Investigating the electrocatalytic reduction of 2,4,6-tri-nitro-toluene (TNT) using density functional theory methods†

Andrew Jark-Wah Wong, Joshua Lee Miller, Brandon Perdue and Michael John Janik  *

2,4,6-Trinitrotoluene (TNT) degradation is of interest in environmental remediation, demilitarization, and national security. Electrochemical TNT reduction to 2,4,6-triaminotoluene is potentially energy efficient and operable at ambient conditions. Determining an elementary reduction mechanism and rate limiting steps is needed to rationally develop TNT electroreduction catalysts. Density functional theory methods determine the TNT reduction mechanism for non-catalyzed and late-transition metal catalyzed paths. The non-catalyzed mechanism is limited by slow initial NO_2 group reduction. The outer-sphere mechanism is more competitive to electrocatalytic reduction on Au (111) and Fe (110) surfaces, which wasn't observed in our previous work on nitrobenzene electroreduction. An inverse tradeoff between the initial reduction of the $\text{NO}_2\text{-R}^*$ group and reduction of surface hydroxyls suggests relative catalytic activity can be tuned by modulating O^* affinity. Metal surfaces with intermediate O^* affinity (Cu, Pt, Pd, and Ir) are predicted to be the most active late transition-metals towards TNT reduction. We extend our investigation to bimetallics and partially reduced Fe_2O_3 (0001) surfaces.

1. Introduction

2,4,6-Tri-nitro-toluene (TNT) is the most commonly utilized nitroaromatic compound as an explosive for military, construction, and mining applications.^{1,2} Extensive usage and production of TNT has led to the contamination of wastewater, resulting in the formation of toxic "pink water" and "red water".^{3,4} Such wastewater sources are difficult to remediate and are harmful towards humans and the environment due to the toxic and mutagenic nature of TNT.⁵ Thus, TNT has been listed as a priority pollutant by the United States Environmental Protection Agency (USEPA) and the European Communities (EC).^{2,6} Degradation of TNT is also of high interest in demilitarization and security applications in identifying and neutralizing explosive ordinances in water sources.⁷

Advanced oxidative, adsorption, photocatalytic, biodegradation, and electrochemical methods have been developed to remediate TNT. Advanced oxidation processes have been reported to degrade TNT using reagents such as O_3 , H_2O_2 , zero valent Fe, and super critical water.^{8–11} Adsorptive

removal of TNT on activated carbon has been performed.^{12,13} Photocatalytic methods degrade TNT on a TiO_2 surface and in the presence of H_2O_2 and ferrous ions.^{7,14,15} Reduction of nitroaromatics ($\text{NO}_2\text{-R}$) to the amine species ($\text{NH}_2\text{-R}$) is another effective degradation approach due to the high electron affinity of the NO_2 group. 2,4,6-Tri-amino-toluene (TAT) is the preferred reduced TNT intermediate due to its lower toxicity and ease to degrade.¹⁶ Biodegradation of TNT to TAT was performed and facilitated by the use of microorganisms and fungi.^{2,17}

Electrochemical reduction methods are of high interest as a practical environmental remediation technology due to their potential energy efficiency, scalability, and ability to operate at ambient reaction conditions.¹⁸ The overall reaction of electrochemical TNT reduction to TAT is presented in Scheme 1.

Prior theoretical studies suggest that TNT reduction is limited by the initial activation of the NO_2 group.¹⁹ This prior work suggests one NO_2 group is reduced to R-NH_2 before proceeding to reduce the next NO_2 group. Initial TNT reductions occurs through a six H^+/e^- reduction by either reducing the *ortho* NO_2 group to form 2-amino-4,6-dinitrotoluene ($\text{O-NH}_2\text{-DNT}$) or the *para* NO_2 group to form 4-amino-2,6-dinitrotoluene ($\text{P-NH}_2\text{-DNT}$). Each TNT R-NO_2 group is reduced to form the reduced amine intermediate and two H_2O molecules. TNT is reduced electrochemically through an 18 H^+/e^- transfer to TAT, producing six H_2O molecules.

Scheme 1 Overall reaction for the electrochemical reduction of 2,4,6-tri-nitro-toluene (TNT) to 2,4,6-tri-amino-toluene (TAT).

Electrocatalysts are pivotal in the advancement of TNT electrochemical reductive methods. Electrochemical reduction of TNT has been performed over exfoliated graphene, alumina on a glassy carbon electrode (GCE), boron-doped graphene, and Au nanoparticles.^{20–23} In particular, Soomro *et al.* investigated the reduction of TNT on various shaped Pd, Pd–Pt alloys, and GCE, where three distinct reduction peaks are observed on all electrodes in the square wave voltammetry (SWV).²⁴ Potentials for the three reduction peaks reported across different electrodes by Soomro *et al.* are converted to the reversible hydrogen electrode scale (RHE) and presented in Table 1.

Though higher current densities are observed for the Pd/Pt based electrodes, the reduction potentials of the three peaks of the Pd-based electrodes occur at similar overpotentials to the GCE reduction peaks. This questions the role of these Pd/Pt based electrodes in catalyzing the reaction, as an inner-sphere catalytic effect would be expected to reduce the over-

potential relative to GCE, where outer-sphere reduction might be expected. The outer-sphere (non-catalyzed) reduction mechanism could be competitive to the inner-sphere (catalyzed) mechanism. If the reduction of TNT primarily undergoes an outer-sphere mechanism, the focus of electrode design can shift towards optimizing properties such as surface area, conductivity, and cost since the electrode's ability to catalyze the reaction only plays a minor role.

Determination of the elementary reaction mechanisms is needed to facilitate the design of active and selective electrocatalysts. Density Functional Theory (DFT) approaches are effective in screening electrocatalysts and determining the elementary reaction mechanisms at the atomistic scale.^{18,25,26} However, few theoretical studies investigated the electrochemical reduction of TNT. Chua *et al.* investigated the elementary step reduction mechanism of outer-sphere TNT reduction combining experimental and DFT results.¹⁹ Their DFT results predicted that the three experimental reduction peaks are due to the successive reduction of each NO₂ group, each limited by the slow initial reduction of the R-NO₂ species. Though their study thoroughly determined the elementary steps to reduce the first NO₂ group of TNT to 2-amino-4,6-dinitrotoluene (O-NH₂-DNT), only the first electron addition step onto each NO₂ group was considered for the six and 12 H⁺/e⁻ reduction intermediates. Theoretical TNT electrocatalysis studies have only studied the adsorption of TNT on Al-hydroxides, MgO (001), and Al (111) surfaces, leaving the elementary reduction mechanism on electrocatalytic surfaces to be determined.^{27–29} We previously used DFT methods to investigate the elementary step electrocatalytic reduction of a similar nitroaromatic, nitrobenzene (NO₂-Phenyl) to aniline

Table 1 Experimentally observed reduction potentials across different electrodes reported in the SWV of Soomro *et al.*²⁴ Potentials are reported on the RHE scale

Electrode	Potential of 1 st reduction peak (V-RHE)	Potential of 2 nd reduction peak (V-RHE)	Potential of 3 rd reduction peak (V-RHE)
Glassy carbon (GCE)	-0.10	-0.27	-0.39
Pd nanocubes/GCE	-0.11	-0.27	-0.39
Pd hollow nanosphere/GCE	-0.15	-0.34	-0.46
Pd–Pt nano alloys/GCE	-0.19	-0.35	-0.47

(NH₂-phenyl), on monometallic and bimetallic surfaces.³⁰ Monometallic and bimetallics that exhibit intermediate binding of O* are predicted to be the most active electrocatalysts for NO₂-Phenyl reduction. To our knowledge, this study is the first to use DFT methods to investigate the elementary electrocatalytic reduction mechanism of TNT across different late transition-metal surfaces.

DFT methods are applied to determine the elementary reduction mechanism of TNT to TAT and its rate limiting step across different late transition-metal surfaces, bimetallics, and partially reduced Fe oxide surfaces. Both the outer-sphere and inner-sphere TNT reduction mechanisms are considered. First, the elementary step reduction mechanism of the non-catalyzed mechanism is investigated to determine its rate limiting steps. The reduction of TNT on the Fe (110) and Au (111) surfaces is then examined to determine the activity tradeoffs between two metal surfaces that exhibit differences in O binding affinity. Using the determined activity tradeoffs from Fe (110) and Au (111) surfaces, reaction energetics and activation barriers are evaluated across late transition-metal surfaces (Co, Ru, Rh, Ni, Ir, Pd, Pt, Ag, Au, and Fe). A “volcano” relationship is then determined to predict optimal TNT reduction electrocatalysts using the binding strength of O* as the surface descriptor. A limiting potential analysis is used to compare the overpotentials of the outer-sphere and catalyzed mechanism across different late transition-metal surfaces. Investigation from monometallic surfaces is then extended to bimetallic surfaces and partially reduced Fe₂O₃ (0001) oxide surfaces to screen potential TNT reduction electrocatalyst candidates.

2. Computational methods

2.1. Electronic structure calculations

DFT calculations of surface bound species were performed in the Vienna Ab Initio Simulation Program (VASP).^{31–34} Core-valence interactions were approximated by the projector augment wave (PAW) approach.^{35,36} Exchange and correlation energies was approximated by the Perdew, Burke, and Ernzerhof (PBE) generalized gradient (GGA) functional.^{37,38} An energy cutoff of 450 eV was used to approximate the plane wave basis set. Geometry optimizations were completed at an atomic force criterion of 0.05 eV Å⁻¹. Dipole corrections were implemented in the direction normal to the surface (LDIPOL = .TRUE. and IDIPOL = 3). Dipole corrections in all directions were implemented for charged gas-phase species (IDIPOL = 4). Spin unrestricted calculations were performed for the Fe (110), Co (0001), Ni (111), Ni/Cu (111) surface, and all partially reduced Fe₂O₃ oxide surfaces. The Fe (110), partially reduced Fe₂O₃ (0001) and Ni/Fe₂O₃(0001) surfaces were optimized at a high initial spin state for the Fe and Ni atoms. The DFT+U method was implemented for the Fe₂O₃ (0001) surfaces to approximate the 3d-orbital localized electrons of the Fe atoms.^{39–41} Ovcharenko *et al.* showed that a value of $U_{\text{eff}} = 4.0$ eV was appropriate due to the lattice constant and band-gap

values of the Fe₂O₃ (0001) showing good agreement with prior experimental work.⁴²

The VASPSol implicit solvation model was implemented to approximate the effects of solvation during TNT reduction.^{43,44} The default VASPSol parameters were utilized to model solution phase and surface calculations: a dielectric constant of the bulk solution of 78.4, cutoff charge density of 0.00025 e⁻ Å⁻³, dielectric cavity width of 0.6 Å, and surface tension parameter of 0.525 meV Å⁻². Transition states were determined through four linearly interpolated images from the Climbing Image Nudged Elastic Band method.^{45,46} First order saddles points of the transition states were confirmed with a vibrational frequency calculation.

DFT energies of solution phase species were also calculated in the Gaussian 16 computational package.⁴⁷ All G16 calculated DFT energies include the zero-point vibration energy (ZPVE) and entropic corrections. The B3LYP exchange–correlation functional was used.^{48,49} The basis set used was the 6-311++ G(d,p).^{50,51} Solvation of solution phase species was modeled by using the integral equation formalism variant of the polarizable continuum model (IEPCM).⁵² Water was modeled as the solvent using the default IEPCM parameters.

2.2. Model construction

Energetics from VASP of isolated gas phase molecular species were modeled in a 15 Å periodic cubic unit cell. A 3 × 3 four-layer slab was used to model the BCC Fe (110) metal surface, where the bottom two layers were constrained, and the top two layers were relaxed.⁵³ A 3 × 3 five-layer slab was used to model HCP Ru and Co (0001) metal surfaces, where the bottom three layers were constrained, and the top two layers were relaxed. A 3 × 3 five-layer slab was used to model FCC M (111) metal surfaces (M = Au, Ag, Cu, Pt, Pd, Ir, and Rh), where the bottom three layers were constrained, and the top two layers were relaxed. X/Cu (111) bimetallic surfaces (X = Pd, Ni, Ir, and Rh) are modeled as a 3 × 3 five-layer slab, where the top layer is replaced with X metal. The top two layers undergo surface relaxation while the bottom three layers are frozen. The partially reduced Fe₂O₃ (0001) oxide surfaces were modeled based on previous work by Maheshwari *et al.*⁵⁴ as a 2 × 1 symmetric five layer surface slab, where a stoichiometric Fe_n–O_{3n}–F_n is vertically stacked. Details in the model construction of the partially reduced Fe₂O₃ (0001) surface are further discussed in the study of Maheshwari *et al.*⁵⁴

A 5 × 5 × 1 Monkhorst pack grid was used for most late transition-metal surfaces to sample the Brillouin zone.^{55,56} A 11 × 11 × 1 Monkhorst pack grid was used for the Au (111) surface. A 3 × 5 × 1 *k*-point mesh grid was used for all Fe₂O₃ (0001) surfaces.

2.3. Calculating potential dependent reaction energetics

Potential dependent DFT reaction energetics of TNT intermediates are calculated based on a similar procedure we used to previously study the electrocatalytic reduction of nitrobenzene (C₆H₅NO₂(aq)). The electrochemical reaction to

reduce TNT ($C_7H_5N_3O_6(aq)$) to any reduced intermediate is written in eqn (1):

where n is the number of coupled proton–electron pairs transferred ($n = 0$ –18), m is the number of uncoupled electrons transferred ($m = -1, 0, 1$), and $y = 2x + n - 12$ by stoichiometry. Reduced anion intermediates are specified as $m = 1$ (addition of one valence electron) and reduced cation species are specified as $m = -1$ (depletion of one valence electron). The Gibbs free energy change associated with the reaction in eqn (1), ΔG_{red} , is given as

$$\Delta G_{\text{red}} = G_A + (6 - x)G_{H_2O} - G_{\text{TNT}} - nG_{H^+ + e^-} - mG_{e^-} \quad (2)$$

where G_A , G_{H_2O} , G_{TNT} , $G_{H^+ + e^-}$, and G_{e^-} are, respectively, the Gibbs free energy of the reduced intermediate, H_2O , TNT, proton–electron pair, and the electron.

The computational hydrogen electrode approach (CHE) was used to approximate the free energy of the coupled proton–electron pair using the free energy of hydrogen gas.⁵⁷ By equating the chemical potential of half of a hydrogen molecule to the proton–electron pair and adding a linear electron energy correction relative to the reversible hydrogen electrode (RHE), the free energy of the coupled proton–electron pair is:

$$G_{H^+ + e^-} = \frac{1}{2}G_{H_2} - |e^-|U_{\text{RHE}} \quad (3)$$

where G_{H_2} , $|e^-|$, and U_{RHE} are respectively the free energy of molecular hydrogen, the elementary charge of the electron, and the electrode potential on the RHE scale.

The free energy of the uncoupled electron was approximated by the dependence of the electron on the applied electrode potential referenced on the normal hydrogen electrode (NHE) scale:

$$G_{e^-}(U_{\text{NHE}}) = -|e^-|U_{\text{NHE}} - |e^-|\Delta U_{\text{abs}} \quad (4)$$

where U_{NHE} and ΔU_{abs} are the electrode potential and absolute potential relative to the NHE reference. ΔU_{abs} is typically within 4.4 to 4.8 V-NHE, where 4.6 is often used.⁵⁸ In this study, ΔU_{abs} was set to 4.281 V to allow for direct comparison with the reaction energetics calculated in Chua *et al.* for TNT outer-sphere electrochemical reduction.¹⁹ The potential dependent free energy to form any reduced TNT intermediate in the solution phase on a NHE scale is calculated by combining eqn (2), (3) and (4) as

$$\Delta G_{\text{red}} = G_A + (6 - x)G_{H_2O} - G_{\text{TNT}} - \frac{n}{2}G_{H_2} + n|e^-|U_{\text{NHE}} + m|e^-|U_{\text{NHE}} + m|e^-|\Delta U_{\text{abs}} \quad (5)$$

eqn (5) allows for the construction of reaction free energy diagrams for the outer-sphere reduction of TNT as a function of the electrode potential on a NHE scale at pH = 0.

Surface catalyzed reaction energetics of TNT electrochemical reduction are calculated by modifying eqn (5)

$$\Delta G_{\text{red}} = G_{A^*} + (6 - x)G_{H_2O} - G_{\text{TNT}} - G_* - \frac{n}{2}G_{H_2} + n|e^-|U_{\text{RHE}} \quad (6)$$

where G_{A^*} and G_* are the solvated surface bound species and the solvated bare metal surface. The free energy change to form surface reduction intermediates is referenced to the pH independent RHE scale since all electron transfers are assumed to be coupled with proton transfer during surface catalyzed reactions.

Free energies of reduction intermediates (A), either in the solution phase or bound to the metal surface (A^*) were calculated as

$$G_A = E_A^{\text{DFT}} + E_A^{\text{ZPVE}} - TS_A^{\text{Vib}} \quad (7)$$

where E_A^{DFT} , E_A^{ZPVE} , and TS_A^{Vib} are respectively the solvated DFT energy at 0 K, the zero-point vibration energy, and the vibrational entropic correction at 300 K. The free energy of $H_2O_{(l)}$ and $H_2(g)$ were respectively determined by using the ideal gas approximation and statistical mechanical corrections at 0.03 atm (the vapor pressure of water at room temperature) and 1 atm for $H_2(g)$.¹³

Adsorption energies for surface bound species were defined by the standard definition as

$$\Delta E_{\text{Adsorption}} = E_{\text{species}^*} - E_{\text{species (aq)}} - E_* \quad (8)$$

where E_{species^*} , $E_{\text{species (aq)}}$, and E_* are respectively the energy of the solvated surface bound species on the metal surface, the species in solution, and the solvated bare metal surface. The exception to eqn (8) is calculating the binding energy of O^* across metal surfaces

$$\Delta E_{O^*\text{binding}} = E_{O^*} - \frac{1}{2}E_{O_2(g)} - E_* \quad (9)$$

where E_{O^*} and $E_{O_2(g)}$ are respectively the energy of surface-bound O^* and O_2 in the gas phase.

2.4. Potential dependent activation barriers

Surface bound TNT intermediates are reduced by approximating that a surface adsorbed proton (H^*) species is along the reduction reaction path. Eqn (10) denotes the initial reduction of TNT by H^* as an example, where N–O bond dissociation occurs upon reduction:

Activation barriers calculated for eqn (10) are referenced to the equilibrium potential of H^* (U_0) on the respective metal surface. The potential of H^* adsorption occurs at different (U_0) across metal surfaces and a Butler–Volmer treatment was implemented to correct the potential dependent activation barrier to 0 V-RHE for comparison across metals.⁵⁸

$$\Delta G_{\text{TS}}(U) = \Delta G_{\text{TS}}(U_0) + \beta(U - U_0) \quad (11)$$

$\Delta G_{TS}(U)$ is the free energy barrier of the transition state at a desired potential, $\Delta G_{TS}(U_0)$ is the free energy barrier at the equilibrium potential of H^* on the metal surface, β is the symmetry factor, U is the desired potential, and U_0 is the equilibrium potential of H^* adsorption on the metal surface. Symmetry factors range from 0.3 to 0.7. A common beta value of 0.5 was used to approximate all calculated potential dependent barriers. Reported values and methods for calculating the equilibrium potential values of H^* on the Fe (110), Cu (111), Pt (111) and Au (111) surfaces are discussed in Table S23.[†]

3. Results and discussion

3.1. Outer-sphere reduction of TNT

Outer-sphere reduction of TNT is considered through uncoupled and coupled H^+/e^- transfer, requiring the calculation of reaction free energetics of anion and cation species. Calculated solvation energies from the VASP/PBE/VASPSol and G16/B3LYP/IEFPCM are benchmarked with experimentally measured solvation energies for formate (CHO_2^-) and ammonium (NH_4^+) in Section S1.[†] G16/IEFPCM had greater agreement with experimentally measured solvation free energies for both anion and cation species when compared with VASP/VASPSol. Differences in DFT predicted solvation energies between the two codes are due to the implicit solvation treatment of solvent-solute interactions rather than the choice of the exchange-correlation functional. As a result, all outer-sphere reaction energetics from G16/B3LYP/IEFPCM are reported in the main text. The same energetics calculated with VASP/PBE/VASPSol are reported in Section S2.[†] Solvation energies of neutral species from both VASPSol and IEFPCM are very similar, validating that VASP/VASPSol is adequate for examin-

ing the energetics of coupled proton-electron transfers within the surface catalyzed process.

Outer-sphere electrochemical reduction of TNT is initiated by reducing the *ortho* NO_2 group to form 2-amino-4,6-dinitrotoluene ($O-NH_2$ -DNT) or the *para* NO_2 group to form 4-amino-4,6-dinitrotoluene ($P-NH_2$ -DNT). The reaction free energy diagram for outer-sphere reduction of the *ortho* NO_2 group of TNT to $O-NH_2$ -DNT at 0 V-NHE and pH = 0 is shown in Fig. 1. Optimized structures of reduced intermediates for the reduction of TNT to $O-NH_2$ -DNT are shown in Fig. S1.[†] The equilibrium potential for the reduction of the TNT to $O-NH_2$ -DNT is 0.76 V-NHE, such that the overall reduction reaction is thermodynamically favorable at 0 V-NHE. Both uncoupled and concerted proton-electron transfer are considered to reduce TNT through the outer-sphere mechanism.

We first consider reduction of TNT initiated by initial electron transfer. TNT (NO_2 -DNT) is reduced to TNT^- (NO_2 -DNT⁻) anion species by initial electron addition, with an uphill reaction energy of 0.24 eV at 0 V-NHE. This initial addition of the electron on TNT could limit the rate for reduction of the first NO_2 group. The TNT^- anion species continues along the reduction path through protonation to $NOOH$ -DNT species with a downhill energy of -0.01 eV at 0 V-NHE and pH = 0.

NO_2 reduction can be, alternatively, initiated by proton addition to form the $NOOH^+$ -DNT cation species, resulting in a free energy change of 1.84 eV at pH = 0. The free energy change to undergo initial uncoupled proton transfer is significantly more uphill, indicating TNT initial reduction is likely to first proceed through uncoupled electron transfer or coupled proton-electron transfer.

Electron addition to reduce $NOOH$ -DNT is less favorable than initial reduction of the NO_2 group, with an uphill free energy change of 0.38 eV at 0 V-NHE. Subsequent reduction

Fig. 1 Reaction energy diagram for outer-sphere electrochemical reduction of TNT to $O-NH_2$ -DNT in the solution phase, calculated using the G16 code with the IEFPCM solvation model. Reduction is initiated by reducing the *ortho* NO_2 group of TNT. Energies are relative to TNT in the solution phase at 0 V-NHE and pH = 0. Water molecules formed during the TNT reduction are omitted for clarity purposes. Black lines represent reduction steps initiated by uncoupled electron transfer followed by proton transfer. Blues lines represent reduction steps initiated by uncoupled proton transfer followed by electron transfer. Atom colors are presented as grey: C, white: H, blue: N, and red: O.

steps are generally more favorable once the NOOH-DNT^- species is formed. Protonation of O-NOOH-DNT^- forms a H_2O molecule and O-NO-DNT with a highly favorable reaction energy change of -1.63 eV at 0 V-NHE and $\text{pH} = 0$. This procedure of uncoupled proton-electron transfer is repeated to further reduce O-NO-DNT to $\text{O-NH}_2\text{-DNT}$. The most uphill reaction step is the electron addition to form NHOH-DNT^- with a free energy change of 0.54 eV at 0 V-NHE. Initial reduction of NO_2 , NOOH , and NHOH show similar uphill reaction energies that can limit the overall rate and can be accelerated by an electrocatalyst. Once NHOH-DNT^- is formed, all reduction steps are downhill in free energy to form the $\text{O-NH}_2\text{-DNT}$ species.

Outer-sphere reduction of TNT may proceed through coupled proton-electron transfer that can avoid less favorable decoupled reaction energetics. Considering all steps as coupling proton and electron transfer, the most uphill reaction step of TNT to $\text{O-NH}_2\text{-DNT}$ reduction is the reduction of TNT to O-NOOH-DNT with a free energy of 0.23 eV at 0 V-NHE. Once the O-NOOH-DNT intermediate is formed, all coupled proton-electron transfers are downhill to form $\text{O-NH}_2\text{-DNT}$.

Initial reduction of TNT can be initiated through the *para* NO_2 group to form $\text{P-NH}_2\text{-DNT}$ rather than the *ortho* NO_2 group. Reduction of TNT to $\text{P-NH}_2\text{-DNT}$ is investigated through a similar procedure used to study the reduction of the *ortho* NO_2 group. The reduction of the *para* NO_2 is less favorable than the *ortho* NO_2 group, with electron addition to reduce NHOH-DNT the most uphill step of 0.59 eV at 0 V-NHE. The reduction sequence of each NO_2 group to the NH_2 is qualitatively equivalent between the *ortho* and *para* NO_2 group.

Once either the $\text{P-NH}_2\text{-DNT}$ or the $\text{O-NH}_2\text{-DNT}$ is formed, these NO_2 species can be further reduced to obtain the $12 \text{ H}^+/\text{e}^-$ species of either 4-nitro-2,6-diaminotoluene ($\text{P-NO}_2\text{-DAT}$) or

2-nitro-4,6-diaminotoluene ($\text{O-NO}_2\text{-DAT}$). The reduction of $\text{O-NH}_2\text{-DNT}$ species is first considered to form $\text{P-NO}_2\text{-DAT}$. The reaction energy diagram to reduce $\text{O-NH}_2\text{-DNT}$ to $\text{P-NO}_2\text{-DAT}$ in the solution phase at 0 V-NHE and $\text{pH} = 0$ is shown in Fig. 2.

Reduction energetics of $\text{O-NH}_2\text{-DNT}$ are less favorable than equivalent TNT electroreduction steps. Considering the coupled reduction path, initial NO_2 group reduction of $\text{O-NH}_2\text{-DNT}$ is again the least favorable step. This step is less favorable than initial TNT reduction by 0.25 eV at 0 V-NHE, suggesting higher overpotentials may be needed to drive the reduction of the second NO_2 group. The inability of $\text{O-NH}_2\text{-DNT}$ to delocalize the negative charge across the NO_2 groups makes electron transfer less favorable. The uncoupled reduction pathway is limited by initial NO_2 reduction with an uphill energy of 0.86 eV at $\text{pH} = 0$, indicating that the lack of delocalization of the negative charge by the NO_2 groups could make electron transfer more unfavorable.

Fig. S4[†] shows the reaction energy diagram for the reduction of $\text{P-NO}_2\text{-DAT}$ to TAT calculated with G16, completing the 18 e^- reduction. The first electron transfer or the first coupled proton-electron transfer are again uphill in energy. These steps are progressively less favorable moving from TNT to $\text{O-NH}_2\text{-DNT}$ to $\text{P-NO}_2\text{-DAT}$. Other than becoming less favorable for deeper reductions, the reaction paths for each NO_2 group are equivalent.

Section S2[†] presents VASP optimized geometries and reduction reaction energetics of TNT intermediates, tables of all G16 and VASP energetics for the outer-sphere reduction.

Differences in the DFT predicted reduction potentials to reduce each NO_2 group can rationalize the three experimentally observed TNT reduction peaks from Chua *et al.*¹⁹ Chua *et al.* predicted that the reduction of TNT is limited by

Fig. 2 Reaction energy diagram for outer-sphere electrochemical reduction of $\text{O-NH}_2\text{-DNT}$ to $\text{P-NO}_2\text{-DAT}$ in the solution phase, calculated using the G16 code and IEFPCM solvation model. Reduction proceeds by reducing the second *ortho* NO_2 group to the methyl group of TNT. Energies are relative to $\text{O-NH}_2\text{-DNT}$ in the solution phase at 0 V-NHE and $\text{pH} = 0$. Water molecules formed during the TNT reduction are not shown for clarity purposes. Black lines represent reduction steps initiated by uncoupled electron transfer followed by proton transfer. Blues lines represent reduction steps initiated by uncoupled proton transfer followed by electron transfer. Atom colors are presented as grey: C, white: H, blue: N, and red: O.

Table 2 Reduction potentials of initial coupled proton–electron transfer to reduce the NO_2 group of key TNT intermediates. Reduction of TNT, $\text{O}-\text{NH}_2\text{-DNT}$, and $\text{P}-\text{NO}_2\text{-DAT}$ were considered. Comparison are made with the DFT (Turbomole/PBE/COSMO) and experimental results from Chua *et al.*¹⁹ Computational code, exchange–correlation functional and continuum solvation models are listed. Basis set used for DFT calculations in Turbomole 6.2, and Gaussian 16 are the def2-SVP and 6-311G++ basis sets, respectively

	Reduction potentials of TNT (V-NHE)	Reduction potentials of $\text{O}-\text{NH}_2\text{-DNT}$ (V-NHE)	Reduction potentials of $\text{P}-\text{NO}_2\text{-DAT}$ (V-NHE)
Experimental: GCE	−0.31	−0.475	−0.629
DFT (Turbomole/PBE/COSMO)	−0.108	−0.265	−0.369
DFT(G16/B3LYP/IEFPCM)	−0.23	−0.35	−0.43
DFT (VASP/PBE/VASPSol)	−0.23	−0.51	−0.60

the initial reduction of each NO_2 group through a coupled proton–electron transfer. Table 2 reports the initial coupled proton–electron transfer reaction energy for each progressive NO_2 group, using both the VASP and G16 computational codes with their respective continuum solvation models. Comparisons are made to the reduction potentials observed from Chua *et al.* from their DFT reaction energetics in Turbomole/PBE/COSMO and experimentally observed potentials on the glassy carbon electrode (GCE). The DFT calculations represent the electrode potential at which the reaction step is isoergonic, a rough approximation for comparison with experimental reduction peaks. Experimentally, the peak current density is a complex consequence of reduction reaction kinetics and species transport. Table 2 denotes the reduction potentials required to make each $\text{R}-\text{NO}_2$ electron addition step isoergonic compared to experimental peak potentials on a GCE.

Electron densities of TNT intermediates during initial electron addition are shown in Fig. 3 to rationalize why TNT reduction becomes more unfavorable as each NO_2 is successively reduced.

The electron added to form TNT^- delocalizes over the three NO_2 groups, residing more on the *ortho* NO_2 groups than the *para* NO_2 . Conversion of each successive NO_2 group to NH_2

reduces the delocalization of this charge, leading to less favorable reduction.

The experimental and outer-sphere computational reduction potentials in Table 2 represent a significant overpotential for TNT reduction relative to our DFT-calculated equilibrium potential for TNT to TAT I of 0.70 V-NHE (with G16, 0.72 V-NHE with VASP). An electrocatalyst can potentially accelerate TNT reduction and reduce the large overpotentials by (1) stabilizing the negative charge of adsorbed TNT intermediates to facilitate coupled proton–electron transfer and (2) stabilizing adsorbed intermediates to open alternative reaction paths. Catalytic effects could become more significant as TNT reduction becomes more unfavorable with successive reduction of each NO_2 group.

3.2. Electrocatalytic reduction of TNT on the Fe (110) surface

Adsorption and reduction of TNT on the Fe (110) surface was investigated to study the NO_2 reduction chemistry on a metal surface that exhibits a high oxophilicity. TNT can be initially adsorbed in the “flat configuration”, where the carbon ring is parallel to the surface, or through a “vertical configuration”. Differentiating which configuration would be preferred at an electrode surface is challenging given the convergence of several aspects that are hard to capture in a DFT model. The differential solvation of the solution and surface bound species will impact preferred adsorption configurations and is challenging to represent at the surface. The PBE functional neglects van der Waals (vdW) interactions that could also differ significantly between the two configurations. These vdW interactions could also occur among adsorbates, whereas a single coverage is used neglecting the likely strong coverage dependence on adsorption energies. We, therefore, consider initial adsorption in the “vertical” configuration because this allows the NO_2 group to directly interact with the surface for further reduction. This configuration requires less solvent–surface displacement and is likely preferred at higher adsorbate coverages. Our prior DFT results on nitrobenzene on Fe (110) and Au (111) surfaces predicted that vertical configuration would be preferred over the flat configuration at higher surface coverages. Preferred adsorption configurations of TNT on the Fe (110) surface in the vertical and flat adsorption configuration are shown in Section S3.†

The initial reduction of TNT is first investigated through the adsorption and reduction of the *ortho* NO_2 group and in the vertical configuration. The reaction energy diagram of the electrocatalytic reduction of TNT to $\text{O}-\text{NH}_2\text{-DNT}^-$ on the Fe (110) surface at 0 V-RHE is shown in Fig. 4. Optimized geometries of reduced intermediates during the reduction of TNT to $\text{O}-\text{NH}_2\text{-DNT}^-$ on the Fe (110) surface are shown in Section S3.†

Reduction is initiated by favorable adsorption of TNT on the Fe (110) surface with an adsorption energy of −1.57 eV. The Fe (110) surface is active for the initial reduction of the $\text{NO}_2\text{-DNT}^*$ to $\text{O}-\text{NO-DNT}^* + \text{OH}^*$, resulting in the spontaneous N–O dissociation during geometry optimization and a reaction energy of −2.33 eV at 0 V-RHE. The transition state for $\text{R}-\text{NO}_2 + \text{H}^*$ to $\text{R}-\text{NOOH}$ was found to have a free energy barrier of 0.01

Fig. 3 Isodensity surface for electron in the highest occupied molecular orbital (HOMO) for TNT^- , $\text{O}-\text{NH}_2\text{-DNT}^-$, and $\text{P}-\text{NO}_2\text{-DAT}^-$ anion species. Atom colors are presented as brown: C, white: H, blue: N, and red: O. A consistent isosurface level value (approximately 0.003) was used to construct the isodensity surfaces.

Fig. 4 Reaction energy diagram for electrocatalytic reduction of TNT to O-NH₂-DNT on the Fe (110) surface at 0 V-RHE. Energies are relative to the bare solvated surface and TNT in the solution phase. TNT reduction is initiated through the vertical adsorption configuration and the *ortho* NO₂ group. Most stable configurations of intermediates are used to construct the reaction energy diagram. Water molecules formed during the reduction of TNT are not depicted for clarity. The transition state for TNT* to O-NO-DNT* + OH* is not depicted as this step was determined to be barrierless. Atom colors are presented as the following: brown = Fe, grey = C, white = H, blue = N, and red = O.

eV at $U = 0.66$ V-RHE, suggesting this step is barrierless at reducing overpotentials. Thus, the Fe (110) surface is predicted to accelerate the initial reduction step of the NO₂ group compared to the non-catalyzed mechanism.

Though the Fe (110) surface accelerates initial TNT reduction, it is limited by the unfavorable reduction of strongly bound O* and OH* intermediates. Reduction of OH* to H₂O(l) is unfavorable with a reaction free energy of 0.76 eV at 0 V-RHE, requiring a highly reductive overpotential to reduce OH* off the surface. Reduction of O-NO-DNT* proceeds favorably to O-NH-DNT* + O* due to the spontaneous N-O bond dissociation observed. This reaction step results in a free energy of -2.17 eV at 0 V-RHE. O-NH-DNT* is further reduced to form O-NH₂-DNT (aq), which is an isoergonic reaction. O* is finally reduced to OH* then to H₂O (l), resulting in respective free energy changes of 0.16 eV and 0.76 eV at 0 V-RHE.

Though the Fe (110) surface is predicted to accelerate the initial reduction of TNT, TNT reduction on the Fe (110) is limited by the reduction OH* with a free energy change of 0.76 eV. The Fe (110) surface is predicted to bind surface hydroxyl too strongly, blocking the surface as the reduction of these intermediates limits the overall reaction. Thus, the Fe (110) surface would not be an ideal electrocatalyst, binding intermediates too strongly.

Reduction beginning from the flat adsorption configuration as well as beginning with the *para* NO₂ group are reported and discussed in Section S3† and show qualitatively similar results.

Once the first NO₂ group is reduced, O-NH₂-DNT (aq) can adsorb on the Fe (110) surface either through the *para* NO₂ group to reduce to O-NO₂-DAT or the *ortho* NO₂ group to reduce to P-NO₂-DAT. Reaction free energy diagrams and optimized geometries for intermediates on the Fe (110) surface are

shown in Section S3.† Unlike the outer-sphere process, the reaction energies required to reduce each NO₂ group of TNT to TAT are similar as the reaction proceeds, suggesting inner-sphere catalysis may avoid the need for successively larger overpotentials to reduce each NO₂ group. However, we conclude the highly oxophilic Fe catalyst would be limited by OH* reduction in the potential range where TNT reduction is desired.

We next consider reduction catalyzed by the less oxophilic Au (111) surface, and we later return to consider whether oxidized forms of Fe could serve as an active TNT electroreduction catalyst.

3.3. Electrocatalytic reduction of TNT on the Au (111) surface

Adsorption and reduction of TNT was investigated on the Au (111) surface to compare elementary reduction energetics on a metal surface that exhibits weak binding of O*. The optimized adsorption configuration of TNT in the vertical and flat configurations are shown in Section S4.† Adsorption of TNT is much weaker on the Au (111) surface than the Fe (110) surface; calculated adsorption energies on the Au (111) surface in the vertical and flat configuration are -0.19 eV and -0.34 eV, respectively. Weaker adsorption of TNT will result in slower initial activation of the NO₂ groups, thus limiting the activity of the Au (111) surface towards TNT reduction. Similar to the Fe (110) surface, reduction from the vertical adsorption configuration of the NO₂ group was initially investigated. The reaction energy diagram of the electrocatalytic reduction of TNT to O-NH₂-DNT on the Au (111) surface is shown in Fig. 5.

Initial reduction of TNT results in the formation of O-NO-DNT* + OH* on the Au (111) surface, which is more stable than O-NOOH-DNT*. Unlike the Fe (110) surface, the

Fig. 5 Reaction energy diagram for electrocatalytic reduction of TNT to $O\text{-NH}_2\text{-DNT}$ on the Au (111) surface at 0 V-RHE. Energies are relative to the bare solvated surface and TNT in the solution phase. TNT reduction is initiated through the *ortho* NO_2 group in the vertical adsorption configuration. Water molecules formed during the reduction process are not listed on the diagram for clarity. Most stable configurations of reduced intermediates are used to construct the reaction energy diagram. Black lines represent free energies of stable TNT intermediates. Blue lines represent the transition state during TNT reduction. Atom colors are presented as following: yellow = Au, grey = C, white = H, blue = N, and red = O.

reduction of the first NO_2 group of TNT on the Au (111) surface to form co-adsorbed $O\text{-NO-DNT}^*$ + OH^* occurs over a high energy barrier. The activation barrier and reaction free energy for this reaction step at 0 V-RHE is 1.35 eV and 0.70 eV, respectively. The Au (111) surface would not be an optimal TNT electrocatalyst, as it is predicted to be relatively inactive towards $\text{NO}_2\text{-R}$ reduction. Once $O\text{-NO-DNT}^*$ is formed, all subsequent reduction steps at 0 V-RHE proceed downhill to form $O\text{-NH}_2\text{-DNT}$ (aq) and H_2O (l), including favorable reduction of surface adsorbed O^* and OH^* species.

In contrast to the Fe (110) surface, the activity of the Au (111) surface is limited by the initial NO_2 reduction due to the high activation barrier and unfavorable reaction energy. When comparing TNT reduction on the Au (111) surface with the outer-sphere reduction mechanism, it is unlikely that Au (111) would accelerate the TNT reduction due to the significant reductive potential required (-0.70 V-RHE) to overcome the initial reduction of the first NO_2 group.

Structures and reaction energetics of all reduction intermediates for initial reduction in the flat configuration as well as the *para* NO_2 group are included in Section S4.†

3.4. Comparing outer-sphere TNT reduction vs. inner-sphere on Au (111) and Fe (110)

The activity of surfaces to reduce TNT is approximated by determining the limiting potential, the potential for $\Delta G_{\text{red}} \leq 0$ for all reduction reactions. Limiting potentials required to reduce TNT to TAT on the Fe (110) and Au (111) surface are summarized in Fig. 6. The reduction of TNT to TAT is considered to proceed through the $O\text{-NH}_2\text{-DNT}$ and $P\text{-NO}_2\text{-DAT}$ intermediates. Fig. 6 compares these surface energetics with the outer-sphere energetics from Table 2.

Fig. 6 Comparison of DFT predicted TNT limiting potentials for outer-sphere and inner-sphere reduction. Limiting potentials are computed for the reduction of TNT to $O\text{-NH}_2\text{-DNT}$ then to $P\text{-NO}_2\text{-DAT}$. Outer-sphere limiting potentials are calculated in G16/B3LYP/IEFPCM for coupled proton-electron transfer to reduce each NO_2 group. All reduction potentials are referred to the RHE scale. Atom colors are as follow: C = grey, N = blue, O = red, H = white.

TNT reduction in the solution phase is potentially competitive for the reduction of the first NO_2 group with the Fe (110) and Au (111) surfaces, suggesting neither of these will successfully serve as electrocatalysts for this reaction. The TNT outer-sphere reduction is competitive with the inner-sphere reduction on Fe (110) and Au (111), contrasting our prior analysis of nitrobenzene reduction. We emphasize that our DFT

analysis has limitations due to the mainly thermodynamic nature in calculating the reaction energetics and our approximation of the electrode–electrolyte interface. Despite these limitations, the DFT energetics are in line with experimental observation that TNT electroreduction occurs at overpotentials of 1 V or more, and the reduction peak positions appear to be independent of electrode composition among the electrodes tested.

We hypothesize that surfaces with intermediate O* binding might better accelerate TNT electroreduction, relative to the Fe (110) surface binding O*/OH* too strongly, and Au (111) surface being limited by weak bonding and activation of the NO₂ group in TNT.

3.5. Electrocatalytic reduction of TNT on late transition-metal surfaces

The Fe (110) and Au (111) surfaces are predicted to not accelerate TNT reduction when compared to the outer-sphere reduction process. However, these surfaces illustrate activity tradeoffs that can be used to screen late transition metal surfaces. O* binds too strongly on the Fe (110) surface and the activity of the surface is limited by the desorption of strongly bound OH*. In contrast, O* binds too weakly on the Au (111) surface, where initial activation of the NO₂ group is unfavorable. The two limiting reduction processes, NO₂-R* to NO-R* + OH* and OH* to H₂O (l), are expected to inversely correlate with the strength of O* binding. A similar trend is observed in our previous study for the electrocatalytic reduction of nitrobenzene.³⁰ Our prior work predicted that late transition-metal surfaces that exhibit intermediate O* affinity balance these activity tradeoffs, thus exhibiting higher activity towards nitrobenzene reduction.

Late transition metal surfaces are screened as potential TNT electrocatalysts using O* binding as a descriptor. A correlation is established between the reaction energies for the two key elementary steps and O* binding strength, using monometallic surfaces. The investigation is then extended to bimetallics (X/Cu (111) skin alloy surfaces) in section 3.5.1. Lastly, par-

tially reduced Fe₂O₃ (0001) oxide surfaces, with and without Ni doping, are considered, emphasizing whether these surfaces can deviate from the scaling relationship between O* binding and key reaction energetics to possibly enable TNT electroreduction at lower overpotentials.

The initial reduction of TNT to O-NO-DNT is evaluated across M late transition-metal surfaces (M = Ag (111), Cu (111), Pd (111), Pt (111), Ir (111), Rh (111), Ni (111), Ru (0001), and Co (0001)), recognizing that subsequent inner-sphere reduction energetics of the other NO₂ groups were similar on Fe (110) and Au (111) surfaces. To accelerate the screening of metal surfaces, Brønsted–Evans–Polanyi (BEP) plots were constructed to correlate activation barriers and reaction energetics for the initial TNT reduction step. Activation barriers of O-NO₂-DNT* to O-NO-DNT* at 0 V-RHE were calculated on the Fe (110), Cu (111), Pt (111), and Au (111) surfaces. Fig. 7 presents these activation barriers plotted against both the reaction energetic of the same step and the binding strength of O* on the metal.

Fig. 7a shows a strong correlation between the activation barrier and reaction energy for the initial TNT reduction elementary step. This allows us to expedite the screening of M late transition-metal surfaces by calculating reaction energies of NO₂-R* to NO-R* + OH*. Fig. 7b shows that stronger binding of O on the metal surface correlates directly with lower activation barriers for this same step. Metal surfaces that have a strong affinity towards O*, such as the Fe (110) surface, exhibit a lower activation barrier towards activating the NO₂ group. Previous DFT studies have shown that the activation barriers for OH* to H₂O (aq) correlate strongly with the reaction energy on late transition-metal surfaces.^{57,59}

Fig. 8 shows the correlation of the key step reaction energies with O* binding across monometallic and bimetallic surfaces.

A qualitative “volcano-tradeoff” is established with the O* binding energy. Fig. 8a shows that metal surfaces with stronger O* affinity are more active in initially reducing the NO₂ group. Fig. 8b shows that reduction of OH* to H₂O (aq) becomes more unfavorable as the binding of O* becomes stronger. As

Fig. 7 Brønsted–Evans–Polanyi relationship of (a) initial reduction of TNT plots the activation barriers (ΔG_{TS}) versus the reaction energy (ΔG_{red}) for the reduction of TNT^* to $\text{O-NO-DNT}^* + \text{OH}^*$ at 0 V-RHE on the Fe (110), Cu (111), Pt (111), and Au (111) metal surfaces. (b) Correlation of the activation barriers for the reduction of TNT^* to $\text{O-NO-DNT}^* + \text{OH}^*$ with the binding energy of O (E_{O^*}) on the Fe (110), Cu (111), Pt (111), and Au (111) metal surfaces. Optimized geometries of transition states are shown on the (a) Pt (111) and (b) Cu (111) surfaces as insets. Atom colors are presented as silver: Pt, orange: Cu, grey: C, white: H, blue: N, and red: O.

Fig. 8 Correlation between O binding strength and reaction energetics of (a) O-NO₂-DNT* to O-NO₂-DNT* + OH* and (b) OH* to H₂O (l) at 0 V-RHE. The following surfaces are represented as black circles: monometallic M late transition-metal surfaces, blue diamonds: X/Cu (111) bimetallic surfaces, and purple triangles: partially reduced Fe₂O₃ (0001) surfaces. Optimized structures of initial and final reaction states on the Pt (111) surface are shown. Atom colors are presented as: light grey: Pt, dark grey: C, white: H, blue: N, and red: O.

the O* binding energy on close-packed surfaces is well-established to correlate with the surface d-band center,⁶⁰ connecting TNT reduction catalysis to O* binding also connects catalyst optimization to selection of a surface offering an optimal d-band center. Optimized structures and tables of values used to construct Fig. 8 are presented in Table S24 and Fig. S27.†

Since our DFT model approximates the electrochemical interface, we can only approximate an optimal O binding energy that might correlate with the “peak” of the volcano plot with DFT alone. A more detailed coupling of experimental and microkinetic analysis would be needed to more precisely locate a peak. However, the qualitative volcano relationship presented can be utilized for experimental guidance to tune monometallic or bimetallic late transition-metal surfaces to an intermediate O* affinity, which are predicted to balance both activity tradeoff reactions. The limiting potential of each metal surface is determined to predict the theoretical overpotential required to reduce TNT and to compare the relative activity of each late transition-metal surface.⁵⁷ A plot of the limiting potentials plotted against the binding energy of O across late transition-metal surfaces is shown in Fig. 9.

Metal surfaces that exhibit more positive limiting potentials are predicted to require a lower overpotential to reduce TNT to O-NO₂-DNT, and thus have higher relative activity. Weak O* affinity monometallic metal surfaces, such as the Au (111) and Ag (111) surfaces, exhibit a lower limiting potential and are predicted to require a larger overpotential to activate the NO₂ group. Late transition-metal surfaces with strong O* affinity, such as Fe (110) and Co (0001) surfaces, require larger overpotentials to reduce strongly bounded intermediates that inhibit their overall activity. A peak in our limiting potential plot represents optimal monometallic metal surfaces in the active range for TNT reduction due to their intermediate binding of

Fig. 9 Limiting potential analysis for the reduction of TNT to O-NO₂-DNT. DFT predicted limiting potentials are plotted against the binding energy of O across different metal surfaces. Dashed black lines represent the limiting potential dictated by the reduction of NO₂-R* to NO-R* + OH* for monometallic late transition-metal surfaces. Dashed grey lines represent the limiting potential dictated by the reduction of OH* to H₂O (l) for monometallic late transition-metal surfaces. The following surfaces are represented as black circles: monometallic M late transition-metal surfaces and blue diamonds: X/Cu (111) bimetallic surfaces. The active range is defined as binding energies within 1 eV stronger than the Pt (111) surface.

O*. These monometallic surfaces, such as Pt (111), Pd (111), Cu (111), and Ir (111) surfaces, are predicted to accelerate the inner-sphere reduction of TNT.

We emphasize that Fig. 9 is useful for qualitative comparison for monometallic surfaces and their relative activity. However, values of DFT predicted binding of O* and limiting potentials can shift due different approximations within our model to capture the electrode–electrolyte environment. There are several limitations within our models when modeling elec-

trocatalysis. (1) A relative permittivity value of 78.4 for bulk water is used in the DFT solvation model, which is likely not representative of interfacial water near the electrode (values of 2 to 9 have been reported^{61,62}), (2) displacement of explicit H₂O molecules upon TNT adsorption, which VASPSol does not capture, is not considered.⁶³ (3) VASPSol implicit solvation approximates that solvation energies are nearly identical across metal surfaces while hybrid DFT/molecular dynamic approaches states that solvation is strongly dependent on the metal identity.⁶⁴ (4) More complex EDL effects including ion/electric field distribution could impact stability of surface bound intermediate species differently across metals. For instance, McCrum *et al.* showed that the modeling of OH* adsorption on different facets of the Pt are sensitive to the choices of how solvation and coverage are modeled, resulting in differences in OH* adsorption potential by 0.6 V-NHE on the Pt (111) surface.⁶⁵ Zhang *et al.* recently observed sensitivity of resulting oxygen reduction reaction (ORR) volcano plots to how solvation was modeled (implicitly, explicitly, and with a bilayer solvation correction) on late transition metal (111) surfaces.⁶⁶ If our current model is underestimating the effects of solvation on OH adsorption, this affects the ΔG of OH* to H₂O (l) and NO₂-R* to NO-R* and OH*, which could shift the peak of the volcano plot and its optimal O* binding towards weaker O* binding metals such as the Ag (111) surface. Fig. 9 can be used to qualitatively assess the relative activities of late transition-metal surfaces. We suggest additional controlled experimental studies that compare GCE with late transition-metal electrodes that exhibit varying degrees of O* affinity (Fe (110), Cu (111), and Au (111) surfaces) to determine whether the “volcano relationship” and activity trends hold.

3.5.1. Electrocatalytic reduction of TNT on bimetallic surfaces. Bimetallic electrodes have shown promise for electrocatalytic reduction of O₂, N₂, and CO₂.^{67–71} Skin layer X/Cu (111) surfaces (X = Pd, Pt, Ni, Ir, and Rh) are used to investigate the relative activity of bimetallic surfaces as TNT reduction electrocatalysts and whether the bimetallics follow similar “volcano-tradeoffs” observed for the monometallic surfaces. Fig. 8 shows that the X/Cu (111) bimetallic surfaces (blue diamonds) qualitatively follow the same inverse correlation between the key elementary reaction energetics and binding strength of O* as the monometallic surfaces (black circles). The limiting potentials of X/Cu (111) metal alloy surfaces are included in Fig. 9, with a number of these surfaces potentially in the range of optimal O* binding.

As the O* binding energy is serving as a reasonable descriptor of limiting potential, previously published values can be used to computationally screen potential TNT electroreduction catalysts. The binding energy of O for 736 different metal surface alloys are reported by Greeley *et al.*⁷² Table S25† reports 210 of the 736 surfaces with O* binding energies in the active range for TNT reduction. 107 of these 210 surfaces are composed of the four recommended (111) monometallic surfaces (Pt, Pd, Cu, and/or Ir). Bimetallic surfaces containing Ag, Au, Ni, Rh, and/or Ru also appear in the active range for TNT reduction, suggesting that these surface alloys may be more

active than their monometallic counterparts. Bimetallics that include metals we did not consider, such as Bi, Cd, Sb, and/or As also appear in the active range. Collectively, we have highlighted several monometallic and bimetallic surfaces that could show improved TNT electroreduction catalysis relative to those previously studied experimentally.

3.5.2. Electrocatalytic reduction of TNT on partially reduced Fe₂O₃ (0001) surfaces. Non-precious iron oxide surfaces are considered as TNT electroreduction catalysts due to their abundance and potential to deviate from scaling relationships defined from monometallics.^{73,74} Fig. 8b suggest that pure metal surfaces with strong binding of O* (Fe (110), Co (0001), and Ru (0001)) will be limited by the reduction of OH* to H₂O (l), suggesting that these surfaces may oxidize and be present in the form of an oxide or hydroxide surface at TNT reduction conditions. Previous studies have reported the use of metal oxide surfaces (Fe, Co, Ni, Cu Mo, and W) for reduction catalysis including for the hydrogen evolution reaction (HER), ORR, N₂ reduction, and CO₂ reduction.^{75–79}

The (0001) surface of hematite, α -Fe₂O₃, is investigated as a potential TNT electroreduction catalyst. Iron oxide has been utilized as an electrocatalyst for N₂ reduction and solar water splitting.^{22,80,81} A previous DFT study by Maheswari *et al.* investigated the stability of different partially reduced terminations of the Fe₂O₃ (0001) surface at reducing potentials by generating a surface Pourbaix diagram.⁵⁴ Partially reduced terminations are predicted to be stable at potentials below 0 V-RHE, where the bulk remains Fe₂O₃ (0001). The H-Fe-Fe-O₂-Fe-R partially reduced termination (partially reduced Fe₂O₃ (0001) surface) was selected to study as a possible TNT reducing surface due to its predicted stability in more negative reducing potentials on the surface Pourbaix diagram.

Ni-Fe oxides are well known as stable oxidation electrocatalysts for the oxygen evolution reaction (OER).^{82–84} Though the stability of these Ni-doped Fe₂O₃ (0001) structures at reducing potentials are not established, doping of Ni on the partially reduced Fe₂O₃ (0001) surface (Ni/Fe₂O₃ (0001) surface) was investigated to explore if Ni-doping could further increase the activity for TNT reduction, and to examine whether such doping would follow the same “volcano tradeoffs” observed for bimetallic surfaces. Ni doping was considered by substituting a surface Fe atom with an Ni atom. Fig. S29 and S30† depicts the surface model and the most stable adsorption configuration of TNT on the partially reduced Fe₂O₃ (0001) and Ni/Fe₂O₃ (0001) surfaces.

The key elementary reaction energies for TNT reduction on the partially reduced Fe₂O₃ (0001) and Ni/Fe₂O₃ surface are included in Fig. 8. Both oxide surfaces deviate from scaling relationships defined for monometallics. The Fe₂O₃ (0001) surface exhibits strong binding of O* with binding energy of -5.19 eV, weaker than Fe (110) by 0.38 eV. However, the Fe₂O₃ (0001) surface is predicted to be inactive towards reduction of the NO₂ group, with a free energy change of 1.54 eV, which significantly deviates from the activity trends predicted from monometallics. The Ni/Fe₂O₃ (0001) surface also deviates from scaling relationships derived in section 3.5. Substitution of

one surface Fe atom with Ni weakens O* binding by 0.21 eV. However, the Ni/Fe₂O₃ (0001) surface is more active towards activating the NO₂ group. The Ni/Fe₂O₃ (0001) surface is predicted to be less favorable towards OH* reduction than the undoped surface, despite weaker binding of O*.

The Fe₂O₃ and Ni-doped Fe₂O₃ (0001) surfaces have potential to deviate from scaling relationships derived from monometallics and expand the design space for electrocatalysts for TNT reduction. It is not especially surprising that correlations between O* binding and TNT reduction energetics among close-packed late transition metals do not directly apply on the oxide surfaces. TNT, O-NO-DNT, and OH adsorbates interact with more localized states on the oxide surface than the delocalized d-band of the extended metals, and adsorption geometries (see Fig. S30†) also differ on the oxides. We recommend further investigation of the activity and stability of these Ni doped Fe₂O₃ (0001) surfaces to fully assess these surfaces as TNT reduction electrocatalysts. A more extensive investigation on other oxophilic metals that may be stable oxides at TNT reduction conditions, such as Cu and Ni based oxides, would be beneficial in the search for reduction electrocatalyst candidates.^{85–88}

4. Conclusions

This study utilized DFT methods to investigate the elementary step mechanisms for TNT electrochemical reduction in the solution phase and across different late transition metal surfaces. Outer sphere reduction energetics suggests that the non-catalyzed TNT reduction pathway is much more competitive with inner sphere mechanism on Fe (110) and Au (111) surfaces than our prior work on nitrobenzene. Overall activity for monometallic and bimetallic surfaces is dictated by a trade-off in initial activation of the NO₂ group and reducing OH*. Though our DFT analysis is mainly thermodynamic focused, both monometallic and bimetallics are recommended that may accelerate the activity of TNT electroreduction. Results on partially Fe₂O₃ (0001) surfaces suggest that oxides may not follow the same scaling relationships. We suggest further exploration of both the activity of oxide surfaces and bimetallic surfaces in reducing conditions as catalysts for TNT electroreduction.
