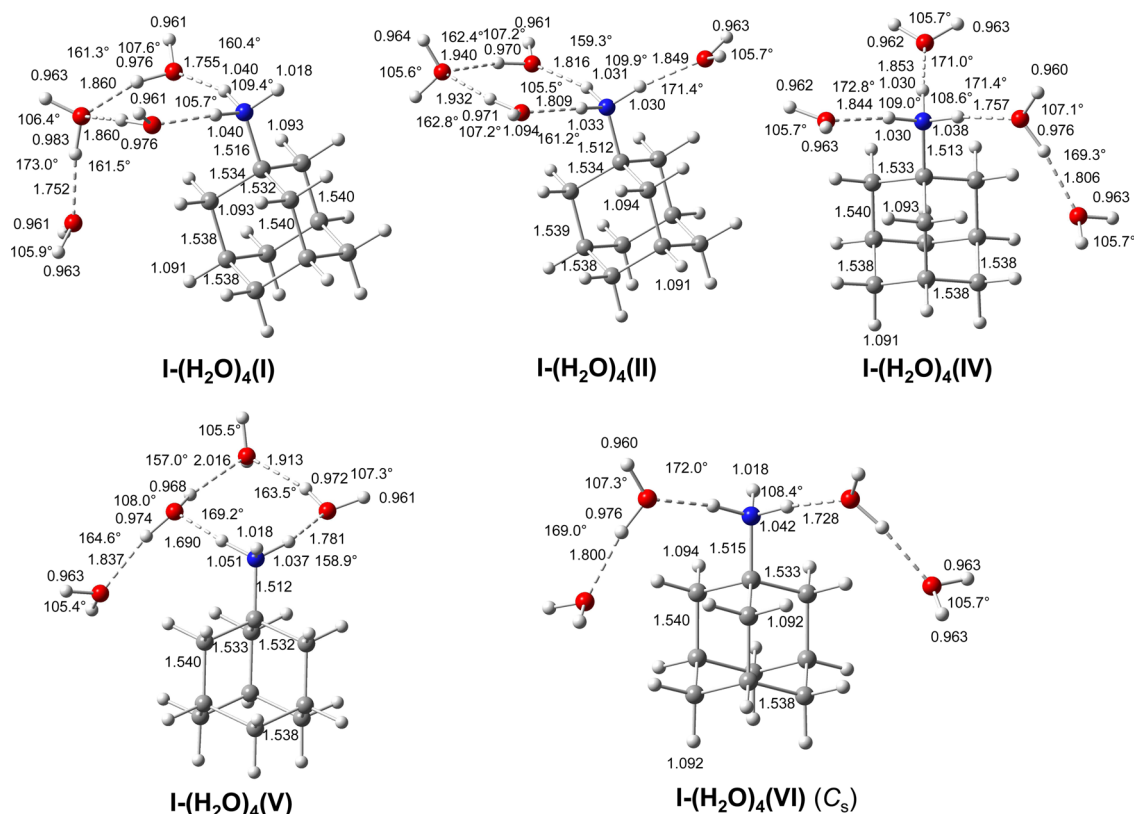

Fig. 8 Calculated equilibrium structures (in Å and degrees) of  $\text{AmaH}^+(\text{I})(\text{H}_2\text{O})_4(\text{I,II})$  and  $\text{AmaH}^+(\text{I})(\text{H}_2\text{O})_4(\text{IV-VI})$  in their ground electronic state (B3LYP-D3/cc-pVTZ). All bond lengths are shown in ESI† (Fig. S25).

H-bonded networks and noncooperativity of interior ion solvation discussed for  $n = 1-3$  are also observed for  $n = 4$ .

Comparison of the IRPD spectrum of  $\text{AmaH}^+(\text{H}_2\text{O})_4$  to calculated IR spectra of  $\text{I}-(\text{H}_2\text{O})_4(\text{I-V})$  in Fig. 9 (Table S10, ESI†) provides evidence for the presence of at least three isomers, because five observed bands (A, H, I, J, K) are assigned to  $\nu_{\text{NH}_3}^b$  modes. The large number of peaks and the several similar frequencies calculated for different isomers prevent a definitive isomer assignment. Nonetheless, it is possible to explain the IRPD spectrum with the six most stable isomers  $\text{I}-(\text{H}_2\text{O})_4(\text{I-VI})$  with  $E_0 < 8 \text{ kJ mol}^{-1}$ . As before, bands C-F can be assigned to the  $\nu_{\text{CH/CH}_2}$  modes of all possible isomers  $\text{I}-(\text{H}_2\text{O})_4(\text{I-VI})$ , as their C-H bonds remain almost unchanged upon hydration. Moreover, the free OH stretch bands X-Z are consistent with their  $\nu_{\text{OH}_2}^{\text{s/f/a}}$  modes. For example, the  $\nu_{\text{OH}_2}^{\text{s}}$  (3655  $\text{cm}^{-1}$ ),  $\nu_{\text{OH}_2}^{\text{f}}$  (3703, 3725, 3727  $\text{cm}^{-1}$ ), and  $\nu_{\text{OH}_2}^{\text{a}}$  (3745  $\text{cm}^{-1}$ ) modes of isomer I agree well with bands X (3642  $\text{cm}^{-1}$ ), Y (3683  $\text{cm}^{-1}$ ), and Z (3705  $\text{cm}^{-1}$ ), respectively, with maximum, mean, and summed deviations of 40, 20, and 23  $\text{cm}^{-1}$ . On the other hand, peak A at 2680  $\text{cm}^{-1}$ , can uniquely be identified with the intense and strongly redshifted  $\nu_{\text{NH}_3}^b$  mode (2776  $\text{cm}^{-1}$ ) of V. The isomer assignment for the other bands (H-W) is less clear. For example, the bound NH stretch peak H (2974  $\text{cm}^{-1}$ ) may be attributed I ( $\nu_{\text{NH}_3}^b = 2944/2948 \text{ cm}^{-1}$ ), III (2937/2961  $\text{cm}^{-1}$ ), IV (2979  $\text{cm}^{-1}$ ), and/or VI (2929  $\text{cm}^{-1}$ ). The three  $\nu_{\text{NH}_3}^b$  modes of II

predicted at 3049, 3068, and 3123  $\text{cm}^{-1}$  correlate with bands I, J, and K (3058, 3144, 3188  $\text{cm}^{-1}$ ) with larger differences (maximum, mean, and summed deviations of 76, 65, and 50  $\text{cm}^{-1}$ ), as expected for proton-donor stretch modes of strong H-bonds. However, band I also fits to  $\nu_{\text{NH}_3}^b$  of V (3008  $\text{cm}^{-1}$ ), and bands J and K to the  $\nu_{\text{NH}_3}^b$  modes of IV (3095/3126  $\text{cm}^{-1}$ ) with similar large maximum, mean, and summed deviations of 62, 50, and 54  $\text{cm}^{-1}$ . Although the differences between calculated and observed  $\nu_{\text{NH}_3}^b$  bands are relatively large, they are of the same order of magnitude as for  $n = 1-3$ , and the observed blueshifts of the peaks upon hydration ( $n = 3 \rightarrow 4$ ) is also predicted by the calculations. For example, the averaged incremental  $\nu_{\text{NH}_3}^b$  blueshifts calculated for II, IV, and V agree well with the observed ones ( $\Delta\text{I} = 45$  vs. 49  $\text{cm}^{-1}$ ,  $\Delta\text{J} = 21$  vs. 26  $\text{cm}^{-1}$ ,  $\Delta\text{K} = 18$  vs. 18  $\text{cm}^{-1}$ ), supporting the suggested assignments. Band M (3271  $\text{cm}^{-1}$ ) is again probably  $2\beta_{\text{OH}_2}$  and/or  $2\beta_{\text{NH}_3}$ , but the  $\nu_{\text{NH}_3}^{\text{f}}$  modes of I, III, and V (all at 3311  $\text{cm}^{-1}$ ) may also contribute to this broad band. The bonded O-H modes of the low-energy isomers I and III at  $\nu_{\text{OH}_2}^b = 3421/3404$  and 3466/3455  $\text{cm}^{-1}$  may be attributed to bands S (3387  $\text{cm}^{-1}$ ) and T (3452  $\text{cm}^{-1}$ ). Their third and remaining intense  $\nu_{\text{OH}_2}^b$  mode agrees well with band M, but their high predicted IR intensity ( $I = 800/1460 \text{ km mol}^{-1}$ ) is not reflected in the measured spectrum, which makes this assignment obsolete and could be taken as an exclusion criterion for I and III. In fact, their free energies  $G$  move them backwards in the stability order. On the other hand, it is well

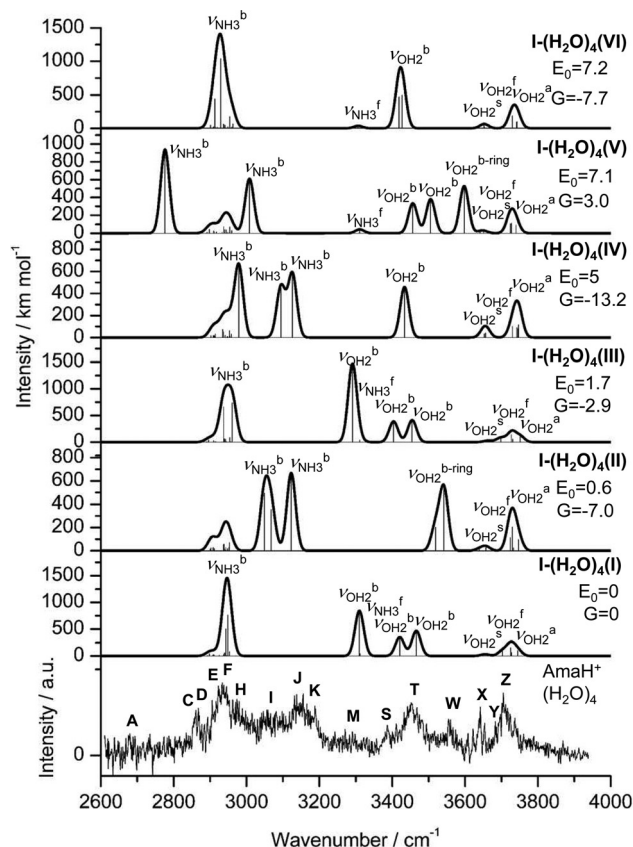

Fig. 9 IRPD spectrum of  $\text{AmaH}^+(\text{H}_2\text{O})_4$  compared to linear IR absorption spectra of  $\text{AmaH}^+(\text{I})-(\text{H}_2\text{O})_4(\text{I-VI})$  calculated at the B3LYP-D3/cc-pVTZ level. The positions of the transition observed in the IRPD spectrum of  $\text{AmaH}^+(\text{H}_2\text{O})_4$  and their vibrational assignment are listed in Table S10 (ESI†). Differences in relative energy ( $E_0$ ,  $G$ ) are given in  $\text{kJ mol}^{-1}$ . Note the different IR intensity scale for the computed IR spectra.

known that proton-donor stretch bands move to the blue at elevated temperature, because intermolecular excitation weakens the H-bond.<sup>108–110</sup> Following this line of argument, these intense modes may indeed be observed by bands S and T. The latter bands also agree with the  $\nu_{\text{OH}_2}^b$  modes of the bound  $(\text{H}_2\text{O})_2$  dimers of **IV** ( $3456 \text{ cm}^{-1}$ ) and **V** ( $3427/3418 \text{ cm}^{-1}$ ), which have the lowest free energies. Even if the ring isomers **I** and **III** were excluded, it is still considered certain that ring isomers are detected, since the signature of such water ring structures, band W, is observed at  $3554 \text{ cm}^{-1}$  and agrees well with  $\nu_{\text{OH}_2}^b$  modes of **II** ( $3519/3542 \text{ cm}^{-1}$ ) and/or **V** ( $3598 \text{ cm}^{-1}$ ).

## 5. Further discussion

The analysis of the IRPD spectra of  $\text{AmaH}^+(\text{H}_2\text{O})_n$  with B3LYP-D3 calculations clearly reveals that mainly hydrates of the ammonium ion (**I**) of  $\text{AmaH}^+$  are detected, indicating that the formation of the iminium isomers of  $\text{AmaH}^+$  (**II–IV**) in a hydration environment is substantially suppressed compared to an Ar solvation environment. Indeed the population of **II-H<sub>2</sub>O** is estimated as  $<10\%$  of **I-H<sub>2</sub>O**, while the corresponding

**II-Ar** population is  $\sim 30\%$  of **I-Ar**.<sup>49</sup> This result is consistent with the observed isomer distribution of the  $\text{Ama}^+(\text{I-III})$  radical cation, for which the population of the iminium ion  $\text{Ama}^+(\text{III})$  is also lower in water solvation than in Ar solvation ( $10\%$  vs.  $35\%$ ).<sup>48</sup> In the latter case, computations show that  $\text{H}_2\text{O}$  attachment substantially increases the barrier for cage-opening required for forming iminium ions.<sup>48</sup> Since it is assumed that isomer **II** of  $\text{AmaH}^+$  is formed by H-radical addition to the distonic  $\text{Ama}^+(\text{III})$  ion and its population is much smaller in a water environment, the population of **II-H<sub>2</sub>O** is thus also reduced.

In addition to the identity of the  $\text{AmaH}^+$  core ion, the analysis of the IRPD spectra provides a consistent picture of the microhydration process of the predominant  $\text{AmaH}^+(\text{I})$  ion, which gradually shifts from interior ion solvation to the formation of a H-bonded solvent network. Except for  $n = 1$ , where a small population of **II-H<sub>2</sub>O(I)** is detected, all main bands of the  $\text{AmaH}^+(\text{H}_2\text{O})_{1-4}$  spectra are assigned to the most stable microhydrates of the ammonium ion **I**. In these clusters, the  $\text{H}_2\text{O}$  ligands form a growing hydration network attached to the acidic  $\text{NH}_3^+$  group, while the spectra contain no signature of much less stable isomers with  $\text{H}_2\text{O}$  binding to the aliphatic adamantyl cage. For  $n \leq 2$ , the  $\text{H}_2\text{O}$  ligands bind preferentially to the acidic protons of the  $\text{NH}_3^+$  group *via* strong and almost linear  $\text{NH} \cdots \text{O}$  ionic H-bonds. However, an isomer with a H-bonded  $(\text{H}_2\text{O})_2$  dimer attached to the  $\text{NH}_3^+$  group is also observed for  $n = 2$  (with an estimated population of  $20\%$ ), which becomes competitive due to the strong cooperative effects of the H-bonded solvent network ( $E_0 = 4.9 \text{ kJ mol}^{-1}$ ). For  $n = 3$ , more types of hydration are observed. In addition to the isomer with a fully hydrated  $\text{NH}_3^+$  group and an isomer with  $\text{H}_2\text{O}$  and  $(\text{H}_2\text{O})_2$  separately attached to two NH protons, an isomer with a linear  $(\text{H}_2\text{O})_3$  trimer attached to one NH group and the adamantyl cage and an isomer with a cyclic eight-member solvation ring including part of the  $\text{NH}_3^+$  group also occur. Although the latter ring isomer is the global minimum on the potential energy surface of **I-(H<sub>2</sub>O)<sub>3</sub>** at 0 K, the isomer with the fully solvated  $\text{NH}_3^+$  group ( $\Delta G = -8.8 \text{ kJ mol}^{-1}$ ) and the isomer with a dangling  $(\text{H}_2\text{O})_2$  ligand ( $\Delta G = -1.2 \text{ kJ mol}^{-1}$ ) become more stable on the free energy surface at  $298.15 \text{ K}$ . The latter effect explains the estimated observed population distribution of **I-(H<sub>2</sub>O)<sub>3</sub>(I–IV)** of 10, 40, 40, and  $10\%$ , respectively. At  $n = 4$ , the formation of the H-bonded solvation network already dominates over internal ion solvation, because the completely saturated  $\text{NH}_3^+$  group offers only three acidic NH protons and bifurcated  $\text{NH} \cdots \text{O}$  H-bonds of one NH donor to two  $\text{H}_2\text{O}$  ligands are less stable and indeed no such minima are found on the potential energy surface. Furthermore, the isomers with cyclic solvation rings dominate at  $n = 4$ , so that among the five energetically best isomers, four isomers have such rings, which benefit from cooperative three-body forces. When considering the free energies, the energetic order changes such that isomer **IV** with a fully saturated  $\text{NH}_3^+$  group (bonded  $(\text{H}_2\text{O})_2$  dimer and two  $\text{H}_2\text{O}$  ligands,  $\Delta G = -13.2 \text{ kJ mol}^{-1}$ ) and the local minimum **VI** with two bonded  $(\text{H}_2\text{O})_2$  dimers ( $\Delta G = -7.7 \text{ kJ mol}^{-1}$ ) are most favourable, but closely followed by isomer **II** with a ring structure ( $\Delta G = -7.0 \text{ kJ mol}^{-1}$ ).

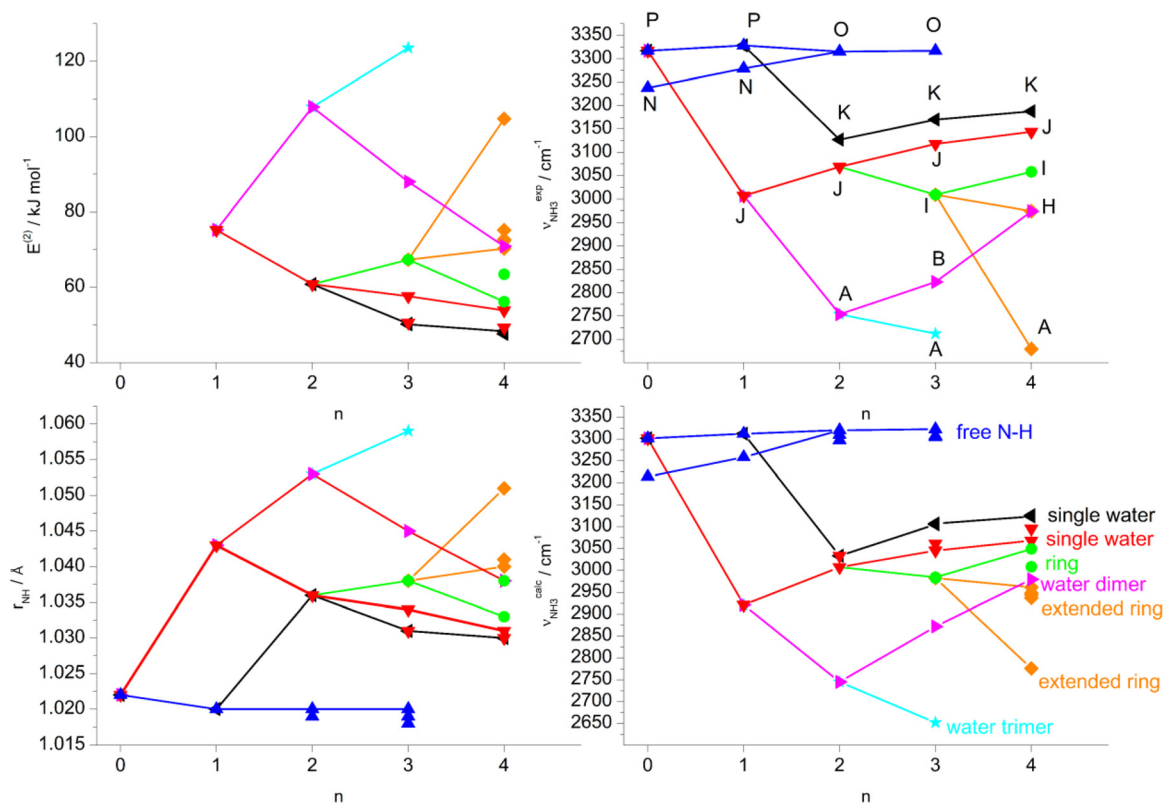

Overall, H-bonded isomers are energetically preferred over other isomers in which the adamantyl cage is gradually solvated by individual  $\text{H}_2\text{O}$  ligands *via* cation-dipole forces supported by weak  $\text{CH}\cdots\text{O}$  contacts. Interior ion solvation dominates over H-bonded solvent network until the  $\text{NH}_3^+$  group is completely saturated with  $\text{H}_2\text{O}$  ( $n \leq 3$ ), although isomers with H-bonded solvent network are also detected in somewhat lower populations, which become competitive due to the strong cooperative effects as  $n$  increases. In general, the hydration energies calculated for  $n = 1-4$  ( $71-51 \text{ kJ mol}^{-1}$ ) are higher than the absorbed IR photon energy ( $h\nu < 48 \text{ kJ mol}^{-1} \sim 4000 \text{ cm}^{-1}$ ), indicating that, under single-photon absorption conditions with an unfocused IR laser beam, only cluster ions with substantial internal energy can undergo the IRPD process. This result also explains the widths of the bands and the entropy contribution required to evaluate the energy ordering of the competing isomers. The calculated binding energies for the observed  $\text{AmaH}^+(\text{I})(\text{H}_2\text{O})_n$  clusters decrease as  $D_0 = 71 > (62-55) > (57-50) > (53-46) \text{ kJ mol}^{-1}$  for  $n = 1-4$  and linear extrapolation to larger cluster sizes suggests that around  $n = 10$  internal ion solvation becomes again more favourable than extending the solvation network (Fig. S31, ESI<sup>†</sup>). However, this prediction ignores the observed enthalpy of sublimation of bulk ice of  $51.0 \text{ kJ mol}^{-1}$ ,<sup>111</sup> and thus larger  $\text{AmaH}^+(\text{I})(\text{H}_2\text{O})_n$  clusters will also favour structures

in which the hydrophobic adamantyl cage is located at the surface of the H-bonded water solvent network, along with increasing charge delocalization into the solvent.

The detailed evolution of the properties of the N–H bonds ( $r_{\text{NH}}$ ,  $E^{(2)}$ ,  $\nu_{\text{NH}_3}^{\text{calc}}$ ,  $\nu_{\text{NH}_3}^{\text{exp}}$ ) of the observed  $\text{AmaH}^+(\text{I})(\text{H}_2\text{O})_n$  clusters as a function of  $n$  is visualized in Fig. 10. To distinguish the different N–H bonds and to deduce correlations, a colour code is used according to the ligand attached to the N–H bond: free N–H bond (blue); single  $\text{H}_2\text{O}$  (red, black);  $(\text{H}_2\text{O})_2$  dimer (magenta);  $(\text{H}_2\text{O})_3$  trimer (cyan); water ring (green); extended ring (orange). In general, the calculated and measured frequencies of the  $\nu_{\text{NH}}$  modes agree very well with respect to the incremental changes, even though in some cases the absolute values differ somewhat, mainly due to improper evaluation of anharmonicity of the proton donor stretch modes involved in the  $\text{NH}\cdots\text{O}$  ionic H-bonds. For clusters with single  $\text{H}_2\text{O}$  ligands (red), the N–H bonds elongate at  $n = 1$ , accompanied by a large redshift of the corresponding  $\nu_{\text{NH}_3}$  mode, due to the  $E^{(2)}$  energy for the donor-acceptor interaction between the lone pairs of O and the antibonding  $\sigma^*$  orbital of the N–H donor bond. As  $n$  increases, the H-bonds become somewhat weaker ( $E^{(2)}$  decreases) due to noncooperative effects typical for interior ion solvation, which in turn leads to a contraction of the N–H bonds and associated incremental blueshifts in  $\nu_{\text{NH}_3}$ . For the

**Fig. 10** Plots of various calculated and experimental properties of the N–H bonds of the most stable  $\text{Ama}^+(\text{H}_2\text{O})_n$  clusters as a function of the cluster size  $n$ : calculated N–H bond lengths ( $r_{\text{N-H}}$ ); calculated second-order perturbation energies ( $E^{(2)}$ ) of donor-acceptor orbital interactions involved in the H-bonds; calculated and experimental NH stretch frequencies ( $\nu_{\text{NH}_3}$ ). Symbols denote individual data points, while the connected points correspond to the values of the assigned isomers. The colour code indicates the type of ligand attached to the N–H bonds: free N–H bond (blue); first single  $\text{H}_2\text{O}$  (red); second single  $\text{H}_2\text{O}$  (black);  $(\text{H}_2\text{O})_2$  dimer (magenta);  $(\text{H}_2\text{O})_3$  trimer (cyan); cyclic water ring (green); extended ring (orange). Experimentally observed peaks associated with  $\nu_{\text{NH}_3}$  modes are labeled (A, B, H, I, J, K, N, O, P).

N–H bonds to which a single water is added in a second step (black), the behaviour is similar, although logically the N–H bond does not elongate until  $n = 2$  and  $E^{(2)}$  is lower due to the first H<sub>2</sub>O already bound to an adjacent N–H bond (interior ion solvation), resulting in a weaker redshift in  $\nu_{\text{NH}_3}$ . The situation is different for N–H bonds to which a (H<sub>2</sub>O)<sub>2</sub> dimer (magenta) or a (H<sub>2</sub>O)<sub>3</sub> trimer (cyan) are attached, resulting in much stronger NH $\cdots$ O ionic H-bonds at  $n = 2$  and  $n = 3$ , respectively. Due to the higher  $E^{(2)}$  energies, the N–H bonds are more stretched, leading to larger redshifts in  $\nu_{\text{NH}_3}$ . For the (H<sub>2</sub>O)<sub>2</sub> dimer,  $E^{(2)}$  becomes lower again at  $n > 3$  due to further internal ion solvation, which in turn leads to blueshifts of the  $\nu_{\text{NH}_3}$  modes. The first intermolecular NH $\cdots$ O H-bonds forming a ring with H<sub>2</sub>O appear at  $n = 3$  (green) and are stronger than those from a single bonded H<sub>2</sub>O, but weaker than those from a bonded (H<sub>2</sub>O)<sub>2</sub> or (H<sub>2</sub>O)<sub>3</sub> cluster, resulting in a moderate redshift of the corresponding  $\nu_{\text{NH}_3}$  modes. When at  $n = 4$  the remaining free N–H bond is hydrated by another H<sub>2</sub>O,  $E^{(2)}$  decreases again, the N–H bonds contract, and the  $\nu_{\text{NH}_3}$  modes become slightly blueshifted. When the solvation network of the ring is extended (orange), the intermolecular bonds become stronger ( $E^{(2)}$  increases) and the N–H bonds elongate, pushing the associated  $\nu_{\text{NH}_3}$  modes further to the red.

The detailed evolution of the properties of the water O–H bonds ( $r_{\text{OH}}$ ,  $E^{(2)}$ ,  $\nu_{\text{OH}_2}^{\text{calc}}$ ,  $\nu_{\text{OH}_2}^{\text{exp}}$ ) of the observed **AmaH<sup>+</sup>(I)(H<sub>2</sub>O)<sub>n</sub>** clusters as a function of  $n$  is shown in ESI† (Fig. S32). Similar to the N–H bonds, it also shows good agreement of the incremental changes of calculated and measured  $\nu_{\text{OH}_2}$  frequencies as well as consistent correlations with the O–H bond lengths and orbital interaction energies  $E^{(2)}$ . Overall, the neutral OH $\cdots$ O H-bonds of the hydration network are weaker than the ionic NH $\cdots$ O H-bonds of H<sub>2</sub>O to the charged NH<sub>3</sub><sup>+</sup> group, resulting in smaller perturbations of the O–H donor bonds and correspondingly smaller redshifts in  $\nu_{\text{OH}_2}^{\text{b}}$ .

Although there is increasing partial charge transfer from AmaH<sup>+</sup> to the (H<sub>2</sub>O)<sub>n</sub> solvent cluster with increasing  $n$ , no proton transfer to solvent is observed up to  $n = 4$  and most of the positive charge remains with AmaH<sup>+</sup>. This result is somewhat expected because the proton affinity of Ama (PA = 948.8 kJ mol<sup>−1</sup>) is substantially higher than that of (H<sub>2</sub>O)<sub>n</sub> clusters in the considered size range (PA = 691, 808, 862, 900, 904, 908 kJ mol<sup>−1</sup> for  $n = 1$ –6),<sup>91–95</sup> and the large difference in PA cannot be compensated by differences in the solvation energies of clusters of the type AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>n</sub> and Ama(H<sub>2</sub>O)<sub>n</sub>H<sup>+</sup>. Although no complete proton transfer is observed, the tendency for NH<sub>3</sub><sup>+</sup> protons to shift from AmaH<sup>+</sup> to (H<sub>2</sub>O)<sub>n</sub> gradually increases with  $n$ . It is possible to derive a lower limit for the cluster size  $n$  for proton transfer from the calculated C–N bond lengths and the partial charges of the adamantyl cage (C<sub>10</sub>H<sub>15</sub>) for the identified **AmaH<sup>+</sup>(I)(H<sub>2</sub>O)<sub>n</sub>** clusters, which decrease continuously for  $n = 1$ –4 and approach the values of neutral Ama. Although linear extrapolations to larger clusters suggest that proton transfer may occur at  $n = 11$ –13, the trends will certainly be nonlinear and thus this cluster size is a safe lower limit (Fig. S33, ESI†). Although we could not find any study reporting the degree of protonation of Ama in liquid water, most Ama molecules occur

in their N-protonated form under physiological cell conditions. Under conditions of pharmaceutical action, AmaH<sup>+</sup> clearly occurs in its N-protonated form and the acidic protons of the NH<sub>3</sub><sup>+</sup> group interact strongly with various bio-active molecular binding sites via H-bonding or cation– $\pi$  interactions (docking).<sup>112</sup>

It is instructive to compare microhydration in **AmaH<sup>+</sup>(I)(H<sub>2</sub>O)<sub>n</sub>** with that in **Ama<sup>+</sup>(I)(H<sub>2</sub>O)<sub>n</sub>** radical cation clusters to evaluate the impact of the additional proton attached to the NH<sub>2</sub> group (NH<sub>3</sub><sup>+</sup>/NH<sub>2</sub><sup>+</sup>) on the structure of the hydration shell as well as on the strength the NH $\cdots$ O ionic H-bonds. Microhydration of **AmaH<sup>+</sup>(I)** shows the same preferential cluster growth as **Ama<sup>+</sup>(I)(H<sub>2</sub>O)<sub>n</sub>**, in which the N–H bonds are first hydrated and then a H<sub>2</sub>O solvent network is formed.<sup>57</sup> Furthermore, populations of clusters with solvent networks are already detected for both core ions starting from  $n = 2$ , and this binding motif becomes more and more competitive with increasing  $n$  due to the cooperative effects. However, the detection of isomers with a cyclic solvation ring in **AmaH<sup>+</sup>(I)(H<sub>2</sub>O)<sub>n</sub>** for  $n \geq 3$  clearly shows a difference in cluster growth from that in **Ama<sup>+</sup>(I)(H<sub>2</sub>O)<sub>n</sub>**, where no such ring structures with three H<sub>2</sub>O molecules are detected. It appears that the additional acidic N–H bond of the NH<sub>3</sub><sup>+</sup> group in **AmaH<sup>+</sup>(I)** favours the formation of small cyclic solvation rings. This observation is probably due to the fact that the NH<sub>2</sub> bond angle of the two neighbouring N–H bonds involved in the ring is much smaller in the NH<sub>3</sub><sup>+</sup> group of **AmaH<sup>+</sup>(I)** than in the NH<sub>2</sub><sup>+</sup> group of **Ama<sup>+</sup>(I)** (108.1° vs. 116.8°). Thus, the NH $\cdots$ O H-bonds of the cyclic solvation ring in **AmaH<sup>+</sup>(I)(H<sub>2</sub>O)<sub>n</sub>** can be more linear (161.5° vs. 154.8°), shorter (1.765 vs. 1.787 Å) and thus more stable ( $E^{(2)} = 67.3$  vs. 30.3 kJ mol<sup>−1</sup>) than in **Ama<sup>+</sup>(I)(H<sub>2</sub>O)<sub>3</sub>(I)**.<sup>57</sup> In related clusters such as aniline<sup>+</sup>(H<sub>2</sub>O)<sub>n</sub>,<sup>88,89</sup> these small cyclic solvation rings with only three bound H<sub>2</sub>O molecules cannot be detected, while for  $n > 4$  populations of isomers with larger hydration rings consisting of four water molecules are observed. Another major difference is revealed for the NH $\cdots$ O H-bonds, which are much stronger, more linear, and shorter in **AmaH<sup>+</sup>(I)(H<sub>2</sub>O)<sub>n</sub>** than in **Ama<sup>+</sup>(I)(H<sub>2</sub>O)<sub>n</sub>**, as seen from the NH $\cdots$ O H-bond parameters of **AmaH<sup>+</sup>(I)(H<sub>2</sub>O)(I)** and **Ama<sup>+</sup>(I)(H<sub>2</sub>O)(I)** (1.742 vs. 1.768 Å, 175.7° vs. 170.5°,  $E^{(2)} = 75.2$  vs. 33.9 kJ mol<sup>−1</sup>). The reason for this is that the positive charge on the NH<sub>2</sub><sup>+</sup> group of **Ama<sup>+</sup>(I)** is lower by a factor of 2 compared to the NH<sub>3</sub> group<sup>+</sup> of **AmaH<sup>+</sup>(I)** (313 vs. 604 me), resulting in less acidic N–H bonds. For example, the redshifted NH stretch bands occur at  $\nu_{\text{NH}_{2/3}}^{\text{b}} = 2943$  and 2992 cm<sup>−1</sup> for the monohydrates of **AmaH<sup>+</sup>(I)** and **Ama<sup>+</sup>(I)**.

## 6. Concluding remarks

IRPD spectroscopy of size-selected AmaH<sup>+</sup>(H<sub>2</sub>O)<sub>n</sub> cluster with  $n = 1$ –4 recorded in the sensitive OH, NH, and CH stretch range are analysed with dispersion-corrected DFT calculations at the B3LYP-D3/cc-pVTZ level to reveal the first steps in the microhydration process of this important pharmaceutical molecular drug. Significantly, these spectra provide the first spectroscopic impression of the intermolecular interaction between the AmaH<sup>+</sup> cation and water solvent molecules at the molecular level. The major results may be summarized as follows. The

population of open-cage iminium ions of  $\text{AmaH}^+$  (II–IV) in the EI expansion of Ama compared to the canonical N-protonated ammonium ion (I), the pharmaceutically active structure, is significantly lower in  $\text{H}_2\text{O}$  environment than in Ar solvation. This result is consistent with the decreased population of distonic iminium ions of the  $\text{Ama}^+$  radical cation in  $\text{H}_2\text{O}$  environment which is considered to be the precursor of  $\text{AmaH}^+$  in the employed EI source. Microhydration of the predominant isomer I of  $\text{AmaH}^+$  can be summarized as follows. Considering free energies, the spectra of the  $n = 1$ –4 clusters are dominated by the most stable isomers predicted by the DFT calculations, although energetically higher isomers with somewhat lower populations are also detected. Microhydration of  $\text{AmaH}^+(\text{I})$  occurs by solvating the acidic NH protons *via* strong  $\text{NH} \cdots \text{O}$  ionic H-bonds until the  $\text{NH}_3^+$  group is completely hydrated. Due to noncooperative effects of this interior ion solvation process, the strength of the  $\text{NH} \cdots \text{O}$  H-bonds decreases slightly with  $n$  for  $n = 1$ –3. However, in addition to isomers with interior ion solvation motifs, isomers with a H-bonded solvent network are also detected with somewhat lower population, which become competitive due to the strong cooperative effects arising from nonadditive induction forces. In particular, for  $n \geq 3$  isomers are observed in which the  $\text{H}_2\text{O}$  ligands form an eight-membered cyclic ring involving the  $\text{NH}_3^+$  group *via* four H-bonds. In contrast to interior ion solvation, the formation of such H-bonded networks is strongly cooperative and the strength of  $\text{NH} \cdots \text{O}$  H-bonding increases with  $n$  because the proton affinity of  $(\text{H}_2\text{O})_n$  clusters rises with size. At  $n = 4$ , the preferred cluster growth continues with further extension of the H-bonded solvent network by formation of  $(\text{H}_2\text{O})_2$  dimers or by attachment of a further  $\text{H}_2\text{O}$  ligand to the cyclic hydration ring *via*  $\text{OH} \cdots \text{O}$  H-bonds. However, interior ion solvation is still competitive due to the saturation of a remaining free N–H bond not involved in a water ring. It is clear that isomers in which  $\text{H}_2\text{O}$  ligands bind to the adamantyl cage *via* weak  $\text{CH} \cdots \text{O}$  contacts (mostly stabilized by charge–dipole forces) are much less stable than those with solvation of the  $\text{NH}_3^+$  group due to its higher positive partial charge. The charge transfer from  $\text{AmaH}^+$  to  $(\text{H}_2\text{O})_n$  increases with  $n$ , but remains below  $0.1 e$  in the size range  $n \leq 4$ . Similarly, no proton transfer is observed in this size range, consistent with the difference in proton affinity of Ama and  $(\text{H}_2\text{O})_n$ , thus justifying the notation of  $\text{AmaH}^+ \cdots (\text{H}_2\text{O})_n$ . In general, the IRPD spectra and calculations show a solvation process similar to that previously observed for  $\text{Ama}^+(\text{H}_2\text{O})_n$  and related  $\text{RNH}_2^+(\text{H}_2\text{O})_n$  clusters, in which the formation of a H-bonded solvation network is favoured over internal ion solvation after saturation of the acidic  $\text{NH}_{2/3}^+$  group.<sup>57,75,88,89,106,107</sup> However, the cluster growth of  $\text{AmaH}^+(\text{H}_2\text{O})_n$  differs by the formation of small cyclic solvation rings involving only three water molecules for  $n \geq 3$  enabled by the additional N–H bond of the  $\text{NH}_3^+$  group. Moreover, the NH protons of the  $\text{NH}_3^+$  group are much more acidic than those of the  $\text{NH}_2^+$  group, leading to much stronger  $\text{NH} \cdots \text{O}$  ionic H-bonds. In the future, it will be interesting to investigate the interaction of  $\text{AmaH}^+$  with amino acids or small peptides using the same experimental and computational strategy to explore the biological activity of this drug at the molecular level.
