Amidoboronates: bringing together the synthesis of BN-heterocycles via a reductive coupling and dynamic covalent chemistry

Anna J. McConnell

This Perspective describes how amidoboronates open up new chemical space spanning the areas of BN-heterocycles and dynamic covalent chemistry. BN-containing heterocycles offer the potential to access new properties and reactivity compared to their C–C analogues. Amidoboronates are introduced as a new class of B–N heterocycles that can be synthesised in three isomeric forms (meso\(_\text{ff} \), rac\(_\text{ff} \) and rac\(_\text{ff} \)) from the reductive coupling of N-aryl iminoboronates. Furthermore, initial investigations on the dynamic covalent chemistry of amidoboronates are discussed, such as the reversibility of C–C bond formation following the reductive coupling and tuning the rac\(_\text{ff} \)/rac\(_\text{ff} \) ratio via dynamic covalent B–N and B–O bonds.

Introduction

Given the isoelectronic nature of CC and BN bonds (Fig. 1a), BN-containing heterocycles\(^1\text{–}^{14} \) have been investigated as CC isosteres. However, the polarity of the B–N bond alters the electronic properties, leading to different reactivity and selectivity compared to their carbon analogues.\(^5\text{,}^{11} \) Furthermore, B–N bonds can take the form of coordinative or covalent bonds (Fig. 1a), offering additional avenues for accessing new types of chemistry and tuning properties. As a result, BN-heterocycles, such as azaborines, BN-naphthalenes and BN-polyaromatic hydrocarbons (PAHs), have been exploited in applications from materials science as BN-doped nanographenes\(^10 \) to catalysis.\(^12 \)

Despite the interest in BN-heterocycles, methods for their synthesis (particularly in the quantities required for applications) are still limited compared with the myriad of synthetic methods available in organic chemistry for the synthesis of CC analogues.\(^7\text{,}^{18} \) Thus, synthetic access to BN-heterocycles is limiting their diversity and the exploration of new chemical space\(^7 \) for example in the context of dynamic covalent chemistry.

Dynamic covalent chemistry combines the strength of covalent bonds with the reversibility of bond formation, enabling for example the self-assembly of supramolecular architectures from mechanically interlocked molecules to cages from smaller building blocks under thermodynamic control.\(^15\text{–}^{19} \) While the dynamic covalent chemistry of a variety of bonds including S–S\(^16\text{,}^{20\text{–}22} \), C–C\(^23\text{,}^{24} \), C–N\(^22\text{,}^{24\text{–}28} \), C–O\(^17\text{,}^{29} \), Si–O\(^30\text{,}^{31} \) and B–O\(^19\text{,}^{22\text{,}32\text{–}34} \) bonds has been established, the discovery of new types of dynamic covalent bonds, e.g. based on B–N bonds, could open up new avenues for applications.

This Perspective highlights how these two research fields, B–N heterocycles and dynamic covalent chemistry, have intersected through the synthesis of amidoboronates 3–4 (Fig. 1b), a new class of BN-heterocycles, and established new research directions. A family of amidoboronates has been prepared via the reductive coupling of N-aryl iminoboronates 1 with reduced synthetic effort exploiting the modular synthesis of the iminoborionate substrates and the formation of up to three isomeric amidoborionate products (meso\(_\text{ff} \), rac\(_\text{ff} \) and rac\(_\text{ff} \)).
Furthermore, the dynamic covalent chemistry of the amido-boronates including the rearrangement between the rac₅ and rac₆ isomers via dynamic covalent B–N bonds is discussed. C–C bond formation via reductive couplings

Synthesis of 1,2-diamines and 1,2-diols

Radical-mediated reductive couplings such as the pinacol coupling have been exploited in organic chemistry to form C–C bonds, giving access to 1,2-diamines³⁵–⁴⁴ and 1,2-diols⁴⁵,⁴⁶,⁴⁷ via the reductive coupling of imines and carbonyl compounds, respectively (Scheme 1a). A variety of metal-based reagents including alkali metals,⁴⁵–⁴⁷ Mg(i) compounds,⁴⁸ “Gal”,⁴¹ SmI₂,⁴⁸ and Mn*⁴⁹ have been used as the stoichiometric reductant. More recently, metal-free reductive couplings⁵⁰,⁵¹ have been reported and replacement of the stoichiometric reductant with a photocatalyst has led to the development of photoredox-catalysed reductive couplings.⁵²

Several mechanisms have been proposed for the reductive couplings (Scheme 1b): (a) one electron reduction forming a radical anion and the formation of the dimer via coupling of two radical anions; (b) two electron reduction to the dianion and disproportionation upon reaction with a second radical anion; two electron reduction to the dianion and reaction with a second aldehyde/ketone/imine.

Synthesis of B–N heterocyclic dimers

Reductive couplings have also been exploited to access B–N heterocyclic dimers following C–C bond formation (Schemes 2 and 3). Given the electron-deficiency of boron, the reactivity of the boryl as well as carbon-centred radicals needs to be considered;⁵¹,⁵² Nozaki and co-workers have reported that anionic ligands and Lewis bases can stabilise boryl radicals, although calculations proposed the carbon-centred radical was the major resonance contributor.⁵ Subsequently, they reported the reductive coupling of oxazoline-stabilised difluoroborane 5 in the absence of stirring (Scheme 2).¹ One electron reduction by KC₈ was proposed to form the boryl radical 6a following loss of a fluoride and coupling of the carbon-centred radicals.
Synthesis of amidoboronates

Reductive coupling of N-aryl iminoboronates

N-Aryl iminoboronates can be prepared exploiting dynamic covalent chemistry from three simple building blocks (Scheme 4): an aniline (blue), 2-formylphenyl boronic acid (red) and a diol (black).54–56 Iminoboronates have been used in the self-assembly of macrocycles and cages,55,57 determining the enantiomeric excess of amines and amino acids via fluorescent sensing,58,59 self-healing polymers,60,61 bioconjugation62–66 and drug delivery applications.57–69 These applications typically exploit the dynamic covalent nature of the imine and boronate bonds (see Dynamic Covalent Chemistry), however, the reactivity of the imine has been underexplored.

Given the structural similarity of iminoboronates to iminocloroborane 8 (Scheme 3), new BN-heterocycles could be potentially accessed as a mixture of diastereomeric meso† and rac† dimers via a reductive coupling of the imine. Furthermore, an advantage of iminoboronates is that a large family of substrates with different steric and electronic properties can be readily prepared by varying the building blocks during the iminoboronate self-assembly. Thus, we investigated the reductive coupling of N-aryl iminoboronates using reductants such as cobaltocene and decamethylcobaltocene, initially focusing on two series of iminoboronates (1 and 2) where the para-substituent of the aniline and the catechol were varied to investigate electronic effects (Scheme 5).70,71

The reductive couplings were initially performed in CD3CN, monitoring the reaction progress by NMR spectroscopy where the loss of the imine signal was observed. In most reductive couplings two new sets of 1H signals appeared including two methine signals between 5–6 ppm, attributed to the formation of a meso and rac diastereomeric mixture based on subsequent NMR analysis (see below, Solution characterisation). However, it was not possible to quantify the amount of the meso and rac diastereomers since one of the amidoboronate products typically crystallised from the reaction mixture of the reductive couplings (Table 1). Nevertheless, these crystals enabled the isolation and characterisation of single amidoboronate isomers both in the solid-state and in solution by redissolving the crystals in DMSO-d6.

6b under diffusion control led to dimer 7 formation in 47% yield.

Similarly, Dostál and co-workers reported the reductive coupling of iminocloroborane 8 with potassium produces a mixture of the meso and rac diastereomeric dimers 9 (Scheme 3).6 The two diastereomers could be separated by fractional crystallisation and the meso isomer was observed to convert to the rac isomer quantitatively upon heating in toluene. Two similar mechanisms to the analogous reductive couplings of imines and carbonyl compounds were proposed, involving the coupling of two carbon-centred radicals following one electron reduction or the reaction of the BN-indenyl anion 10 (formed by 2 electron reduction) with iminocloroborane 8.
Scheme 5 The synthesis of up to three amidoboronate products (meso₅, rac₅, and rac₆) from the reductive coupling of N-aryl iminoboronates (pyrocatechol series: 1a–1e; tetrachlorocatechol series 2a–2e) using cobaltocene or decamethylcobaltocene.

The isomer was characterised in the solution state only by NMR spectroscopy.

Solid-state characterisation

X-ray crystal structures of [meso₅,3a]Co₂ and [meso₅,3b]Co₂ were obtained showing the meso isomer in two different conformations, anti and gauche (Fig. 2a and b). X-ray analysis of crystals obtained from the tetrachlorocatechol series (R′ = Cl) revealed the rac₅ isomer crystallised as the cobaltocenium and/or decamethylcobaltocenium salts (Fig. 2c).

For rac₅, crystal structures of three polymorphs of the cobaltocenium salt were obtained in addition to one crystal structure of the decamethylcobaltocenium salt. The X-ray crystal structures of the meso₅ and rac₅ isomers confirmed dimerisation via C–C bond formation between the two five-membered rings and Fig. 2 highlights the different stereochemistry around the new C–C bond for the two diastereomers using Newman projections.

Unexpectedly, X-ray analysis of crystals obtained from analogous reductive couplings of 1a and 1b on separate occasions were not meso₅ or rac₅ structures but an isomeric and previously unknown B–N heterocyclic scaffold consisting of two fused six-membered rather than five-membered rings (Fig. 2d). Thus, these amidoboranes were named the rac₆† product and similar X-ray crystal structures were obtained of [rac₆,3a,d]Co₂ in the pyrocatechol series (R′ = H). Since significant quantities of the rac₆ product were not observed in the reaction mixtures in CD₃CN, further studies in DMSO-d₆ (see below, Solution characterisation) probed whether it forms in the solid state only or also in solution.

Unlike the tetrachlorocatechol series where crystals were obtained of the rac₅ isomer only, crystals of all three isomers were obtained from the pyrocatechol series (Table 1). Amidoboranes 3a–b containing electron-withdrawing Cl and F aniline substituents crystallised as either the meso₅ or rac₅ isomer (depending on the reaction conditions) and 3a–d,f crystallised as the rac₆ isomer. Although crystals were also obtained from the reductive coupling of 3e, they were not suitable for X-ray analysis. However, subsequent solution studies revealed the rac₅ isomer crystallised.

The number of crystal structures of the amidoborinate isomers as well as several iminoborinate starting materials has enabled comparison of different structural parameters (Table 2). Firstly, the formation of covalent B–N bonds in the amidoborinate products is confirmed by the shortening of the B–N bond (1.50–1.55 Å) compared to the dative B–N bond (1.66–1.68 Å) in the iminoborinate. In addition, the two counterions (Co₂⁺ or Co⁺⁺) per dimer indicated the formation of two anionic tetrahedral boron centres. A slight lengthening of the B–O bonds was also observed in the amidoborates compared to the iminoborates.

The X-ray structures also revealed the conformation and bond length of the newly formed C–C bond (Table 2). The thermodynamic stability of the gauche and anti conformations has been reported for dimers formed from carbon-centred radicals. Indeed, the gauche conformation (59–70°) was observed in all crystal structures except for meso₅,3a where the anti conformation (179°) was observed, likely due to different crystallisation conditions. Furthermore, the C–C bond lengths for all isomers (1.53–1.57 Å) were consistent with a sp³-hybridised C–C bond, suggesting bond lengthening due to a contrib-
solution structure of the meso₅, rac₅ and rac₆ isomers was probed by redissolving the isolated crystals in DMSO-d₆. Regardless of the substitution of the amidoboronates, characteristic signals were observed for each product: a methine signal around 5.4 ppm for the meso₅ diastereomer; a methine signal around 5.2 ppm and doublet around 7.7 ppm for the rac₅ diastereomer; a methine signal around 4.9 ppm and two doublets around 6.9 and 6.8 ppm for the rac₆ isomer. Similar shifts were observed for the amidoboronate products in both DMSO-d₆ and CD₃CN, enabling identification of the isomeric mixtures in the corresponding reductive couplings in CD₃CN.

The existence of the rac₆ product in solution was investigated in time-course NMR experiments (Scheme 6). For the reductive coupling of 1f in CD₃CN where the rac₅ isomer crystallised from the reaction mixture, the rac₅ signals were observed to decrease over time and this enabled the characterisation of the remaining isomer in solution, meso₅-3f. In analogous reductive couplings with 1b and 1d in DMSO-d₆ where crystallisation was prevented, the meso₆ and rac₅ diastereomers initially formed and the rac₅ converted into the rac₆ isomer over time, as evidenced by the appearance of a third methine signal consistent with redissolved rac₆ crystals. Thus, the rac₆ isomer was proposed to form via breakage and rearrangement of the covalent B–N bonds in the rac₅ isomer. The following sections introduce dynamic covalent chemistry with a focus on examples relevant to the subsequent discussion of the dynamic covalent chemistry of amidoboronates, including the B–N bonds in more detail.

**Solution characterisation**

As revealed by X-ray analysis, up to three isomeric amidoboronates crystallised from the reductive couplings in CD₃CN. The distribution from the radical form is minimal at the temperature of the measurements (100 K or 180 K).

**Fig. 2** X-ray crystal structures and Newman projections of: (a) [meso₅-3a](Cp₂Co)₂; (b) [meso₅-3b](Cp₂Co)₂; (c) [rac₅-4d](Cp₂Co)₂; (d) [rac₆-5a](Cp₂Co)₂. For clarity, the X-ray structures do not depict the Cp₂Co⁺ counterions and solvent molecules. The Newman projections do not depict the R and catechol substituents and the two halves of the dimer are shown in red and black, particularly to show the change in connectivity in the rac₅ isomer. Dynamic covalent chemistry

Dynamic covalent chemistry is a diverse research field encompassing a variety of reversible covalent bonds from C=N to B-O bonds. The combination of several dynamic covalent bonds offers the potential for addressing the different functional groups orthogonally, thus increasing the complexity of the system.

N-Aryl iminoboronates (the substrates for the synthesis of amidoboronates) contain two types of dynamic covalent bonds, an imine and boronate ester, leading to synergistic effects during their self-assembly from an aniline, diol and 2-formylphenyl boronic acid (Scheme 4). Nitschke and co-workers reported the amine and diol subcomponents influence the stability and yield of the resulting iminoboronate; synergistic stabilisation of the imine and boronate ester was proposed from the combination of an electron-rich aniline and catecholate due to greater resonance delocalisation over the catecholate, resulting in a B-N dative bond in aprotic solvents. In contrast, incomplete iminoboronate formation was observed with an electron-rich aniline and an electron-rich alkoxide, attributed to increased electron density around the boron centre leading to destabilisation and the absence of a B-N dative bond.

In addition, both the aniline and diol subcomponents can be orthogonally exchanged when a thermodynamically more stable iminoboronate results from exchange. More electron-rich amines (e.g. an alkylamine) replaced electron-poor ones (e.g. an aniline) driven by the formation of a more electron-rich imine stabilising the boron centre (Scheme 7a). Furthermore, aliphatic diols were displaced by pyrocatechol due to better delocalisation of the oxygens' partial negative charge over the aromatic catechol (Scheme 7b).

While combinations of two types of dynamic covalent bonds can be orthogonally exchanged (e.g. imines and boronate esters as in Scheme 7), extension to three dynamic covalent bonds introduces additional orthogonality issues. Matile and co-workers investigated the orthogonality of hydrazone (red, Scheme 8a), boronate ester (green) and disulfide (blue) bonds in multicomponent self-assembly as well as model systems like 12 (Scheme 8b) and increasing the stability of the boronate ester was necessary for orthogonality under the acidic hydrazone exchange conditions. This was achieved using the boronate esters of benzoboroxoles where the anionic esters as in Scheme 7).
Dynamic covalent chemistry of amidoboronates

Amidoboronates are thus interesting candidates for use in dynamic covalent chemistry applications given the initial implication of dynamic covalent B–N bonds in the rac/drac rearrangement and the potential for dynamic covalent C–C and B–O bonds. The dynamic covalent chemistry of the amidoboronates was explored and of particular interest was the discovery of new chemistry, for example compared to iminoboronates and other reductively coupled dimers.

C–C bonds

The reversibility of C–C bond formation was investigated in a series of experiments to gain insight into the reductive coupling mechanism. Based on the analogous reductive coupling of iminochloroborane 8 reported by Dostál and co-workers (see Synthesis of B–N heterocyclic dimers), radicals are proposed to be involved. Firstly, isolated crystals of the meso, rac and rac isomers were redissolved in DMSO-d₆ to probe the existence of a radical/dimer equilibrium. However, there has been thus far no evidence of a conversion between the meso and rac isomers at room temperature via reversible C–C bond formation in the redissolved crystals. Furthermore, decomposition was observed upon heating solutions of the redissolved crystals of meso-3b and rac-3c at elevated temperatures (90 °C or above). This contrasts the finding by Dostál and co-workers that meso-9 can be converted to rac-9 upon heating in toluene (Scheme 3).5

However, the addition of the tritylium cation to an isomeric mixture of 3c or 4c led to quantitative regeneration of the corresponding iminoboronates 1c or 2c at room temperature within 10 minutes (Scheme 10). The tritylium cation acts as an...
electron abstractor leading to oxidative decoupling of the dimers as well as Cp₂CoBF₄ and the formation of the trityl dimer from subsequent radical coupling. This ability to break the newly formed C–C bond in the dimer has not been reported in the related reductive couplings of imine and carbonyl compounds (see Synthesis of 1,2-diamines and 1,2-diols).

In another experiment, the TEMPO radical was added to an isomeric mixture of 4c and upon heating at 70 °C in CD₃CN for 3 days, an additional species appeared in the ¹H NMR spectrum (Fig. 3a).⁷⁰ X-ray analysis of crystals obtained from the reaction revealed the formation of 14 where TEMPO rather than the imine is coordinated to the anionic tetrahedral boron centre (Fig. 3b). The formation of an imine was also consistent with the observation of a singlet above 9 ppm for the new species in the NMR spectrum. The formation of 14 was proposed via electron abstraction from the nitrogen lone pair by TEMPO giving a nitrogen-based radical cation, homolytic cleavage of the C–C bond generating an imine and finally, nucleophilic attack of TEMPO⁻ on the boron centre. This contrasts the formation of radicals via homolytic substitution of trigonal catecholborane derivatives by TEMPO.⁸⁸–⁹⁰

These experiments demonstrated that the new C–C bond can be broken upon addition of an electron abstractor (CPh₃⁺) or a radical (TEMPO). The existence of a radical/dimer equilibrium will be probed in future experiments to investigate whether the reductive coupling can be implemented for the formation of dynamic covalent C–C bonds like in Scheme 9.

**Scheme 10** Addition of the tritylium cation to an isomeric mixture of 3c or 4c regenerates the corresponding iminoboronate (1c or 2c) as well as the trityl dimer and Cp₂CoBF₄. For clarity, only the meso₅ and rac₅ isomers are depicted as they were the major species observed in the reaction mixture in CD₃CN.

**B–N bonds**

The reductive coupling converts the B–N dative bond observed in iminoboronates 1a–1f and 2a–2e to covalent B–N bonds with anionic tetrahedrally coordinated boron centres. Unexpectedly, these covalent B–N bonds were found to be dynamic as the rearrangement of the rac₅ into the rac₆ isomer was observed over time in time-course NMR experiments (see Solution characterisation). In contrast, redissolved crystals of meso₅-3a-b did not interconvert into either of the rac isomers and there has been no evidence thus far of the formation of a meso₅ product.

The rac₅/rac₆ rearrangement was investigated in more detail by redissolving isolated crystals in DMSO-d₆ (Scheme 11). Initial investigations suggested increased electron density facilitates cleavage of the B–N bond since the rate of interconversion of 3b,c–f was qualitatively fastest with 3d containing the most electron-donating aniline substituents in the series.⁷⁰

Further investigations focused on the amount of the rac₅ and rac₆ isomers following equilibration as a function of the para-substituent on the aniline and the catechol (Fig. 4).⁷¹ For the pyrocatechol series, rac₆-3a,c–d and rac₅-3e crystallised from the reductive couplings. While rac₅-3a did not interconvert to the rac₆ isomer, the amount of the rac₅ isomer for the other derivatives increased with more electron-donating substituents (Scheme 11a, Fig. 4a). A 1 : 1 rac₅/rac₆ mixture was obtained for 3e with the most electron-rich NMe₂ substituent.

**Fig. 3** (a) Formation of 14 from the reaction of a 4c isomeric mixture with the TEMPO radical. For clarity, only the major amidoboronate species in solution are depicted; (b) X-ray crystal structure of 14 with Cp₂Co⁺ counteraction removed for clarity.
In contrast, redissolved rac₅ crystals as either the cobaltocene or decamethylcobaltocenium salt from the tetrachlorocatechol series (4a,c–e) were not observed to interconvert to the rac₆ isomer (Scheme 11b, Fig. 4b).

Conformational analysis of the rac₅ and rac₆ isomers may provide an explanation for the rac₅/rac₆ rearrangement (Fig. 5). Of the three most likely conformations (two gauche and one anti), only the gauche conformation (black box) where the aniline lines are anti to one another has been observed in the X-ray crystal structures (Fig. 2c). A similar gauche conformation (black box, Fig. 5) was also observed in the X-ray crystal structures of the rac₅ isomer (Fig. 2d), suggesting that the rac₅/rac₆ rearrangement occurs via breakage of the B–N bonds and rotation of the phenylboronate ester groups so that the five-membered rings are converted to a fused six-membered ring scaffold. Fig. 5 represents the two halves of the rac₅ dimer in red and black to highlight the change of the connectivity in the rac₆ isomer where the red nitrogen forms a covalent bond to the boron centre in black and vice versa.

Based on the observed interconversions (Scheme 11), electronic effects were proposed to control the rac₅/rac₆ rearrangement; an electron-withdrawing Cl aniline substituent (3a) or catechol such as tetrachlorocatechol (4a,c–e) resulted in no interconversion of the rac₅ and rac₆ isomers, respectively, attributed to strengthening of the B–N bond from the reduced electron density. However, increasing the electron density in

Scheme 11 rac₅/rac₆ interconversion upon redissolving crystals of (a) rac₅-3a,c–d and rac₆-3e; (b) rac₅-4a,c–e. Adapted with permission from ref. 71.

Fig. 4 Comparison of the rac₅/rac₆ isomeric ratios following: (a) equilibration of redissolved crystals of 3a,c–e from the pyrocatechol series; (b) equilibration of redissolved crystals of 4a,c–e from the tetrachlorocatechol series; (c) catechol exchange of pyrocatechol for tetrachlorocatechol in equilibrated rac₅/rac₆ mixtures from (a). Reprinted with permission from ref. 71.
the B–N bond through more electron-donating aniline substituents is proposed to weaken the B–N bond, resulting in increased rac\textsubscript{5}/rac\textsubscript{6} interconversion.

**B–O bonds**

The diol subcomponents within boronate ester bonds are known to undergo exchange via dynamic covalent B–O bonds\textsuperscript{19,22,55,74}. However, in most cases the boron centre has a vacant p orbital (e.g. in iminoboronates in the absence of a BN dative bond, Scheme 7b), whereas in amidoboronates this is filled since the boron is anionic and tetrahedrally coordinated. Nevertheless, Matile and co-workers reported catechol exchange with boronate esters of benzoboroxoles containing anionic tetrahedral boron centres (Scheme 8b).\textsuperscript{22} Therefore, the dynamic covalent nature of the B–O bonds of amidoboronates was explored in catechol exchange experiments.\textsuperscript{71}

Addition of tetrachlorocatechol to equilibrated mixtures of rac\textsubscript{5}/rac\textsubscript{6}-3a,c–e in DMSO-\textit{d\textsubscript{6}} led to complete catechol exchange and the formation of rac\textsubscript{5}/rac\textsubscript{6}-4a,c–e (Scheme 12). The rac\textsubscript{5}/rac\textsubscript{6} ratio was changed from a preference for the rac\textsubscript{6} isomer prior to catechol exchange (Fig. 4b) to a preference for the rac\textsubscript{5} isomer (Fig. 4c). The presence of the rac\textsubscript{6} isomer following catechol exchange is attributed to the catechol exchange pathway allowing the direct conversion of rac\textsubscript{6}-3 to rac\textsubscript{6}-4 rather than via the rac\textsubscript{5}/rac\textsubscript{6} interconversion since redisolved rac\textsubscript{5}-4 crystals did not interconvert to the rac\textsubscript{6} isomer.

While catechol exchange of pyrocatechol for the more electron-deficient tetrachlorocatechol was observed, addition of excess pyrocatechol to rac\textsubscript{5}-1d showed no catechol exchange. It

---

Black box: the gauche conformations of the rac\textsubscript{5} and rac\textsubscript{6} isomers observed in X-ray crystal structures. The red and black represent the two halves of the dimer to highlight the change in connectivity upon the rac\textsubscript{5}/rac\textsubscript{6} rearrangement.

---

**Scheme 12** Boronate ester exchange of pyrocatechol for tetrachlorocatechol via dynamic covalent B–O bonds converts an equilibrated mixture of rac\textsubscript{5}-3 and rac\textsubscript{6}-3 to rac\textsubscript{5}-4 and rac\textsubscript{6}-4. Adapted with permission from ref. 71.
was proposed that the tetrachlorocatechol analogues are thermodynamically more stable due to better negative charge delocalisation with tetrachlorocatechol vs. pyrocatechol and this is the driving force for catechol exchange.

Conclusions and outlook

While the number of synthetic methods for BN-heterocycles are limited compared to their carbon analogues, this is an active field with an increasing number of reports particularly given the growing importance of BN-heterocycles in catalysis and materials chemistry applications. On the other hand, dynamic covalent chemistry is an established field but new applications and types of dynamic covalent bonds (e.g. based on radicals\textsuperscript{18}) are emerging.

Amidoboronates bring together BN-heterocyclic synthesis and dynamic covalent chemistry and new research directions have been made possible through this intersection of these two seemingly disconnected research fields. Amidoboronates are a new class of BN-containing heterocycles that can be prepared from N-aryl iminoboronate substrates via a reductive coupling (Scheme 13). Their synthesis opens up new chemical space since up to three isomers can be prepared from a single substrate, which itself can be modularly self-assembled from three building blocks using dynamic covalent chemistry. Thus, a large family of new BN-heterocycles was synthesized with reduced effort.

In addition, initial studies have revealed the interesting and unusual dynamic covalent chemistry of amidoboronates involving C–C, B–N and B–O bonds. Unlike the analogous reductive couplings of carbonyls and imines, C–C bond formation is reversible for amidoboronates since oxidative decoupling of the dimer through the addition of the tritylium cation regenerates the iminoboronate. An unprecedented rearrangement between the rac\textsubscript{5} and rac\textsubscript{6} isomers via dynamic covalent B–N bonds has also been observed where the aniline para-substituent and the catechol tune the isomeric ratio at equilibrium. Furthermore, boronate ester exchange can be exploited as another tool to control this ratio.

Further exploration of this chemical space will offer new opportunities for applications of this chemistry. Future efforts will focus on exploring the mechanism of the reductive coupling, particularly to control the diastereoselectivity and therefore, selectively synthesize a particular isomer. The three types of dynamic covalent bonds also offer an exciting opportunity for exploring the orthogonality of transformations and the design of more complex stimuli-responsive systems.
