The current status in computational exploration of Pt(IV) prodrug activation by reduction

Fortuna Ponte,[†] Stefano Scoditti, [†] Gloria Mazzone * and Emilia Sicilia*

Octahedral Pt^{IV} complexes are considered highly promising candidates for overcoming some shortcomings of clinically approved Pt^{II} drugs. Pt^{IV} compounds, owing to their inertia, appear to be capable of resisting premature aquation and undesired binding to essential plasma proteins and have shown remarkable potential for both oral administration and for reducing side effects. Additionally, their pharmacological properties can be finely tuned by choosing appropriate axial ligands. The reduction inside the cell by biological reducing agents to the corresponding active cytotoxic Pt^{II} species, accompanied by the loss of the axial ligands, is considered an essential step of their mechanism and has been extensively studied. However, a detailed understanding of the mechanism by which Pt^{IV} prodrugs are activated, which should be highly beneficial for their proper design, is lacking, and many contradictory results continue to be collected. In the hope of contributing to the advancement of knowledge in this field, this perspective focuses on the insights gained from computational studies carried out with the aim of finding answers to the many still open questions concerning the reduction of Pt^{IV} complexes in biological environments.

Introduction

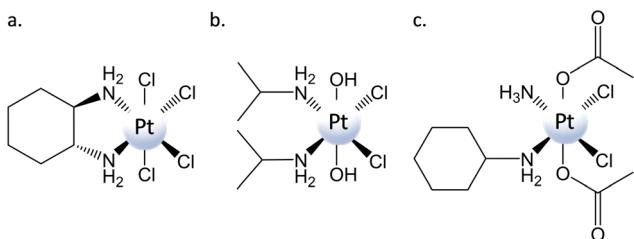

Cancer is considered one of the world's most serious health problems and causes one in six deaths.¹ For fighting cancer, various strategies can be practiced, including chemotherapy, radiotherapy, and surgery. Chemotherapy is a technique in which an anticancer agent with a specific mechanism of action is introduced into the organism to inhibit the growth and induce the death of tumor cells.² The most famous chemotherapeutic agent is cisplatin, which represents one of the greatest successes in the story of medicinal inorganic chemistry. Synthesized for the first time by Michele Peyrone in 1845, cisplatin's cytotoxic activity was accidentally discovered by Barnett Rosenberg when he tried to evaluate the role of electrical current in *Escherichia coli* cellular division.³ After undergoing clinical trials, cisplatin was approved in 1978 by the Food and Drug Administration (FDA).⁴ Subsequently, various cisplatin structural analogues have been developed, including carboplatin and oxaliplatin, that have been approved for worldwide clinical use.^{5,6} Cisplatin and its analogues are drugs belonging to the class of DNA alkylating agents. Indeed, their mechanism of action is mostly based on the formation of DNA adducts through the binding of the Pt^{II} center to double-helix nucleobases.⁷

† F.P. and S.S. contributed equally.

Inside the cancer cells, Pt^{II} complexes are hydrolyzed to produce the corresponding activated aqua Pt^{II} species. These active aquated species are able to form both intra- and inter-strand DNA crosslinks, mainly with nitrogen in the N7 position of guanine nucleobases, causing distortion of the DNA helix and proteins to signal for apoptosis.^{8–12} Both genomic and mitochondrial DNA can be damaged by the action of these drugs.¹³ Although widely used, the clinical utility of Pt^{II} drugs is strongly limited by severe side effects and tumor resistance. The latter is mainly due to the increased repair of damaged DNA, reduced cellular accumulation, and increased cytosolic inactivation, whereas high toxicity to healthy tissue and organs and low chemical stability cause the former.¹⁴ In spite of the enormous number of proposed and synthesized Pt^{II} alternative compounds and, in some cases, their Pd^{II} analogues,^{15–19} whose coordination sphere has been modified to properly tune their properties and reduce well-known shortcomings, none of them has demonstrated a superior anticancer activity than cisplatin and its approved derivatives. Among the strategies pursued to improve the therapeutic index and decrease side effects, Pt^{IV} prodrugs have received a significant amount of attention. Octahedral Pt^{IV} prodrugs are more inert to ligand substitution than their parent Pt^{II} complexes and less prone to deactivation *en route* before reaching the tumor cells.²⁰ In addition, axial ligands can be properly chosen to tune both their physical and chemical properties without altering the structure of the active pharmacophore that is ultimately released.^{21–23} Pt^{IV} prodrugs are synthesized by oxidation of the corresponding square-planar Pt^{II} precursors, and since,

Scheme 1 Structure of (a) tetraplatin, (b) iproplatin, and (c) satraplatin/JM216.

in the beginning, Cl_2 or H_2O_2 was used for carrying out the oxidation, tetraplatin and iproplatin (Scheme 1) were the first two Pt^{IV} complexes that entered clinical trials.^{24,25} Axial positions are occupied by two chlorido ligands in the former case and by two hydroxido ligands in the latter. The possibility of carrying out the carboxylation of the corresponding dihydroxido compounds allowed the preparation of a wide category of dicarboxylato complexes such as satraplatin²⁶ (included in Scheme 1 and named also JM216) that, even if included in several clinical trials, has not been approved yet.²⁷ Carboxylato ligands have been further exploited to enhance the pharmacological properties of Pt^{IV} prodrugs and add bioactive ligands to the axial positions to exert multi-action effects.^{23,28–32} The nature of the axial and, although to a much lesser extent, equatorial ligands is, therefore, of key importance in determining the properties of Pt^{IV} prodrugs and, in particular, their propensity to undergo two-electron reduction that provokes the breaking of the bonds between platinum and the axial ligands.³³ The rate of the reduction/activation step has to be appropriately tuned to avoid occurring too rapidly before the prodrug reaches the tumor, or too slowly if the prodrug resists the reductive nature of the reducing agents.^{34,35}

What this comes down to is that for a successful design of Pt^{IV} prodrugs, a detailed understanding of the factors that determine the reduction rate is required. Electron transfer mechanisms for the reduction of Pt^{IV} complexes have been the subject of many studies over several decades and, on the basis of kinetic measurements, they have been classified as inner- and outer-sphere and Pt^{II} -catalysed.^{33,36,37} Inner-sphere involves direct contact with the reducing agent, leading to the formation of a new bond that facilitates the flow of the electrons. In the outer-sphere reduction, instead, the electrons are transferred without the establishment of any contact. The Pt^{II} -catalysed mechanism is a particular kind of inner-sphere mechanism proposed by Basolo and Pearson^{38,39} that should involve the catalytic assistance of the produced Pt^{II} complex and, for that reason, is considered unlikely under cellular Pt^{II} complex concentrations. The rates of reduction have been commonly associated with the values of the reduction potentials, considered to be the most important parameters for determining the effectiveness of Pt^{IV} complexes to work as anticancer agents. Information concerning the ease of reduction is usually obtained by cyclic voltammetry measurements that provide the values of the potential for irreversible reduction, but not the standard redox potential. Indeed, due to the irreversibility of the reduction process, the peak potential of the irreversible cathodic response

at a single scan rate is used to approximate the facility with which the metal centre of Pt^{IV} complexes is reduced^{40–42} and some caution has to be taken in using these values. Baik and co-workers have proposed, on the basis of the results of a series of electrochemical experiments, a decomposition scheme that separates the Pt^{IV} to Pt^{II} two-electron reduction process into electron transfer and Pt-ligand bond cleavage steps.⁴³ DFT calculations have been employed to elucidate the mechanism, and the calculated reduction potentials have been found to be in excellent agreement with experimentally determined values that are generally more positive than measured peak potentials extracted from voltammograms. Nevertheless, numerous experiments have demonstrated that, very often, measured reduction potentials do not follow the trend in reduction rates of Pt^{IV} complexes.^{44,45} Other experimental methods can be used to obtain information about the Pt^{IV} reduction process, such as UV, NMR, and X-ray absorption near edge spectroscopies. All these techniques are useful to follow the disappearance of Pt^{IV} species and the formation of Pt^{II} products. However, information on the identity of the ligands bound to the metal centre is difficult to obtain, and the biological environment represents an obstacle to investigations. Very importantly, none of these methods can provide information on the mechanism by which the reduction occurs. Computational analyses are very precious alternative tools for disentangling the mechanistic details of the reduction process and have been extensively used in the course of the years to add further information about the characteristics of the reduction mechanisms generically classified as inner- and outer-sphere.^{46–54} Moreover, computations can be proficiently used to complement experimental outcomes.^{55,56} In this perspective, the main results of the computational investigations carried out on this topic will be summarized, examining both inner- and outer-sphere mechanisms viability. Although many potential biological reducing agents are present in both cells and plasma, L-ascorbic acid (AscH_2) and L-glutathione are commonly believed to be the species causing the activation of Pt^{IV} prodrugs.^{34,37,57–59} Of the three forms of AscH_2 , *i.e.*, neutral, monoanionic, and dianionic, the monodeprotonated one (AscH^-) is assumed to be that with the highest concentration at physiological pH. Computations considering the presence of the other two forms will also be reported. Concerning L-glutathione, instead, L-cysteine (L-Cys) is generally used as a model of sulfur-containing bioreductants in order to reduce the required computational effort. It is worth mentioning that almost all the reported studies have been carried out exclusively by means of DFT, adopting the B3LYP exchange-correlation functional as the best performing one. The choice of the basis sets, instead, is wider. Details about the computational protocols have been reported only in a limited number of cases, while the rest refer to the original papers.

The most investigated axial ligands are chlorides, hydroxides, and carboxylates that influence the propensity of Pt^{IV} complexes to be reduced in the order $\text{Cl}^- > \text{CH}_3\text{COO}^- > \text{OH}^-$ on the basis of what has been suggested by Hambley examining a large series of Pt^{IV} compounds.⁶⁰ However, the outcomes of the investigations carried out to elucidate the role played by the identity of the axial ligands in influencing the reduction rate do not allow for

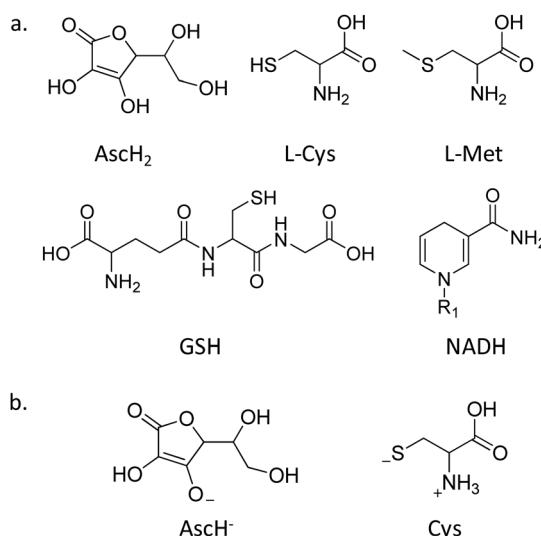

pinpointing a clear trend^{33,35,44,57,59,61} and the examples described in the next paragraphs demonstrate that many variables have to be taken into due consideration.

Discussion

Reducing agents

A critical role in the reduction of Pt^{IV} complexes is played by the reducing agent (RA), which actively takes part in the reaction mechanism as, depending on its nature, different pathways could be in principle accessible. The RAs overly present in the physiological environment that could be implicated in the reduction of Pt^{IV} prodrugs to active Pt^{II} complexes include L-ascorbic acid or sulphur-donor biomolecules, such as glutathione, L-cysteine, and L-methionine, but even NADH, as a direct RA or indirectly involved in the reductive action of cytochrome *c* or haemoglobin⁶² (Scheme 2a). All these reductants have been taken into consideration through the exploration of Pt^{IV} prodrug reduction in recent years, though GSH and ascorbic acid remain the most used RAs. In particular, from a computational point of view, except particular examples for which other RAs such as NADH or light activated molecules have been taken into consideration,⁵⁴ Asch₂ and L-Cys, as the simplest models of sulphur-containing residues, are the most used for this purpose.

The active species of ascorbic acid is certainly the mono-anionic ascorbate, Asch⁻, though the dianionic form Asch²⁻ has been proven to be much more reactive than Asch⁻;^{45,63} however, its occurrence at physiological pH is very limited, contrary to Asch⁻, which is the most abundant form in such conditions. Accordingly, Asch⁻ is widely considered the putative species for assisting the two-electron transfer for Pt^{IV} → Pt^{II} reduction. On the other hand, in physiological conditions, L-Cys exists in its zwitterionic form with intact thiol function. However, a computational study has evidenced the poor reactivity of such a form of cysteine and a low barrier in favour of the more active species

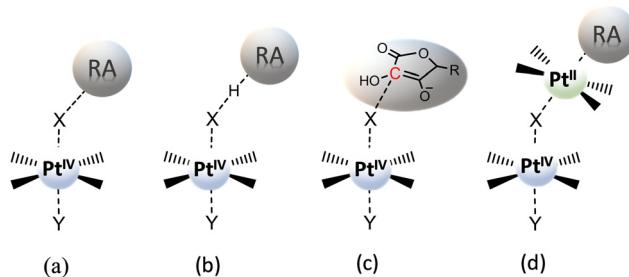

Scheme 2 (a) Reducing agents (R₁ = adenine dinucleotide); (b) the most used models for computational explorations.

formation that is reported in Scheme 2b, named Cys.⁴⁷ The formation of the active species is due to a H transfer from sulphur to oxygen atoms to afford a thiolate, which is proven to be extremely more reactive than the thiol functional group.

Reaction mechanisms

The usually invoked classification describes the reduction mechanism of Pt^{IV} complexes as inner- and outer-sphere two-electron transfer. However, this general grouping does not adequately take into consideration all the conceivable alternatives. In particular, for the inner-sphere mechanism, where the flow of the two electrons takes place through a direct interaction between the RA and the Pt^{IV} complex, several mechanistic hypotheses, that have been proposed in the course of the years and allow a more accurate description of the reduction process, are sketched in Scheme 3. The mechanism most commonly reported in the scientific literature is (a) ligand-bridge electron transfer, but three other reduction modes have been suggested and defined as (b) ligand-bridge-H transfer, (c) enolate β-carbon attack, and (d) Pt^{II}-catalysed mechanisms. In the first mechanism (a), one of the axial ligands is able to form a bridge between the Pt^{IV} centre and the reductant, facilitating the electron transfer from the RA to the metal centre, simultaneously provoking the release of the second ligand in the axial position and, then, the formation of the active square planar Pt^{II} species.

In the second mechanism (b), proposed by us for the reduction of Asplatin,⁵³ a cisplatin-based Pt^{IV} complex, the two-electron transfer occurs in one step through the shift of a hydrido unit (H⁻) from the reducing agent to the bridging ligand, leading to the formation of the RA oxidized form and the concomitant loss of the *trans* axial ligand. The mechanism (c) was discovered *in silico* by Aria and co-workers and involves the reduction of Pt^{IV} complexes by the monodeprotonated form of ascorbic acid, Asch⁻. Specifically, the mechanism involves the nucleophilic attack of the enolate β-carbon of Asch⁻ on one axial ligand (X), leading to the formation of a new C-X bond, and the simultaneous release of the second axial ligand. Finally, in the mechanism (d), proposed by Basolo and co-workers,^{38,39} Pt^{II} reduction is catalysed by a Pt^{II} agent. In particular, the Pt^{II} complex is sandwiched between the RA and the Pt^{IV} complex to yield the Asch⁻-Pt^{II}-X-Pt^{IV}-Y dimer, where X and Y are the Pt^{IV} axial

Scheme 3 Inner-sphere mechanisms for the reduction of Pt^{IV} complexes by a generic reducing agent (RA) or a specific one (Asch⁻). (a) Ligand-bridge electron transfer; (b) ligand-bridge-H transfer; (c) enolate β-carbon attack; (d) Pt^{II}-catalysed mechanisms.

ligands, and the bridging ligand mediates the two-electron transfer. During the reduction reaction, the two electrons are transferred from the RA to the Pt^{IV} metal centre, the bridging ligand passes from the Pt^{IV} complex to the Pt^{II} catalyst agent that already coordinates the RA system, and the other axial ligand is spontaneously released. A second RA molecule should help in restoring the Pt^{II} catalyst. Besides the low cellular concentration of Pt^{II} , the steric hindrance of the axial ligands of the complex undergoing the reduction could deactivate this type of catalytic mechanism.³³

Concerning the outer-sphere mechanism, the propensity of Pt^{IV} complexes to be reduced is measured by their redox potential, and, experimentally, this information is usually obtained by cyclic voltammetry. As it has been underlined above, however, cyclic voltammetry measurements can provide, owing to the irreversibility of the reduction process of such complexes, only the peak potential of the irreversible cathodic response (E_p) but not the standard redox potential. Indeed, both chemical and electrochemical events are involved; two electrons are transferred, and the process can be significantly influenced by the nature of the axial ligands and the ease with which they are released. From a theoretical point of view, various computational approaches can be used for predicting reduction potentials in solvent.⁶⁴ One group of such methods is based on the use of thermodynamic cycles, allowing the evaluation of condensed-phase reduction potentials from the standard-state Gibbs free energy of the corresponding reaction or half-reaction. The reaction free energy is computed as a difference in the free energies of products and reactants, with the free energy of each reactant being computed as a sum of the gas-phase free energy and the free energy of solvation. The reduction process of Pt^{IV} complexes involves the transfer of two electrons from a reducing agent so that the corresponding Pt^{II} derivative is formed and two ligands, in principle the axial ones, are released. Considering the two-electron transfer for the reaction (Scheme 4a):

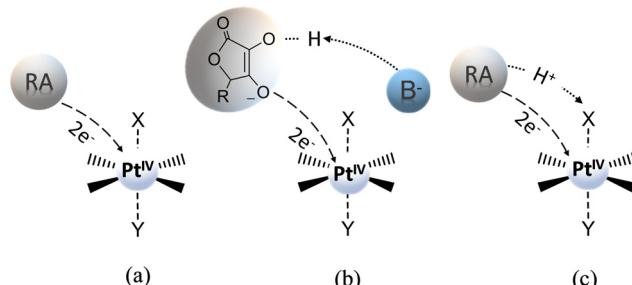

where L are the released ligands, the redox potential can be calculated using the formula:

$$E^\circ = -\frac{\Delta G}{2F} + E_{\text{SHE}} \quad (1)$$

ΔG represents the Gibbs free energy change that accompanies the two-electron reduction reaction reported above, F is the Faraday constant, and E_{SHE} is the standard hydrogen electrode potential.

Adopting such an approach, Burda and coworkers have calculated the redox potential of several Pt^{IV} complexes having chlorido, hydroxido, and carboxylato ligands in axial positions.⁵⁰ DFT results, obtained using numerous exchange-correlation functionals, have been compared with those of MP2 and CCSD(T) post-HF methods. In order to take into account the impact of the solvent, the implicit IEF-PCM model has been used employing scaled-UAKS radii, whereas to handle the change in the entropy contributions to Gibbs free energies in going from the gas- to the condensed-phase, the correction scheme proposed by Wertz has been used. For the E_{SHE} , the value of -4.281 eV has been adopted. The authors have demonstrated that DFT calculations, including

Scheme 4 Proposed outer-sphere mechanisms: (a) two-electron transfer, (b) base-assisted electron transfer, (c) proton-assisted electron transfer.

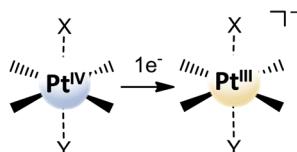

Wertz corrections and scaled radii, are able to reproduce experimental potentials.

Due to the unresolved controversy concerning the utility of the reduction potential obtained as the irreversible peak, E_p , in the cyclic voltammogram, Baik and co-workers have proposed experimental and theoretical approaches able to give reliable results for Pt^{IV} complexes in solution-phase redox processes.⁴³ During the study of some Pt^{IV} cisplatin-based complex reductions, the authors have shown that the reduction occurs in two steps. Within each step, a single electron is transferred, and the process can be decomposed into electron transfer and Pt-ligand bond cleavage. In particular, in the first step, which involves a one-electron addition to the Pt^{IV} centre, the formation of a metastable six-coordinate Pt^{III} intermediate occurs and the standard reduction potential for the $\text{Pt}^{\text{IV}}/\text{Pt}^{\text{III}}$ couple from the irreversible peak potential in the cyclic voltammogram, within the framework of Marcus theory, can be extracted. In the same way, the magnitude of the standard redox potential can be computationally determined as the energy change that accompanies the one-electron transfer for the reduction of the six-coordinate Pt^{IV} to the corresponding six-coordinate Pt^{III} species with the axial ligands remaining in the metal centre coordination sphere (see Scheme 5). The reduction potential is calculated as:

$$E^\circ = -\Delta G_{\text{sol}} - E_{\text{SHE}} \quad (2)$$

where ΔG_{sol} is the Gibbs free energy change in solution of the first step and E_{SHE} is the absolute potential of the standard hydrogen electrode used as a reference, which has been determined to be 4.43 eV.

In light of the decomposition scheme suggested by Baik *et al.* to be used for the estimation of the redox potential of Pt^{IV} complexes, a detailed theoretical study on the mechanism of electrochemical reduction of the prototypical Pt^{IV} anticancer complex $[\text{Pt}(\text{NH}_3)_2\text{Cl}_2(\text{CH}_3\text{COO})_2]$ to the corresponding cisplatin active species has been performed by Re and coworkers.⁴⁶ The outcomes of this investigation confirm that the initial one-electron reduction occurs through a stepwise mechanism *via* a metastable six-coordinate Pt^{III} intermediate and subsequent acetate ligand detachment. Several combinations of DFT functionals and basis sets have been tested, and the results have also been used to estimate the redox potential of the complex under investigation, selecting the B3LYP/aug-cc-pVTZ

Scheme 5 First step one-electron transfer for the reduction of six-coordinate Pt^{IV} complexes in the decomposition scheme proposed by Baik *et al.*⁴³

level of theory as the most accurate for reproducing the experimental value.

Furthermore, an outer-sphere mechanism named “base-assisted outer-sphere” electron transfer (Scheme 4b) has been proposed and computationally tested by Ariaftard and coworkers in the presence of ascorbic acid as RA.⁴⁸ This mechanism has been recognized considering that, although the monodeprotonated form of ascorbic acid has the highest concentration in physiological conditions, the dianionic form, Asc²⁻, is several orders of magnitude more reactive. Due to this very high reactivity, Pt^{IV} complexes are immediately reduced *via* an outer-sphere two-electron transfer mechanism. This mechanism involves the presence of an appropriate base in the environment for accelerating the reduction reaction by deprotonating the AscH⁻ most abundant form of the reducing agent. This deprotonation reaction requires that an energetic cost be paid as a transition state has to be overcome.

One of the first detailed computational studies on the reduction mechanism of Pt^{IV} complexes has been performed by Burda and co-workers.⁴⁹ The authors have investigated the mechanism of activation by reduction of satraplatin (*cis,trans,cis*-[PtCl₂(OAc)₂(cha)(NH₃)], cha = cyclohexylamine), in the presence of ascorbic acid as a RA. All three protonation forms of ascorbic acid have been considered, and a further variant of the outer-sphere mechanism, named “proton-assisted electron transfer”, has been introduced (Scheme 4c). As it can be deduced from the denomination of the mechanism, a proton shift from the RA to an axial ligand of the Pt^{IV} complex takes place, whereas two electrons pass from the reducing species to the metal center *via* an outer-sphere mechanism. In the examined satraplatin complex, the proton is transferred to one of the acetato ligands. As a consequence, the Pt^{II} species is released into the reaction environment, together with the formed acetic acid, the second axial ligand, and the fully oxidized form of the RA, which is dehydroascorbic acid (DHA). This mechanism is considered only for the AscH₂ and AscH⁻ forms, where the corresponding proton is present, and, when the reaction is investigated in the presence of the AscH₂ agent, an additional water molecule is included in the reduction system, which acts as an acceptor of the second proton from the RA to generate DHA. It is worth mentioning that both proposed base-assisted and proton-assisted mechanisms, even if classified as outer-sphere mechanisms, depend not only on the value of the complex redox potential, but also on the presence in the environment of specific compounds able to assist the process.

Axial ligands

As underlined above, axial ligands are of pivotal importance in determining the chemical and biological properties of Pt^{IV}

complexes and can be properly designed to accomplish specific aims such as modulating the reduction potential, increasing lipophilicity, interfering with cellular processes, targeting cancer cells, or targeting intracellular compartments. According to what was proposed by Gibson,^{33,65} axial ligands can be classified into three categories: (1) “innocent” because they are devoid of any biological activity, such as hydroxides, acetates, and chlorides; (2) targeting agents able to make the complex selective towards cancer cells; and (3) “bioactive” ligands that disturb cellular processes.

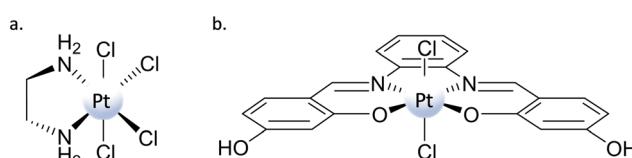

In the next paragraphs, several examples of computational investigations of the reduction of Pt^{IV} complexes having ligands essentially belonging to the first class will be illustrated.

Chlorido ligands

Among the potential axial ligands, chlorides are very representative examples, as they have been included in the axial position of many Pt^{IV} complexes bearing several leaving and ancillary ligands in equatorial positions. Concerning the role played by axial ligands in influencing the propensity of Pt^{IV} complexes to be reduced, it has been reported that the presence of chlorido ligands in the axial position instead of hydroxido or carboxylato ligands should favour the reduction reaction.³⁴ This propensity is ascribed to both the less negative reduction potential values and the possibility of forming a bridge between the platinum centre and the RA, enabling the electron transfer according to an inner-sphere mechanism (mechanism (a) in Scheme 3).

Despite several studies reported in the literature for the synthesis of Pt^{IV} prodrugs bearing chlorido ligands in axial positions, only for a few of them has a detailed computational investigation been carried out to clarify the mode of release of the square-planar Pt^{II} active species.^{47,48,52,66,67} Among these, three examples have been selected that can be useful for elucidating the real mechanism of Pt^{IV} complex reduction. Two of them are classical Pt^{IV}-based complexes of the type [Pt(N⁺N)Cl₄], with N⁺N = ethylenediamine, diaminocyclohexane (tetraplatin in Scheme 1), whose activity, once reduced, remains that of classical Pt^{II} complexes: hydrolysis and DNA platination. The third system is a Pt^{IV}-salphen complex [Pt(salphen)Cl₂] able to target a structurally different DNA, the G-quadruplex.⁶⁸ In the theoretical exploration, to reduce the computational effort, the complex structure has been simplified by replacing piperidine groups with hydrogen atoms and named Pt^{IV}-Sal (Scheme 6).⁶⁷ The mechanisms of action of these two types of complexes will be separately addressed and discussed on the basis of the employed RA.

Reduction mechanism of [Pt(N⁺N)Cl₄] type complexes. The complexes with the general formula [Pt(N⁺N)Cl₄] are among the first ones systematically studied from a computational

Scheme 6 Structure of (a) [Pt(en)Cl₄] and (b) Pt^{IV}-Sal complexes.

viewpoint in order to identify the most probable reduction mechanism. In particular, tetraplatin $[\text{Pt}(\text{dach})\text{Cl}_4]$ has been first accounted for by Ejehi and Ariafard to clarify the preferred reaction mechanism depending on the RA taken into consideration.⁴⁸ In such work, they have proposed for the first time the mechanism labelled (c) in Scheme 3, observable only when ascorbate acts as a reductant. As described in detail above, such a mechanism involves the nucleophilic attack of the enolate β -carbon on one of the axial chlorido ligands, finally leading to the release of the Pt^{II} active species. Fig. 1 reports the comparison between such a mechanism (c) (on the left) and the classical (a) ligand-bridge one (on the right). It has been demonstrated by the authors that among the inner-sphere mechanisms, along the mechanism (c) pathway, a considerably lower amount of energy is required. Indeed, while the nucleophilic attack of the enolate β -carbon takes place surmounting an energy barrier of 13.4 kcal mol⁻¹, the ligand-bridged transition state has been located 27.2 kcal mol⁻¹ above the reference adduct (2). Actually, along the two paths, the reductant establishes different interactions with the Pt^{IV} complex in the adduct resulting from the IRC calculations starting from the TSs located for the two mechanisms. Indeed, a stabilizing hydrogen-bond between the ascorbate and the NH_2 moiety of the dach ligand has been observed only in the starting reactant interaction (3) of mechanism (c), which results in about 7 kcal mol⁻¹ more stability than the other (2). Moreover, from the inspection of the two TSs downhill, the relative formed intermediates have different stability. Indeed, the protonated dehydroascorbate (4) formed along the mechanism (a) pathway is significantly less stable than the Cl-ascorbate adduct formed along the pathway of the (c) mechanism (5). The last step of the reaction, involving the release of Cl^- by reaction with ascorbate for mechanism (c) or deprotonation of protonated dehydroascorbate leading to DHA formation for mechanism (a), are both barrierless. Therefore, tetraplatin should prefer mechanism (c) for kinetic and thermodynamic reasons to be reduced by ascorbate.

Outer-sphere mechanisms have also been explored, and on the basis of the obtained results, the novel mechanism classified

as (b) base-assisted in Scheme 4 has been proposed. The assistance of both AsCH^- or HCO_3^- bases has been tested for their ability to deprotonate the ascorbate to form the very reactive Asc^{2-} species that transfers two electrons to the Pt^{IV} complex by an outer-sphere mechanism. On the basis of the obtained results and the calculated energy barriers, the authors concluded that both inner- and outer-sphere mechanisms are viable. Nevertheless, since the enolate β -carbon attack inner-sphere reduction (Fig. 1) is calculated to be faster than the deprotonation of AsCH^- , the inner-sphere prevails.

Shortly after, Ariafard and co-workers added another tessera to the puzzle of Pt^{IV} complexes reduction, inspecting the reduction mechanism of $[\text{Pt}(\text{en})\text{Cl}_4]$ (en = ethylenediamine) by sulphur-containing biological reductants, like L-Cys and L-Met.⁴⁷ Such types of compounds can act according to the inner-sphere mechanism (a), with Cl^- as the bridging ligand. The reduction is supposed to involve the electrophilic attack of the highly polarised chlorido ligand of the Pt^{IV} complex on the thiol.⁶⁰ The reductive elimination results in the production of the RSCl species and the concomitant release of the *trans* ligand. The RSCl is further consumed, leading to the formation of an RSSR unit. Exploring the reaction mechanism using the most abundant zwitterionic form in the physiological environment of the RA, the authors have evidenced that the reaction can be assisted by the carboxylate group. However, the energy cost required for the Cl-bridged mechanism to occur is very high along both carboxylate-assisted and non-assisted reaction paths. Moreover, the activation energy barrier computed for the oxidation of L-Cys, mediated or not by its carboxylate group, has been computed to be considerably higher than that of L-Met, contrary to what has been experimentally observed. Since the thiol functional group is considerably more reactive when it is converted into thiolate, the authors have demonstrated that in the case of the L-Cys agent, an unusual tautomerization can occur, surpassing a low energy barrier for a transition state that permits the transfer of the proton from the S atom to one of the oxygen atoms of the carboxylato group (TS₂₋₁₂). The free energy profile describing the whole mechanism that involves the active tautomer (13), formed by an H-transfer, is sketched in Fig. 2.

The reduction requires only 7.4 kcal mol⁻¹ to take place, thus justifying the higher activity of L-Cys towards Pt^{IV} to Pt^{II} reduction.

Additionally, we have applied the Baik approach to both tetraplatin and $[\text{Pt}(\text{en})\text{Cl}_4]$ complexes to estimate their redox potential. The calculated values with respect to the SHE are 0.412 eV for the former and 0.444 eV for the latter. Additionally, for these two di-chlorido Pt^{IV} complexes, highly positive values have been obtained, in line with the trend of the propensity to be reduced of Pt^{IV} complexes as a function of the identity of axial ligands.^{33,43} Therefore, an outer-sphere mechanism appears to be viable for both complexes.

Reduction mechanism of the $[\text{PtCl}_2(\text{salphen})]$ complex. In the search for more active and less dangerous anticancer drugs, much effort has been devoted to the design of metal complexes with more than one mode of action to maximize the cytotoxic effect. The identification of novel potential biological targets

such as DNA non-canonical structural arrangements with possible roles in carcinogenic events is a promising strategy for the development of new metal-containing anticancer drugs. For this reason, G-quadruplex (G-Q) nucleic acids, which are structurally quite different from the regular DNA double helix, have attracted much attention. They are characterized by the self-assembling of single-stranded guanine-rich DNA sequences arranged into planar guanine quartets. Such tetrads are stabilized by π - π stacking interactions and alkali-metal cations (such as Na^+ and K^+), which electrostatically interact with the guanine carbonyl groups. This type of structure is present in oncogene promoters as well as in telomeres, regions that have been identified as suitable targets for antineoplastic drugs, as it has been shown that the formation of telomeric G-Q nucleic acids inhibits the telomerase action, causing the cells death. Thus, the ideal drug suitable for targeting G-Q should be able to interact with such a secondary DNA structure, stabilizing it. The structural features of drugs able to stabilize G-Qs include an extended π -system, essential to establishing π - π interactions with guanine units, and a limited steric hindrance that could inhibit the entrance of the drug within the guanine tetrads. Recently, a salphen-based Pt^{IV} complex having two chlorido ligands in the axial position, shown in Scheme 6, has been synthesized, and the affinity for G-Q has been explored using c-myc and H-telo as G-rich DNA structures.⁶⁸ While the octahedral Pt^{IV} -Sal shows a low G-Q affinity, the corresponding Pt^{II} square planar complex resulted in an excellent G-Q binder. Thus, a favourable preliminary reduction of the Pt^{IV} complex in the cellular environment is of crucial importance to release the Pt^{II} complex, which acts as a G-Q binder.

The reduction of the Pt^{IV} -Sal complex has been explored by considering the action of two possible bioreductants: the active form of ascorbic acid, AscH^- , and Cys as a model of sulphur-containing reductants. All the plausible reaction mechanisms proposed for the leaving of Cl^- axial ligands, which include inner-sphere (a) ligand-bridged, (c) enolate β -carbon attack, and outer-sphere mechanisms, have been fully explored. It is worth reminding ourselves that mechanism (a) can be accessible to

both the considered RAs, while mechanism (c) may only occur in the presence of ascorbate. The outcomes summarized here showed that when ascorbate is the RA, the enolate β -carbon attack is preferred over the ligand-bridged mechanism, as the corresponding activation energy barriers are 3.0 and 20.9 kcal mol⁻¹, respectively. In addition, while the former mechanism is accompanied by an energy gain of 14 kcal mol⁻¹, the formation of the Pt^{II} active species is endergonic by 6.0 kcal mol⁻¹ in the latter. On the other hand, the only viable inner-sphere mechanism for the reductive action of Cys relied on the (a) ligand-bridge type, which is accompanied by S-Cl bond formation and the concomitant loss of the chloride occupying the *trans* position. It requires 7.2 kcal mol⁻¹ to take place and is also favoured from a thermodynamic point of view, being exergonic by 15.5 kcal mol⁻¹.

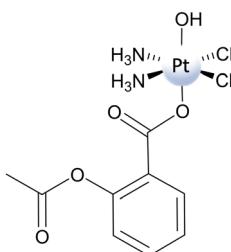

The outer-sphere mechanism has been explored as well, and the decomposition scheme proposed by Baik *et al.* (Scheme 5) has been adopted to estimate the reduction potential. Accordingly, the free energy change in solution that accompanies the first one-electron transfer leading to the formation of the six-coordinate Pt^{III} complex has been evaluated and the reduction potential calculated employing eqn (2). The obtained value of 0.162 eV, if compared with that computed for *cis*- $[\text{PtCl}_4(\text{NH}_3)_2]$ using the same approach (0.374 eV), suggested that the Pt^{IV} -Sal complex may also be reduced following an outer-sphere mechanism.

Hydroxido ligands

The information about the ease of reduction of Pt^{IV} prodrugs gained from the measurement of the peak potential leads to the conclusion that, typically, the potentials are more negative when the axial ligands are hydroxides. However, the presence of OH^- ligands, while rendering the electrochemical potential more negative and, then, the corresponding complexes less prone to reduction, offers the possibility of creating a bridge facilitating the electron transfer. As a consequence, many examples exist in the literature that evidence how the observed rates of reduction may or may not be correlated^{44,61} to the E_p values when Pt^{IV} complexes with hydroxido ligands are taken into consideration. Here, an example of a computational study trying to identify the correct mechanism that is operative for the reduction of Pt^{IV} complexes bearing hydroxido axial ligands is reported.

Asplatin hydroxido complex reduction mechanism. Asplatin or platin-A is a new Pt^{IV} cisplatin-based complex, $[\text{c},\text{c},\text{t}-[\text{PtCl}_2(\text{NH}_3)_2(\text{OH})(\text{Asp})]]$,^{69,70} having aspirinate (Asp) and hydroxido ligands in axial positions (Scheme 7). Thanks to the presence of a bioactive ligand in the axial position, the complex can combine anti-inflammatory and chemotherapeutic actions. An *in vivo* assay demonstrated that Asplatin possesses higher antitumor efficacy with lower toxicity in comparison with cisplatin. Asplatin, upon reduction, releases both cisplatin, which binds to DNA and triggers cell apoptosis, and aspirin, which should enhance the drug efficacy of the platinum complex. A detailed computational investigation of the reduction mechanism of the Asplatin complex has been performed by us in the presence of L-ascorbic acid, in its monoanionic form AscH^- , as RA. Several mechanistic hypotheses for the inner-sphere mechanism have

Scheme 7 Structure of Asplatin.

been explored by means of DFT. Specifically, the mechanisms (b), (c), and (d) in Scheme 3 have been found viable. For an Asplatin complex having a hydroxide in the axial position, an inner-sphere reduction mechanism of type (a) has been envisaged. This kind of mechanism, however, has been considered unfavorable³⁷ due to the reluctance of the OH unit to work as a bridge for allowing the two-electron transfer. During the detailed investigation of the reduction mechanism, a peculiar behavior was highlighted, as reported in Fig. 3a.

Indeed, the hydroxido ligand plays the role of a bridge, but it is the shift of a hydride (H^-) unit from the OH group of the ascorbate to the hydroxido ligand that allows the two-electron transfer and the simultaneous formation of a water molecule. *Trans* Asp ligand release, cisplatin formation, and the oxidation of ascorbate to DHA complete the process. Therefore, the OH^- ligand permits the electron transfer, but it is also directly involved in the reduction process as it generates the water molecule and leads to the formation of DHA. The reaction occurs through the TS depicted in Fig. 3a, overcoming an energy barrier of 14.6 kcal mol⁻¹, and is calculated to be highly exergonic (-34.5 kcal mol⁻¹). Therefore, the new type of mechanism named “ligand-bridge-H transfer”, as aforementioned, has been proposed for the first time. The investigation of mechanism (c) in Scheme 3 involves the nucleophilic attack of the enolate β -carbon of the ascorbate on the OH ligand, leading to the formation of a geminal diol product, causing the subsequent loss of the *trans* Asp ligand and the generation of the cisplatin active species. The height of the energy barrier

that is necessary to overcome is 20.7 kcal mol⁻¹. The subsequent step involves the elimination of water from the geminal diol product, which leads to the formation of the DHA oxidized species. In this process, an auxiliary water molecule, acting as a proton shuttle, assists the elimination, and the calculated energy barrier for the transition state is 24.4 kcal mol⁻¹. The whole process is calculated to be exergonic by 31.8 kcal mol⁻¹.

The (d) type reduction, instead, takes place following an autocatalytic mechanism and involves the Pt^{II} complex catalytic action that, in the reported case, is cisplatin. As described above, to carry out its catalytic action and facilitate the two-electron transfer, the Pt^{II} complex has to be sandwiched between the Pt^{IV} complex and the RA ($AscH^-$). Indeed, in the first step, an initial dimer adduct, $AscH^-$ -Pt^{II}-OH-Pt^{IV}-Asp, is formed (Fig. 3b). The hydroxido ligand, together with the deprotonated oxygen of the $AscH^-$ unit, begins to coordinate with the square planar Pt^{II} complex in the transition state TS1, and, as a final product, the new OH-Pt^{IV}-AscH complex is formed. The second ligand in the axial position of Asplatin, Asp, is released spontaneously, and cisplatin formation is achieved. Along this pathway, the two electrons are transferred through the bridge action of the OH^- ligand. The process is completed when the Pt^{IV} intermediate, generated in the first step, is further reduced by a second $AscH^-$, realized according to TS2. The second reduction takes place, overcoming an activation energy barrier of 17.2 kcal mol⁻¹. The rate-determining step of the process involves the action of the catalyst, with the Asplatin reduction and $AscH^-$ -Pt^{IV}-OH intermediate formation, and requires 24.9 kcal mol⁻¹ to occur.

It clearly appears that, among the three explored mechanistic hypotheses, the most viable is the ligand-bridge-H transfer. This conclusion has been further confirmed by a metadynamics study of the Asplatin reduction by ascorbate in which, in order to reduce the complexity of the problem, a new approach named harmonic linear discriminant analysis (HLDA) has been applied.⁷¹ The standard redox potential of the Asplatin complex has been calculated adopting the decomposition scheme proposed by Baik and coworkers, and a value of -0.239 eV has been obtained. If this value is compared with

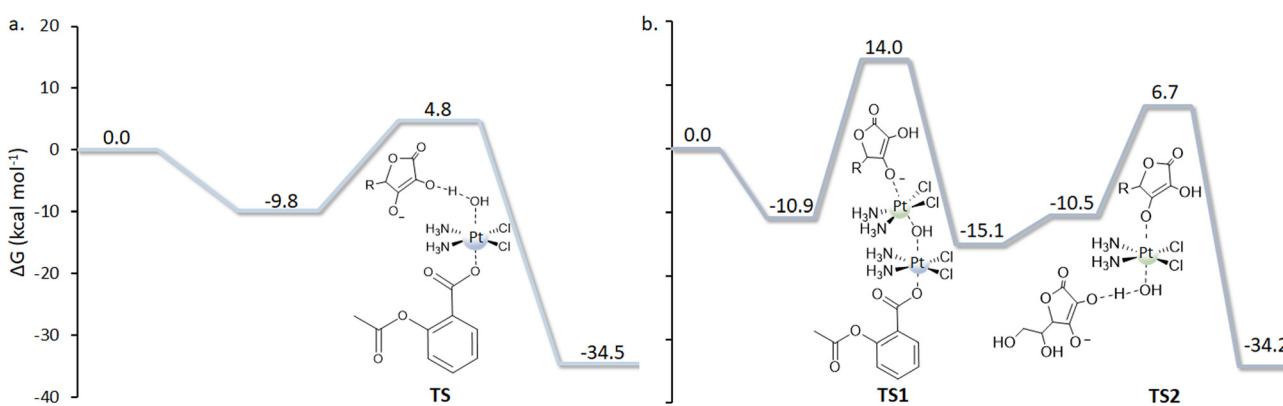

Fig. 3 Reduction mechanism following mechanism (b), the shift of a hydride (H^-) unit from the OH group of the ascorbate to the hydroxido ligand (panel a), and the Pt^{II}-catalyzed mechanism (d) (panel b).

the measured value of -0.536 eV *versus* the normal hydrogen electrode, it is confirmed that the peak potential is more negative than the normal potential, corresponding to a redox stability higher than the real one. Nonetheless, this negative value of the redox potential proves that the outer-sphere reduction is not viable.

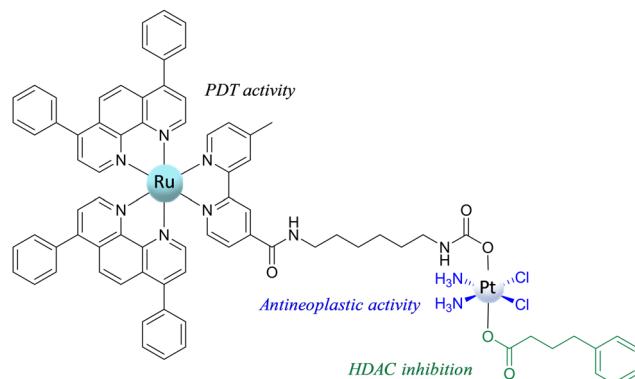

The results of the investigation on the Asplatin reduction summarized here demonstrate that the inner-sphere ligand-bridge-H transfer mechanism is the preferred one, corresponding to the lowest energy barrier. The calculated redox potential, even less negative than the experimentally measured peak potential, confirms the low propensity of the complex to be reduced by an outer-sphere mechanism. Moreover, the classical inner-sphere ligand-bridge mechanism is proven to be unlikely for hydroxido ligands. The new proposed ligand-bridge-H transfer mechanism allows for the resolution of the contradiction between the measured rapidity of the hydroxido Pt^{IV} complex reduction and the impracticality of outer-sphere and classical inner-sphere ligand-bridge mechanisms.

Carboxylato ligand

The preparation of carboxylato Pt^{IV} complexes commenced later with respect to that of hydroxido and chlorido complexes that are synthesized by oxidation of the corresponding square-planar Pt^{II} precursors with Cl₂ or H₂O₂. Only the optimization of the carboxylation process of di-hydroxido Pt^{IV} precursors has allowed the synthesis of a large number of carboxylato complexes. Among them, the diacetato satraplatin complex is the first oral deliverable platinum-containing anticancer drug that has entered a Phase III trial.⁷² Since no increase in overall survival has been noted, however, the drug has not obtained FDA approval. With respect to chlorido and hydroxido ligands that can act as electron bridges, carboxylato ligands are considered to be weak electron transfer bridges, and their measured peak potentials are intermediate between those of hydroxido and chlorido ligands. Furthermore, while halido and hydroxido ligands cannot be subjected to modification, carboxylato groups are the ligands mainly investigated for the synthesis of functionalized Pt^{IV} prodrugs with tuned chemical, physical, and pharmacological properties. A computational screening has been carried out by Cerón-Carrasco on a series of Pt^{IV} complexes decorating oxoplatin with five of the latest FDA-approved oncology drug sets (AOD9) coordinated through the carboxylato moiety.⁷³

Two examples of computational studies carried out on carboxylato Pt^{IV} complexes are illustrated here, aiming at highlighting that both the characteristics and the versatility of these complexes can be exploited.

Mechanism of reduction of a multi-action Ru^{II}-Pt^{IV} conjugate. Conjugating bioactive ligands to the axial positions of Pt^{IV} complexes has, in recent years, become increasingly popular in order to achieve synergistic actions, and several research groups have exploited carboxylato groups as linkers between the metal centre and biologically active molecules for the purpose of assembling new classes of Pt^{IV} compounds exerting multiple actions.

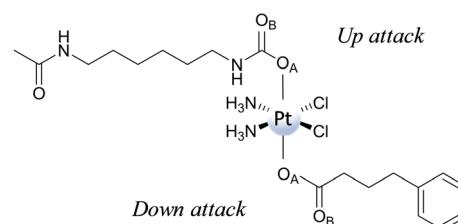

Scheme 8 Structure of the Ru^{II}-Pt^{IV} conjugate complex.

One of the most recent and interesting multi-action Pt^{IV} complexes is the Ru-Pt complex proposed by Karges *et al.*⁷⁴ This novel Ru^{II}-Pt^{IV} conjugate complex (Scheme 8) combines three biological activities: (i) the antineoplastic activity of the platinum complex; (ii) the light-mediated action of the Ru complex acting as a photosensitizer for photodynamic therapy (PDT); and (iii) the histone deacetylase (HDAC) inhibition action of 4-phenylbutyrate (PB). All these actions should be activated by the primary reduction of the conjugate to yield cisplatin, PB, and the Ru-based chromophore in the presence of a biological RA.

The reduction mechanism, assisted by ascorbate, of the Pt^{IV} prodrug to the Pt^{II} active species has been explored, taking into consideration all the possible modes of attack of the reductant for releasing the axial ligands and affording active cisplatin.⁷⁵ Specifically, ligand-bridge-H transfer and enolate β -carbon attack in the presence of AscH⁻ as a model of the RA have been studied by taking into account that the interaction may be established through both the axial ligands, carbamate (Ru-motif) and carboxylate (PB-motif). As in the reference paper, it is underlined that the long aliphatic chain has been used to make the Ru^{II} and Pt^{IV} portions independent, and the elucidation of the reduction mechanism has been performed considering a model of the complex reported in Scheme 9.

Then, both axial ligands have been considered to be directly involved in the reduction mechanism, distinguishing the two paths as Up and Down attacks. Furthermore, the participation of both oxygen atoms, labelled O_A and O_B, of the two ligands has been explored. The ligand-bridge-H transfer pathway that involves a bridge formation with the O_A atom occurs, overcoming an

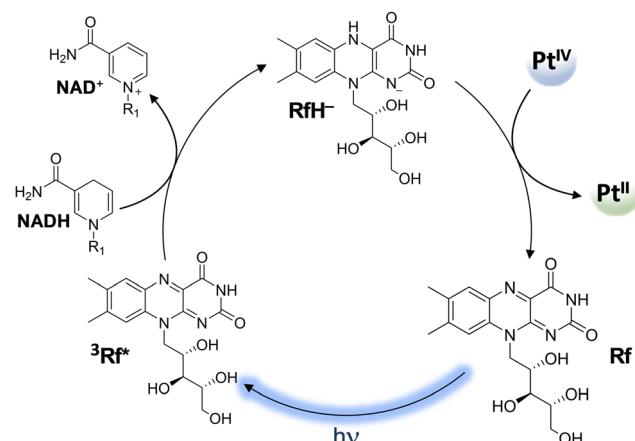

Scheme 9 Portion of the Ru^{II}-Pt^{IV} complex used to elucidate the reduction mechanism.

energy barrier of 25.5 and 32.1 kcal mol⁻¹, respectively, for Up and Down attacks. Furthermore, the reaction is exergonic by 8.6 kcal mol⁻¹ for Up and 6.1 kcal mol⁻¹ for Down attacks, respectively. The same reactions, but with O_B playing the role of bridge, entail energy barriers of 29.4 and 30.6 kcal mol⁻¹, respectively, for Up and Down attacks. The product is more stable than the initial adduct by 0.3 kcal mol⁻¹ and 1.7 kcal mol⁻¹ along the Up and Down attack pathways, respectively. From a kinetic point of view, the reduction mechanism is favoured when ascorbate approaches carbamate (Up attack). Similar behaviour has also been found for the enolate β -carbon attack, with the favoured pathway being that entailing the ascorbate interaction with the carbamate ligand from the Up side, requiring 27.1 kcal mol⁻¹ to take place *versus* 35.1 kcal mol⁻¹ needed for the Down attack. Cisplatin formation is accompanied by the generation of an ascorbate with an additional carboxylate moiety bound to the enolate β -carbon. The reaction is exergonic by 11.0 and 7.8 kcal mol⁻¹ for Up and Down attacks, respectively. Comparing the energy profiles of the two different mechanisms, the ligand-bridge-H transfer turns out to be the favoured mechanism when functional groups such as carboxylates and carbamates are present in the axial position; the same result was found for hydroxido axial ligands. In addition, as a covalent C–O bond between ascorbate and the ligand is formed, the enolate β -carbon attack needs an additional step for the formation of final products to occur. The conclusion that the favoured reduction mechanism is the ligand-bridge-H transfer on the carbamate is consistent with the experimentally observed behaviour of a series of Pt(IV) complexes having carbamates and carboxylates as axial ligands, showing that complexes having carbamates are reduced faster.⁷⁶

To evaluate whether the Pt^{IV} complex can be reduced by an outer-sphere mechanism, the standard reduction potential has been calculated using the Baik decomposition method. The computed value with respect to the SHE of -0.314 eV suggests, if compared with that of other complexes, that this complex is difficult to be reduced by this route.

Flavin-mediated photoactivation of Pt^{IV} prodrugs. Salassa and co-workers have demonstrated that flavins (FL), like riboflavin, and flavoproteins are able to catalyse the reduction of Pt^{IV} complexes under light irradiation.^{54,77–79} In this photocatalytic reaction, upon light excitation, the FL excited singlet state undergoes an intersystem spin crossing to the excited triplet state, which is then reduced by NADH to yield the reduced form of flavin and NAD⁺. The FL reduced form, FLH⁻, decays in its singlet ground state and can then cause a rapid conversion of Pt^{IV} into Pt^{II} while the catalyst is restored and can restart the catalytic cycle. A schematic representation of the catalytic process by riboflavin Rf is sketched in Scheme 10. The mechanism of photoactivation of Rf to its triplet excited state has been recently studied by means of Time-Dependent DFT.⁸⁰ The key steps of the photocatalytic mechanism of Pt^{IV} complexes reduction by Rf,⁵⁴ as a flavin model, have been elucidated by means of DFT using two Pt^{IV} prodrugs containing carboxylato groups as axial ligands (Scheme 11): *cis,cis,trans*-[Pt(NH₃)₂Cl₂(CH₃CO₂)₂] (1) and *cis,cis,trans*-[Pt(NH₃)₂(C₄H₆–CO₂)₂](CH₃CO₂)₂] (2), which, upon reduction, release the

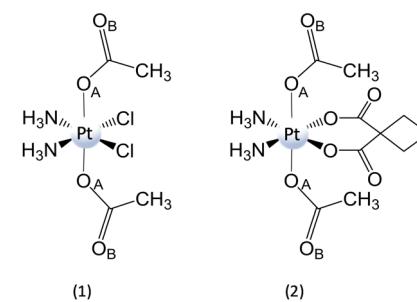

Scheme 10 Mechanism of the photocatalytic activation of Pt^{IV} prodrugs by riboflavin. (R₁ = adenine dinucleotide)

clinically-approved cisplatin and carboplatin. The ligand-bridge-H transfer mechanism has been explored as the most probable inner-sphere mechanism for both complexes. The reducing ability of the reduced form of riboflavin, RfH⁻, has been investigated and compared with that of two possible reducing agents: AsCH⁻ and 1-methylnicotinamide (MADH), as a model of NADH.

It is worth underlining that carboxylato ligands are able to form bridges with RAs by both oxygens: the one bound to the metal centre and the carbonylic one. Therefore, DFT calculations for the conversion of Pt^{IV} complexes by RfH⁻, MADH, and AsCH⁻ have been performed considering two different interaction modes. However, comparable trends have been calculated along both pathways, even if the pathway involving the formation of a bridge with oxygen O_A is slightly preferred kinetically. Focusing only on O_A, for all three donors, the hydride-donating moiety (N–H, C–H, and O–H) transfers 2e⁻ and a proton to the O_A, causing the detachment of the two axial ligands and the formation of cisplatin or carboplatin.

All the products obtained are strongly stabilized with respect to the entrance channel. The obtained free energy profiles prove that the reduction of both complexes takes place in the order RfH⁻ > AsCH⁻ > NADH, the same trend observed experimentally.⁵⁴ Moreover, RfH⁻ results in a very efficient RA with an activation barrier lower than 10 kcal mol⁻¹. In addition, calculations show

Scheme 11 Structure of complexes (1) *cis,cis,trans*-[Pt(NH₃)₂Cl₂(CH₃CO₂)₂] and (2) *cis,cis,trans*-[Pt(NH₃)₂(CBDCA)(CH₃CO₂)₂].

that complex (1) having cisplatin in the square plane is reduced more readily than (2).

Moreover, the values of the reduction potential have been calculated for both complexes. The low reduction potentials of (1) ($E_p = -0.324$ V vs. SHE) and (2) ($E_p = -0.693$ V vs SHE)⁸¹ suggest that an outer-sphere mechanism is unlikely for both complexes.

Conclusions

Reduction of Pt^{IV} complexes by bioreductants appears to be the key step of their mechanism of action for eliminating the axial ligands and releasing the corresponding active Pt^{II} species that are protected from deactivation *en route* before reaching their biological targets. Several parameters can be varied for tuning the activity of the prodrugs, requiring that their reduction be neither too fast, in order to avoid premature activation outside the cell, nor too slow to ensure the cytotoxic Pt^{II} drug is released effectively in tumor cells. The mechanisms of reduction, classified as inner- and outer-sphere, depend essentially on the nature of the axial ligands and, when an inner-sphere mechanism is operative, also on the identity of the reducing agent. In the present paper, an overview is given of the computational studies performed to identify the correct mechanism of the decisive step for the activation of Pt^{IV} compounds. All the proposed inner- and outer-sphere mechanistic hypotheses have been taken into consideration, and several examples of computational investigations of the reduction of Pt^{IV} complexes bearing hydroxido, chloride, and carboxylato ligands have been illustrated. We hope, with the overview given here, to contribute to properly addressing all the efforts presently directed towards the design and synthesis of Pt^{IV} prodrugs with both controllable activation characteristics and enhanced properties allowing targeted treatments and mitigation of severe side effects.
