Human mini-brains for reconstituting central nervous system disorders

You Jung Kang,[ab] Yingqi Xue,[ab] Jae Hee Shin[ab] and Hansang Cho *[abc]

Neurological disorders in the central nervous system (CNS) are progressive and irreversible diseases leading to devastating impacts on patients' life as they cause cognitive impairment, dementia, and even loss of essential body functions. The development of effective medicines curing CNS disorders is, however, one of the most ambitious challenges due to the extremely complex functions and structures of the human brain. In this regard, there are unmet needs to develop simplified but physiopathologically-relevant brain models. Recent advances in the microfluidic techniques allow multicellular culture forming miniaturized 3D human brains by aligning parts of brain regions with specific cells serving suitable functions. In this review, we overview designs and strategies of microfluidics-based human mini-brains for reconstituting CNS disorders, particularly Alzheimer's disease (AD), Parkinson's disease (PD), traumatic brain injury (TBI), vascular dementia (VD), and environmental risk factor-driven dementia (ERFD). Afterward, the applications of the mini-brains in the area of medical science are introduced in terms of the clarification of pathogenic mechanisms and identification of promising biomarkers. We also present expanded model systems ranging from the CNS to CNS-connecting organ axes to study the entry pathways of pathological risk factors into the brain. Lastly, the advantages and potential challenges of current model systems are addressed with future perspectives.

1. Introduction

Central nervous system (CNS) diseases are progressive and irreversible disorders, majorly found in the elderly, leading to cognitive impairment, dementia, or even loss of essential body functions.[1] Such CNS disorders involve neurodegenerative conditions (Alzheimer's disease (AD), Parkinson's disease (PD)), structural impairment (traumatic brain injury, vascular dementia), and environmental factor-driven dementia.[1–6] Given the fact that an aging population becomes dominant in the world, there are high demands on the development of new pharmaceutics targeting neurological disorders.[7] The market for the therapeutics was valued at $80 billion in 2021 and is expected to reach 125 billion by 2029.[7] Despite the efforts for the development of cures rewinding such progressive neurodegeneration, no successful clinical outcome has been accomplished compared to other therapeutic areas.[8,9] The complexity of the human brain, attributed to the interconnected cross-talks among the hundreds of different neural cells, makes it extremely difficult to identify novel therapeutic targets expressed in specific cells.[4,10] To decipher the comprehensive pathogenesis in the brain, a number of *in vitro* and *in vivo* models representing CNS disorders have been developed.

Current *in vitro* models for CNS diseases highly rely on the simple 2D culture of neuronal cells expressing rare familial mutations found in the specific disease. To develop *in vitro* AD models, for instance, overexpression of genes associated with familiar AD (FAD) in neural cells or neuroprogenitor cells is the most popular method.[11] However, the major drawback of 2D culture is that the monolayer of single- or co-cultured models could alter cellular morphology and polarity as well as local concentration of soluble factors, chaining key cellular responses in disease progression.[12] In addition, these models do not involve the immune system, which plays significant roles in the pathology of CNS disorders.[13–15] Alternatively, *in vivo* transgenic mice with mutations in Aβ precursor protein (APP) and/or presenilin (PS) have been gold-standard AD models, which recapitulate not only AD features such as amyloidosis and tauopathy but also innate immunity.[11] Since such animal models mimicking human CNS diseases are founded with rare familial forms, other aspects attributed to non-familiar cases are not established yet. Even if the transgenic animal models could reflect damaged human brain structures and reactive innate immunity found in CNS disorders, there is some discrepancy in the pathology due to the different genetic backgrounds.[16] To overcome these

issues, human multicellular organoids have been suggested and employed to study CNS disorders.[17]

Among the human multicellular organoids, a brain-on-a-chip, in which neural cells along with other glial cells around neurons are co-cultured together, has been a representative CNS disease model.[17,18] Microfluidics, initially employed for handling liquid dynamics, is now advantageous for cell culture due to its ability to supply continuous nutrient and remove waste.[17] Furthermore, it enables the formation of stable gradients for soluble factors from cell-to-cell or cell-to-environment interactions that can induce chemotaxis.[17,19] Furthermore, this compartmentalized system having multiple chambers connected through several microchannels is capable of multi-cellular culture by aligning multiple parts of brain regions with specific cells.[13] Therefore, the major benefit of using compartmentalized microfluidics is the simplification of the extremely complex human brain in terms of its structures and functions depending on the location and disease status.[17] In addition, microfluidic devices are very thin and optically transparent, allowing multiple robust and high-throughput analyses in parallel.[17]

In this review, we explore the details on brain-on-a-chip representing multiple CNS disorders, including AD, PD, TBI, vascular dementia, and environmental factor-driven dementia. Furthermore, we expand our model scopes from the CNS to CNS-connecting organ axis. We particularly focus on (1) the major characteristics of CNS diseases to be implemented into the brain chips, (2) the design and application of the brain chips, (3) advantages and potential challenges, and (4) perspectives at the end.

2. Signatures for modelling CNS disorders

This section provides essential backgrounds regarding key features to be accomplished in models for CNS disorders (Fig. 1). The evaluation criteria are summarized in Table 1.

2.-1. Alzheimer's diseases (AD)

Alzheimer's disease (AD) is known to be the most common cause of dementia typically observed in elderly as it involves progressive and irreversible neurodegeneration (Fig. 1a).[20]

At early stages of AD, one of evident features involves the accumulation of amyloid fibrils and formation of amyloid plaques in the patient brain, which activates the innate

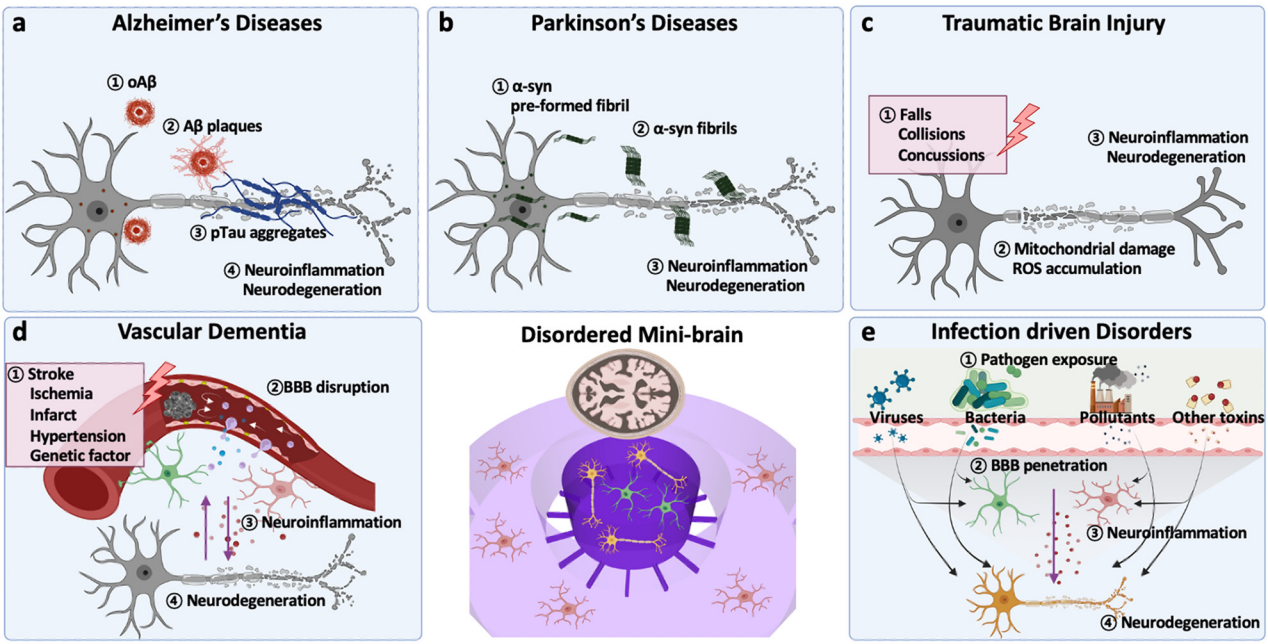

Fig. 1 Overview of signatures in major CNS disorders. (a) Alzheimer's disease (AD): in early stages of AD, aggregation of amyloid beta forming amyloid beta oligomers (oAβ) and Aβ plaques activates neuroinflammation. At middle and late stages, deposition of hyperphosphorylated tau protein accelerates neurodegeneration such as synaptic impairment and neuronal loss. (b) Parkinson's disease (PD): deposition of α-syn PFF, an amyloid-like structure forming the aggregate, is the pivotal factor in PD development. Such misfolded α-syn aggregates are neurotoxic and induce neuroinflammation. Also, α-syn PFF can promote tau accumulation, accelerating loss of dopaminergic neurons. (c) Traumatic brain injury (TBI): neurodegeneration in TBI is mainly caused by the secondary damage after the primary external physical brain damage: falls, collisions, and concussions. The secondary damage involves mitochondrial damage and ROS accumulation in neural cells, leading to neuroinflammation and neuronal death. (d) Vascular dementia (VD): vascular dementia is a progressive cognitive disorder caused by the impairment of blood vessels allowing the uncontrolled entrance of pathogens or neurotoxins to the brain. Direct damage on the tight junction of endothelial cells or inflammatory cytokines can cause such vascular impairment and accelerate neurodegeneration. (e) Environmental risk factor-driven disorder (ERFD): exposure to pathogens including viruses, bacteria, pollutants, and neurotoxins may weaken biological barriers and increase inflammation; the inflammation can be further transmitted to the brain and increase neurological loss. Another hypothesis is that such pathogens can directly penetrate the biological barriers and reach to the brain resulting in neuroinflammation followed by neurodegeneration.

		PHF/NFT formation	rTg4510 mice,[23] APP/PS1 3D AD[21], chip[13]
		Tau propagation	Chip[79,80]
	Neuroinflammation	Astrocyte activation	APP/PS1 mouce,[26] chip[13]
		Microglia activation	5xFAD/TREM2KO mouse,[14] chip,[13,14,19]
	Neurodegeneration	Defect in neural functions	Chip,[13] spheroid[81]
		Reduction in neural cells	Chip[13,75]
Parkinson's diseases (PD)	α-syn deposition	α-syn PFF/Lewy body	α-syn rat,[82,83] α-syn mouse[44,84,85]
		α-syn/α-syn PFF propagation	α-syn rat,[82] chip[40,86–88]
	Tauopathy	Tau propagation	α-syn mouse,[44,85] chip[22,88]
	Neuroinflammation	Astrocyte activation	α-syn mouse,[44,84,85] chip
		Microglia activation	α-syn rat,[82,83] α-syn mouse,[84] chip[40]
	Neurodegeneration	Loss of dopaminergic neurons	α-syn rat,[83] α-syn mouse,[84,85] PINK1^{KO} mouse,[50] PINK1^{KO} rat,[52] DJ-1^{KO} mouse,[51] DJ-1^{KO} rat,[52] LRK2^{mut} mouse,[53] chip[88]
		Motor impairment	α-syn mouse,[44,84] PINK1^{KO} rat,[52] DJ-1^{KO} rat[52]
Traumatic brain injury (TBI)	Neurochemical alteration	Massive glutamate release	FPI rat,[57] CCII mouse[56]
		Calcium/sodium dysregulation	FPI rat[57]
		ROS accumulation	FPI rat[57]
	Neuroinflammation	Reactive astrocytes	FPI rat,[60] aged CCI mouse,[62] CCII mouse,[56] CCII rat[63]
	Neurodegeneration	Axonal damage	Aged CCI mouse,[62] CCII mouse,[56] CCII rat,[63] chip[89–95]
		Reduction in neural cells	FPI rat,[57] CCII mouse,[56] chip[94–97]
Vascular dementia	Vascular dysfunction	Permeability ↑	BBB-spheroid,[70] chip[75,98]
	Neurochemical alteration	Plasma protein influx	RHRSP rat,[68] BCAS/ApoE^{KO} mouse[69]
	Neuroinflammation	Astrocyte activation	BCAS/ApoE^{KO} mouse[69]
	Neurodegeneration	Reduction in neural cells	BCAS/ApoE^{KO} mouse,[69] chip[75,98]
Environmental risk factor-driven disorders (ERFD)	Tauopathy	Phosphorylated tau	3xTgAD mouse,[71,72] chip[15,99]
	Neuroinflammation	Reactive astrocytes	3xTgAD mouse,[71] chip[15,99]
		M1 type microglia	3xTgAD mouse,[71] chip[15,99]
	Neurodegeneration	Defect in neural functions	3xTgAD mouse,[72] chip[15]
		Reduction in neural cells	Chip[100,101]

immune system.[20] In this regard, both *in vitro* and *in vivo* AD models are overexpressed FAD mutations, such as APP mutations (KM670/671NL (Swedish), V717I (London), V717F (Indiana), *etc.*) and/or PS mutations (PS2-N141I, PS1-L166P, PS1-M146L, PS1-I213T, *etc.*).[11] Previous studies have validated that AD models with APP/PS1 mutations could achieve the production of higher Aβ42/Aβ40 ratios, the major forms of Aβ inducing the formation of Aβ plaques.[13,21]

In addition, the formation of tau aggregates as well as neurofibrillary tangles (NFTs) in the neuronal cells is the major hallmark observed in the patient's biopsy at middle to late stages of AD.[11] Tau proteins are supposed to perform roles stabilizing microtubules under normal physiological conditions. When it comes to the AD condition, the tau proteins are hyper-phosphorylated and self-aggregate into paired helical filaments (PHF) followed by NFTs. Wu *et al.* employed a microfluidic device with murine hippocampal and cortical neurons exposed to NFTs and validated the tau transport through the synapses between two neurons.[22] Kuchibhotla *et al.* showed that *in vivo* rTg4510 mice, overexpressing the human mutant form of tau (P301L), could form NFTs in the cortical region of the brain.[23] Later, a number of studies found a significant correlation between NFT formation and neurodegeneration. For instance, the MAPT transgenic system exhibited a notable axonal degradation and synaptic impairment. Furthermore, tauopathy could decrease the blood–brain barrier (BBB) integrity, increase inflammation, and exacerbate AD pathology consequently.[24] Therefore, the formation of NTFs is the second characteristic to be implemented in AD models.

Thirdly, the prominent activation of innate immune cells has been reported in entire stages of AD progression. Among the innate immune cells, astrocytes and microglia, the most abundant glial cells in the CNS, play distinctive roles depending on the severity of AD.[25] In early stages of AD, both astrocytes and microglia are known to retain anti-inflammatory phenotypes in response to moderate deposition of Aβ and tau aggregates in the brain.[14,25] In later stages of AD, such glial cells are polarized into proinflammatory phenotypes and secrete neurotoxic soluble factors as sources of oxidative stress (hydrogen peroxide (H_2O_2), nitric oxide (NO)), proinflammatory cytokines (IL1β, IL6, TNFα, IFNγ) and chemokines (CCL1, CCL2, CXCL1).[13,25,26] Several studies validated their neurodetrimental roles as the increase of oxidative stress as well as tau accumulation in neurons and the recruitment of other innate immune systems that further exacerbated AD pathology.[26,27] Since the glial cells obtain mutations on the AD risk factors (APOE e4, TREM2, *etc.*) as well,[14,28] AD models with astrocytes and microglia can reconstitute the unique characteristics found in sporadic AD (SAD) as well.

Lastly, significant neurodegeneration is a general hallmark found at late stages of AD.[25] At this point, AD patients show significant loss of white matter connectivity and cortical thinning with clinical symptoms such as progressive decline in memory, thinking, language, and essential body functions.[29] Such loss of functions is attributed to synaptic impairment followed by neuronal loss.[29] Previous studies showed that the downregulation of synaptic proteins in AD conditions, such as calsyntenin, GluR, neurexin, syntaxin, and synapsin, led to failure of essential processes of neural cells such as dendritic spine assembly, postsynaptic Ca^{2+} signaling, synaptic transmission, synaptogenesis, and presynaptic differentiation.[30] In addition, Park *et al.* revealed that the loss of neural functions was closely correlated to the reduction of neural population (MAP2- or Tuj1-positive cells) in *in vitro* AD models.[13] Therefore, the validation of neurodegeneration would be a significant criterion for the development of effective AD models.

2.-2. Parkinson's diseases (PD)

Parkinson's disease (PD) is the second-most common progressive neurodegenerative disorder mainly characterized by motor symptoms of bradykinesia, rigidity, tremor and postural instability (Fig. 1b).[31] Some non-motor symptoms, including neuropsychiatric symptoms, sleep disorders, autonomic symptoms and sensory symptoms, are also thought to play an important role in advanced PD and reduced quality of life.[32]

PD is caused by the accumulation of misfolded α-synuclein (α-syn) followed by the loss of dopaminergic neurons in substantia nigra.[33,34] α-syn has been identified to induce Lewy bodies in the presynaptic nerve terminals and nucleus, resulting in neurodegeneration.[35–37] Growing evidence shows that α-syn fibrils can be transmitted cell-to-cell through receptor-mediated endocytosis as well as fluid-phase endocytosis, causing the recruitment of monomeric α-syn into pathological inclusions.[38–40] Recent studies have confirmed Braak's hypothesis that α-syn aggregates can also be transmitted from neuron-to-neuron; yet, the specific molecular mechanism of how α-syn accumulates and leads to PD remains unsolved.[41–43] In this regard, the addition of α-syn or genetic mutations/deletions leading to α-syn depositions and dopaminergic neurons loss have been adopted in the development of PD models.

To develop PD conditions, several groups introduced transgenic animal models overexpressing human α-syn or mutants leading to α-syn fibrils in the brain. Giasson *et al.* proposed a transgenic mouse model overexpressing mutant A53T human α-syn, found in early-onset PD patients, encoded in the MoPrP.Xho vector system so that it is specifically overexpressed in the brain region.[44] The transgenic mice expressing mutant A53T successfully presented major PD features, such as the formation of α-syn fibrils, activation of glial cells, and degeneration of motor neurons. However, increasing evidence showed that the overexpression of endogenous α-syn *via* vector transduction resulted in the formation of α-syn fibrils in limited parts of the brain near injection spots.[45] Recently, the injection of α-syn preformed fibrils (PFFs) has been suggested to induce the deposition of α-syn fibrils diffused through the entire brain.

Loss of function mutations observed in early-onset PD patients, such as PARKIN, PTEN-induced putative kinase 1 (PINK1), and DJ-1,[46] has been employed to develop PD models. PARKIN encodes an integral ligase in the ubiquitin proteasome system; therefore, loss of function mutations on PARKIN would promote aggregation of α-syn.[47] However, there were contradictory results on PARKIN-deficient mice models, inducing mitochondrial dysfunction while no significant PFF formation and dopaminergic neuronal loss.[48] In this regard, PARKIN-based models were suggested to co-express with other mutations such as PINK1 and DJ-1, a mitochondrial kinase recruiting PARKIN and a chaperone protein, enhancing PARKIN-mediated mitophagy and PD pathology.[49] Recent studies also showed that PINK1 and DJ-1 deficiency models could represent PD signatures in early-onset as mitochondrial dysfunctions and oxidative stress leading to moderate dopaminergic neuronal loss.[50–52] For the late-onset PD models, Ramonet *et al.* introduced transgenic mice expressing the disease-causing mutant of leucine rich repeat kinase2 (LRK2) (G2019S), found in late-onset familiar PD, accomplishing both induction of α-syn depositions and dopaminergic neuronal loss in the aged brain.[53]

2.-3. Traumatic brain injury (TBI)

Traumatic brain injury (TBI) is the major cause of death and disability worldwide triggered by a sudden, external, and physical damage on the brain (Fig. 1c).[54] TBI consists of two

Published on 16 January 2023. Downloaded on 2/15/2026 2:40:59 AM.

phases: the primary damage at the incident involving immediate contusion, laceration, and intracranial hemorrhage and the second delayed damage after the incident including ischemia, edema, and other long-term disabilities in brain functions.[54] Recent studies showed that TBI has a high correlation to increase risks of other dementia such as AD and PD due to the second delayed damage, which would alter neurochemical mechanisms and neurodegeneration.[55]

Changes in neurochemical conditions are the major characteristics found in cerebrospinal fluid (CSF) and body fluids obtained from most TBI patients. The prolonged damage on the brain leads to the disruption of membrane integrity and activation of glutamate receptors (iGluRs) and metabotropic glutamate receptors (mGluRs) without control.[56,57] Such aberrant activation of glutamate receptors can result in the massive release of glutamates in the brain. Dysfunction in membrane proteins modulating calcium, such as calcium channels and calcium/sodium pumps, is also known to impede the control over calcium homeostasis in the neuronal cells.[57] Sun *et al.* revealed that long-term dysregulation in calcium homeostasis after TBI, induced by fluid percussion injury (FPI), elevated the calcium level and increased necrotic or apoptotic neurons in hippocampal regions of mice.[57] Afterward, the excessive glutamate and calcium in the brain are known to impair mitochondrial function, elevate ROS (NO and H_2O_2), and activate apoptotic cell death in neuronal cells. Therefore, the disruption of membrane integrity followed by increased levels of both glutamate and calcium after the stimulus would be the important criteria to be confirmed in TBI models.

The local changes in neurochemical environments are known to activate resident glial cells and recruit other peripheral immune cells to the damaged brain.[56] The changes involve not only the increased glutamate/calcium levels but also proinflammatory cytokines (IL1β, IL-6, IL-12, TNFα, IFNγ, TGFβ) and chemokines (CCL2, CCL3, CCL4, CXCL1, CXCL2) released by damaged neural cells or other glial cells near the TBI regions.[55] In this regard, the increased level of proinflammatory factors would offer another evidence for TBI-driven neuroinflammation. Recent studies with mouse models after contusion injury generated by controlled cortical impact (CCI) suggested that the reactivity of astrocytes, measured by the expression level of glial fibrillary acidic protein (GFAP), could be a representative marker for evaluating the severity of TBI.[56,58–60] In mild TBI, several studies confirmed that moderate astrogliosis produces neurotropic factors and anti-inflammatory mediators that ameliorate TBI conditions. In addition, they played pivotal roles in the control over homeostasis of the brain by buffering the imbalanced neurotransmitters.[61,62] On the other hand, a number of studies with severe TBI models, involving aged animals after CCI or animals after chronic constriction impact injury (CCII), revealed the induction of overly-reactive astrocytes producing proinflammatory mediators that further exacerbated the TBI-driven neuroinflammation followed by neurodegeneration.[56,62,63] Thus, the reactivity of astrocytes can be another key feature to be represented in TBI models.

2.-4. Vascular dementia

Vascular dementia (VD), a progressive cognitive decline, is caused by the impaired blood flow in the brain leading to neurodegeneration (Fig. 1d).[64] According to Vascular Impairment of Cognition Classification Consensus Study (VICCCS), there are 4 major subtypes of VD: post-stroke dementia (PSD), subcortical ischemic vascular dementia (SIVD), multi-infarct (cortical) dementia, and mixed dementia with other CNS disorders, particularly AD and PD.[64]

Leaky vessels increasing the impaired blood flow passing through the BBB are the common feature in VD. In the normal condition, an intact BBB permits only essential molecules to maintain CNS homeostasis while the damaged BBB found in the aged brain does not. Initial studies validated the leaky vessels by showing morphological changes followed by increased diffusion of endogenous proteins such as albumin and IgG passing through the vessels in brains of animal models.[65–67] Other VD animal models exhibiting the plasma leaky feature involve stroke-prone renovascular hypertensive (RHRSP) and bilateral common carotid artery stenosis (BCAS) rats or mice.[68,69] The advent of techniques (CT, MRI, PET images) enabled the tracking of plasma albumin concentrations among the entire CSF in brains of human elderly and confirmed the significant passage of albumin from vessels to brain regions. Several *in vivo* and *in vitro* BBB models confirmed the increased permeability by showing reduction in tight-junctions (ZO-1, occludin, claudin) and increase of the TEER value or permeability coefficient value of fluorescently-labelled molecules.[70] Therefore, the development of a swollen and leaky BBB with increasing permeability of molecules found in CSF has become a gold standard to develop VD models.

Elevation of neuroinflammation, especially near the leaky vessels, is another hallmark reported in many VD cases. Endothelial cells on the damaged BBB are known to release various proinflammatory mediators and activate residential glial cells around them. In the normal case, beneficial astrocytes are activated and secrete growth factors such as vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), and glial cell line-derived neurotrophic factor (GDNF) that maintain the BBB integrity. In addition, such astrocytes release tumor growth factor beta (TGFβ), which guides pericytes around the BBB to enhance BBB tightness. In the aged brain, however, proinflammatory mediators such as IL1β and TNFα induce reactive astrocytes, which decrease BBB tightness and increase neurodegeneration in VD. Moreover, endothelial cells can release proinflammatory chemokines to recruit monocytes and macrophages. These peripheral immune cells then penetrate brain parenchyma and release neurotoxic factors as free radicals and other proinflammatory mediators. In this

Published on 16 January 2023. Downloaded on 2/15/2026 2:40:59 AM.

regard, effective VD models should recapitulate neuroinflammation followed by neuronal damage around the BBB.

2.-5. Environmental risk factor-driven disorders

Environmental risk factors (ERFs), such as pollutants (particulate matter (PM), microplastic particles (MP)), pathogens (bacteria and viruses), and their derivates, have been highlighted recently since epidemiological studies have alarmed us about the high correlation between exposure to ERFs and incident of CNS diseases including AD, PD, and other types of dementia (Fig. 1e).

Because ERFs originate from outside of our body, the presence of ERFs in the brain or their entrance mechanisms should be validated prior to testing ERF-driven neurodegeneration. Kang *et al.* confirmed that PM downregulated tight-junctions on the BBB and decreased BBB integrity resulting in the penetration of PM to the brain regions.[15] In addition, a number of studies revealed that external pathogens such as bacteria and viruses as well as their derivates could reach the brain area *via* the olfactory bulb–brain, gut–brain, or lung–brain axis and increase the risk of CNS disorders. Therefore, models for ERF-driven dementia are required to validate the entry pathway of environmental factors into the brain regions.

The common features found in the brain exposed to either air pollutants or pathogens are the induction of neuroinflammation. Several studies validated that PM induced reactive astrocytes increasing oxidative stress, amyloidosis, and tauopathy, leading to cognitive decline in PM-inhaling mice models or PM-treated *in vitro* models. Kang *et al.* revealed that M1 type microglia in brain models polluted with fine PM is the major source of neuroinflammation, which facilitated tauopathy and neurodegeneration.[15] Recent studies with AD mice revealed that PM can further induce astrogliosis and microgliosis that would contribute to increase of AD severity significantly.[71,72] In addition, Tran *et al.* validated that conditioned media of oral pathogenic bacteria (*Porphyromonas gingivalis*) activated both astrogliosis and microgliosis driving neuroinflammation followed by tauopathy in human brain models. Thus, ERF-mediated neuroinflammation leading to neurodegeneration is a criterion to be confirmed in ERF-driven dementia models.

3. Brain-on-a-chip platforms for modelling CNS diseases

3.-1. Alzheimer's disease-on-chip

Several AD models based on microfluidics have been developed and used for investigating the underlying mechanisms of amyloidosis and tauopathy contributing to AD progression. Park *et al.* introduced a simple AD model by preparing 3D neurospheroids in the microfluidics and validated Aβ-mediated neurodegeneration.[81] Wu *et al.* designed a microfluidic device composed of two somatodendritic and axonal compartments, which were connected through multiple channels so that dendrites and axons of murine hippocampal and cortical neurons from each compartment form synapses at the center of channels.[22] Afterward, they added tau aggregates into the somatodendritic compartment and monitored tau transportation from one side to the other. Later, Dujardin *et al.* employed the same device to culture rat neurons transduced with lentivirus encoding V5-hTau46, which produced tau proteins from the primary neurons (Fig. 2a).[79] This study confirmed axonal transport of tau from the primary to the secondary neurons confirming tauopathy through cell-to-cell interaction. Furthermore, Takeda *et al.* designed a three-chamber system for modelling dual-layered neurons and validated the axonal transport of NFTs from the primary to secondary neurons (Fig. 2b).[80]

Neuroinflammation has emerged as another key therapeutic target since the severity of inflammation is closely related to the stage of AD.[17,25] The unique feature of innate immune cells in AD is their chemotactic activity in response to AD ques which initiate neuroinflammation.[102] The microfluidic system has emerged as an ideal platform to construct such cell-to-cell or cell-to-environment interactions based on chemotaxis, which could contribute to AD progression. Cho *et al.* introduced a chemotactic microfluidic platform forming stable chemical gradients for AD ques such as soluble Aβ, Aβ fibrils, and conditioned media from AD brain tissues, which stimulated human microglia (Fig. 2c).[19] This unique platform allowed stimulated microglia with a specific phenotype to be separated from the heterogeneous population in response to AD ques; however, single-cultured models could not recapitulate other aspects from the multi-cellular crosstalk found in AD pathology.

Recent advances in the technique of cell culture within microfluidics allow the development of multicellular AD models, reproducing physio-pathogenically relevant AD signatures leading to neurodegeneration. For instance, Park *et al.* constructed a 3D human AD brain model along with an innate immune system around the brain by co-culturing human neuroprogenitor cells expressing APP/PS1 and human adult microglia in the microfluidic device (Fig. 2d).[13] It should be noted that the neuroprogenitor cells were later differentiated into neurons and astrocytes producing Aβ; therefore, the model became a tri-culture system. The model involved two compartments with one for the AD brain with AD neurons and astrocytes and another for microglia, which were interconnected with multiple channels allowing microglial recruitment in response to soluble factors from the AD brain compartment. This study revealed that the astrogliosis driven by the interaction between AD neurons and astrocytes in the AD brain could induce M1 type microglia, which further promoted tau accumulation and neuronal death at the end. This model was further advanced with the use of iPSC-derived microglia in order to investigate the critical role of TREM2 in the microglial activity offering

neuroprotection in AD conditions.[14] In summary, the multicellular AD models in microfluidics were able to reproduce key AD features such as pathological accumulation of Aβ, induction of neuroinflammation, deposition of tau, and neurodegeneration.

3.-2. Parkinson disease-on-chip

To date, several models based on microfluidics have successfully simulated PD progression in terms of spreading of α-syn in the brain through neuron-to-neuron interactions. Freundt *et al.* employed microfluidics to align two neurons from mice forming a synapse between presynaptic soma and postsynaptic axon and revealed neuron-to-neuron transmission of α-syn PFFs through axonal transport.[86] Fernandes *et al.* employed a microfluidic platform comprising two compartments interconnected by multiple channels with pneumatic valves to control the diffusion of α-syn.[40] This study found neuronal transmission of α-syn as well as microglial recruitment in response to the α-syn gradient. Later, Prots *et al.* seeded neurons and astrocytes expressing α-syn oligomer-forming mutants (E46K and E57K) differentiated from iPSCs of PD patients in the microfluidic device, forming axon-to-soma projection (Fig. 3a).[88] This study revealed that accumulation of α-syn oligomers impaired the anterograde mitochondrial axonal transport as well as facilitated tau spreading through neuron-to-neuron interactions. The dysfunction in synucleinopathy led to energy deflects and synaptic impairment at the end. Recently, Mao *et al.* employed a two layered axon-to-soma chip and revealed a key mediator, lymphocyte-activation gene 3 (LAG3), that bound to α-syn and promoted α-syn transmission through dopaminergic neurons (Fig. 3b).[87]

Another key signature found in PD is dopaminergic neuronal loss in the brain. Prior to development of PD models representing dopaminergic neuronal degeneration,

Copyright 2021, Springer Nature.[98]

Moreno *et al.* introduced a 3D OrganoPlate, a microfluidic platform with a perfusion system allowing for the continuous differentiation of dopaminergic neurons from neuroepithelial stem cells.[103] Later, Bolognin *et al.* employed the same platform for the construction of a PD model in the microfluidics with 3D cultured dopaminergic neurons carrying a pathogenic mutation (LRRK2-G2019S) from PD patient-derived iPSCs. This model validated PD pathology such as mitochondrial dysfunction in dopaminergic neurons leading to neurodegeneration, but did not reproduce another pathology such as α-syn accumulation yet. Pediaditakis *et al.* developed a substantia nigra brain-chip, culturing iPSC-derived dopaminergic neurons, microglia, astrocytes, and pericytes in the microfluidics (Fig. 3c).[98] They added α-syn PFFs to the model to induce the pathological conditions. The exposure of this device to α-syn fibrils led to mitochondrial dysfunction and progressive neuronal death along with the activation of astrocytes and microglia. Given the recent advance in dopaminergic neuronal culture in the microfluidics, there is tremendous potential to develop PD models reproducing both dysfunction of synucleinopathy and loss of dopaminergic neurons in the future.

3.-3. Traumatic brain injury-on-chip

To develop TBI conditions inducing delayed brain damage, a number of studies have designed microfluidic platforms with well-controlled mechanical stimuli, such as fluid shear stress, hydrostatic pressure, compression, and shear strain.

Microfluidics equipped with a vacuum aspiration system have been widely applied for inducing axonal injury. TBI models in the two-compartments interconnected by multiple microchannels, in which synapses could form in the center of microchannels, were the most popular configuration as they could apply vacuum aspiration to one side and induce

Published on 16 January 2023. Downloaded on 2/15/2026 2:40:59 AM.

damage only on the axonal part. Taylor *et al.* found that the vacuum-assisted axonal damage changed groups of mRNA transcripts for cytoskeletal and mitochondrial maintenance.[89] Zhang *et al.* employed a microfluidic device with the same configuration and revealed that collapsin response mediator protein-2 (CRMP2) was the key mediator to facilitate mitochondrial damage followed by axonal degeneration in the TBI models.[90] This TBI model was further utilized to discover a promising strategy to induce axonal regeneration after the injury, such as neurotrophins-3, peroxisome proliferator-activated receptor gamma (PPAR-γ), and therapeutic peptide NOGO-66.[91,92,104] The vacuum-induced neural injury method is, however, limited in a specific region of the microfluidics due to the high fluidic resistance between the interconnected compartments.

To further expand the injury region of the brain prepared in microfluidics, Rogers *et al.* cultured neurons and glial cells in a microfluidic device forming neural networks and incubated the entire device in the impact chamber, exposing it to controlled *g* force (Fig. 4a).[95] This study validated the force-dependent post-impact on the neurodegeneration driven by neuroinflammation and oxidative stress. Hosmane *et al.* introduced an axonal injury micro-compression (AIM) platform, where pneumatic pressure in a range of moderate (<55 kPa) to high (55–95 kPa) was directly applied onto axons (Fig. 4b).[93] TBI models prepared in AIM microfluidics precisely reflected the delayed damage presumably due to the rearrangement of neurofilaments and microtubules in neurons. In addition, physical force by stretch and strain motions was applied to develop TBI models. Dollé *et al.* introduced a pneumatic strain-based injury model in the microfluidics by inducing deformation of the PDMS surface (Fig. 4c). In this platform, neurons straightened their axons on the PDMS membrane, which can be stretched by pressurizing a cavity underneath the PDMS surface.[94] The stretching axons increased the mitochondrial membrane potential dramatically which led to axon degeneration.

As described previously, massive influx of neurotransmitters involving glutamates is the major

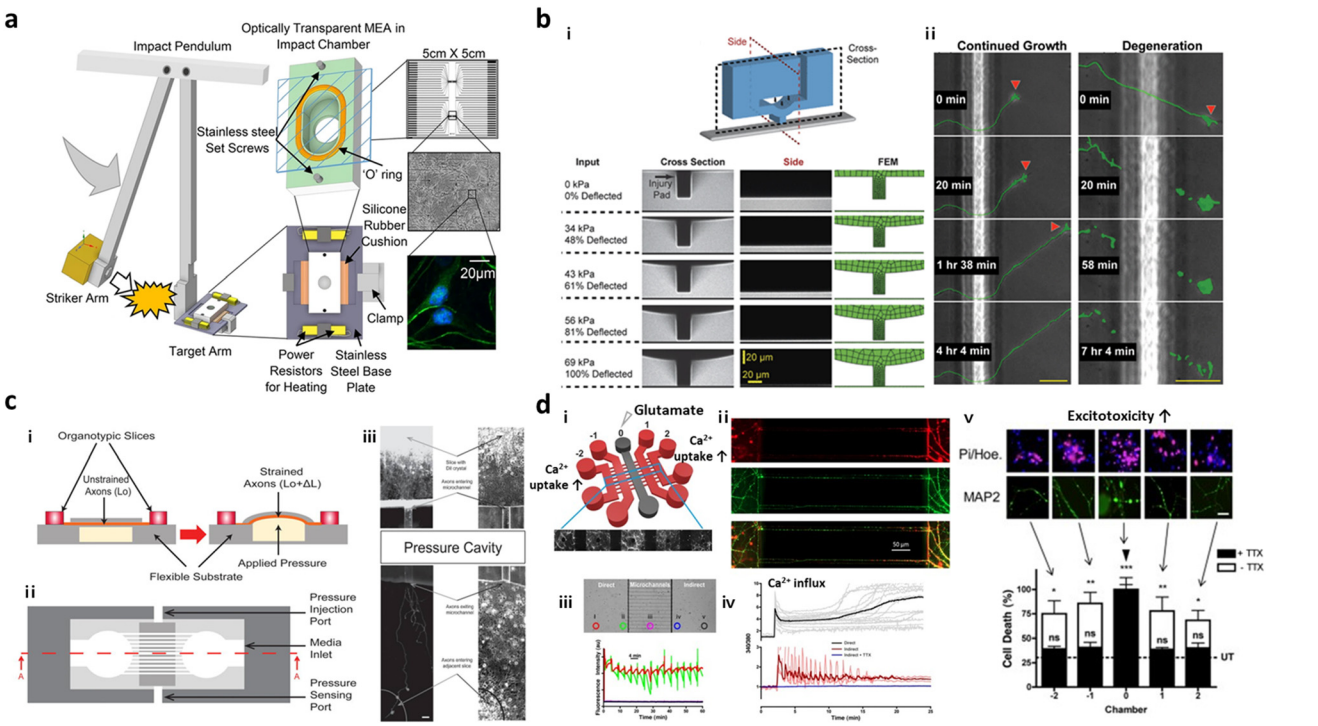

Fig. 4 Mini-brains reconstituting traumatic brain injury (TBI). (a) Post-TBI was reproduced by the direct mechanical impact on the chip forming a neural network between neurons and glial cells. characteristic observed during the secondary damage on neurons. Samson *et al.* generated neuronal networks in microfluidics, where hippocampal neurons were cultured in 5 chambers and their axons–somas were interconnected by multiple channels (Fig. 4d).[96] To induce the secondary damage, they added a high concentration of glutamate at the central chamber, and validated the spread of neuronal damage through cell–cell interactions in the network. Among the receptors for neurotransmitters, the GluN2B type *N*-methyl-D-aspartate (NMDA) receptor was majorly engaged in the spread of secondary damage induced by the glutamate storm. Charier *et al.* prepared TBI models in microfluidics by addition of lysed blood or blood clot and validated that NMDA played pivotal roles in damage transmission.[97]

3.-4. Neurovascular unit-on-chip

Present *in vitro* VD models simulate the transmission of neurotoxic factors, originating from the neurovascular unit (NVU), into the brain and the initiation of neurodegeneration. NVU chips are majorly composed of the BBB part along with other accessory parts such as pericytes and astrocytes; further advanced NVU chips are connected to brain tissue parts with neuronal cells.

NVU chips have described the correlation between the impaired BBB and neurodegeneration in AD progression. Cho *et al.* created an *in vitro* 3D capillary-like structured BBB integrated with chemotactic channels, allowing infiltration of neutrophils from the BBB lumen to the brain compartment in response to proinflammatory mediators originating from the brain side (Fig. 5a).[105] Later, the 3D tubular BBB was connected to 3D AD brain models cultured with APP/PS1neuroprogenitor cells in the microfluidics (Fig. 5b).[75] This study revealed that proinflammatory factors such as Aβ, MMP-2, and IFNγ from AD brains induced ROS accumulation and tight-junction reduction in endothelial cells in the BBB part. Afterward, they discovered that the leaky BBB permitted the increased influx of neurotoxin to the brain part and promoted neuronal damage at the end.

In addition, NVU chips clarified that α-syn PFFs could affect BBB integrity in PD progression. Pediaditakis *et al.* employed microfluidics comprising two compartments of a 3D brain and a cylindrical structured BBB and demonstrated that α-syn PFFs impaired BBB tight-junctions and increased the risk of PD.[98] This study also revealed the disruption of BBB integrity after the treatment of α-syn PFFs to the BBB side of the model while no discernible effects by the α-syn monomer were observed, confirming that α-syn PFF was the pathological form of α-syn.

3.-5. Environment risk factor-driven dementia-on-chip

To test potential neurotoxicity driven by ERFs, a number of groups introduced brain models in the chip, which reconstituted the human brain continuously exposed to various pathogens or pollutants. DeOre *et al.* employed a 3D BBB model, previously described by Partyka *et al.*, to study the entrance mechanism of viruses such as SARS-CoV-2 (Fig. 6a).[106,107] This study found that the treatment of SARS-CoV-2 spike proteins activated RhoA and disrupted BBB

tightness. Tran *et al.* developed chip-based brain models exposed to oral bacteria-conditioned media to test the induction of any neurotoxicity driven by the bacteria (Fig. 6b).[99] Koo *et al.* investigated the effects of organophosphate-based compounds (OPs) in the human brain by using a membrane-free tetra-cultured brain on chip, which reconstituted a blood vessel embedded in the brain tissue with innate immune cells.[100] The addition of dynamic media flow at the center of the blood vessel part enabled the investigation of not only OP entry mechanisms but also its roles in neurodegeneration. Liu *et al.* further improved the brain tissue part with iPSC-derived GABAerinc inhibitory neurons and astrocytes exposed to OPs, which simulated an OP-driven neurodegenerative model.[101] This study validated the therapeutic efficacy of butyrylcholinesterase, one of the exogenous bioscavengers of OPs. Kang *et al.* engineered a biomimetic model of a PM-polluted brain in the microfluidics, mimicking proinflammation followed by neurodegeneration driven by reactive astrocytes and microglia under PM conditions (Fig. 6c).[15] This model showed the notable recruitment and activation of microglia in response to soluble factors from neurons and astrocytes under long-term exposure to PM. The model found that PM could induce M1 type microglia, which increase pTau accumulation, synaptic impairment, and neuronal loss.

4. Multi-organ chips for investigating the entry of risk factors to the brain

4.-1. From organ chip to multi-organ chip

In our body, there are multiple paracellular layers comprising epithelium cells and neuronal cells that serve as the first front-line of defence against environmental risk factors such as pathogens or microbiomes. The layers involve epithelial layers for the gut, lung, nasal cavity, cornea, and skin. Therefore, dysregulation of these defensive layers, in terms of lowered tightness or damaged neurons, could allow the invasion of pathogens in our bodies leading to inflammation. Previous studies hypothesized that the accumulation of these risk factors and inflammation originating from these layers could further transmit to the brain region through the circulatory system or nervous system linking a specific organ to the brain.[108–110] In this regard, the recent paradigm for organ chips has been expanded to multi-organ chips. Here, we review recently proposed multi-organ chips in terms of key characteristics they achieved and future directions at the end.

4.-2. Gut–brain axis

One of the most popular tracks to reach the CNS is the gut–brain axis (GBA), a bidirectional link passing through either

Published on 16 January 2023. Downloaded on 2/15/2026 2:40:59 AM.

the systematic circulatory system or enteric nervous system.[108] Many studies have suggested that environmental risk factors or other risk factors accumulated in the gut would penetrate to the brain and promote neurodegeneration diseases such as Parkinson's disease, Alzheimer's disease, and autism spectrum disorders.[111–120] Kim *et al.* came up with a modular microfluidic device, on which co-cultured gut epithelial cells and brain endothelial cells develop the GBA track on a chip (Fig. 7b).[121] They measured the permeability of lipopolysaccharides, butyrates, and exosomes derived from the gut to both barriers of the intestinal system and the BBB, demonstrating that such molecules produced in the intestine can be delivered to the brain and affect the microenvironment in the brain. Trapecar *et al.* further connected the gut–liver–brain together on a physiological model in order to simulate the physiology in the human body.[122] They identified that short-chain fatty acids produced by gut microbiome promoted maturation of healthy brain cells but exacerbated neuronal death in PD conditions. Furthermore, they showed that these kinds of opposite effects may be mediated by lipid metabolism instead of the immune system by observing the pathology-related transcriptomic changes after removing immune cells from the platform. Overall, GBA microfluidic platforms have great potential for us to investigate the pathology of neurodegenerative diseases at the molecular level *in vitro*; however, there is no existing model connecting the gut-to-brain with the enteric nervous system yet.

4.-3. Lung–brain axis

The lung–brain axis (LBA) is assumed to connect the CNS and lung through the autonomic nervous system or circulatory system, by which primary pulmonary diseases can affect the brain and lead to neurodegenerative disorders.[109,110] There were initial efforts on the development of functionalized liver models prepared on the chip prior to creating LBA chips. Huh *et al.* introduced a 'breathing' lung model in the chip, simulating breathing-induced physiologically-relevant mechanical force by co-culturing epithelium and endothelial cells on the stretchable PDMS forming an alveolar–capillary barrier.[123] This model was employed to closely reconstitute pathogen entry, neutrophil recruitment, and pulmonary edema.[124] Xu *et al.*[125] further developed an LBA track on a chip by combining two microfluidics such as lung-on-a-chip and brain-on-a-chip and investigated lung cancer metastasis pathology (Fig. 7c). They isolated the brain metastasis cells from the device and identified that these cells possessed different protein expression profiles and overactive glutathione (GSH) metabolism pathways acquiring drug-resistance ability *via* endogenous alteration. The microfluidic LBA chips, therefore, have great potential for studying disease pathology as a contribution of lung-derived risk factors to CNS diseases. However, further study is required to develop LBA track on chips to reconstitute the autonomic nerve system.

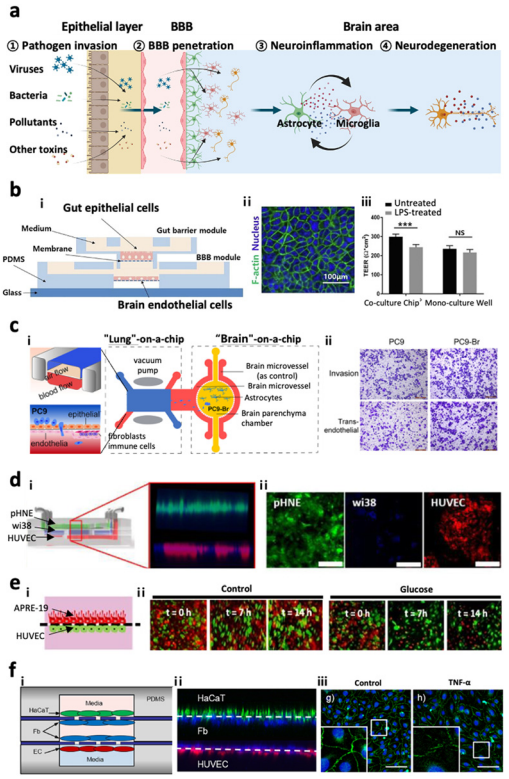

Fig. 7 Multi-organs-on-chips as the potential platforms for CNS disorders. (a) Entry pathways of risk factors to the brain passing across two distinctive paracellular barriers. Risk factors such as viruses, bacteria, pollutants, and other toxins can penetrate the first barrier of epithelial layer in organs followed by the second barrier of cerebral endothelial layer of the brain blood vessel, also known as the blood–brain barrier (BBB). Such pathogens reaching the brain can further promote neuroinflammation as well as neurodegeneration leading to dementia. Published on 16 January 2023. Downloaded on 2/15/2026 2:40:59 AM.

4.-4. Olfactory bulb–brain axis

The olfactory bulb (OB) is anatomically located in the forebrain of humans and vertebrate animals which detects and transduces odorant information to the brain parts such as pyriform cortex, hypothalamus, and amygdala.[129] The most distinctive feature of the olfactory bulb is a glomerulus, in which the axons of sensory neurons come into contact with the apical dendrites forming synapses and project odorant signals.[129] Recent studies show that inhaled airway risk factors can be accumulated in the brain through the sensory neurons connecting the OB and brain bypassing the lung or blood brain barrier systems.[130,131] Other independent studies revealed that the risk factors and other environmental pathogens accumulated in the OB could be transferred to the brain and further propagate neurodegenerative diseases including AD, PD, and dementia.[132–134] To clarify the penetration of pathogens to the OB followed by the BBB, Na *et al.* developed a mucosa gland-on-a-chip, which reconstituted the mucosa layer with primary human nasal epithelial cells (hNECs) exposed to the air way along with blood vessels with human microvessel endothelial cells (hMVECs) underneath of the mucosa layer.[135] In between the epithelial layer and endothelial layer, there was an intermediate chamber filled with ECMs that allowed the formation of mucosa glands originating from the epithelial layer that may further develop polys and invade the circulatory system. Later, Byun *et al.* engineered a similar platform as a mucosa-BBB chip and employed the chip to investigate the underlying mechanisms of PM penetration from mucosa to the BBB layer (Fig. 7d).[126] However, further effective models adding the brain component and reconstituting the OB–brain axis are needed to clarify the underlying mechanisms of OB-driven pathogenesis leading to CNS disorders in the future as well.

4.-5. Eye–brain axis

Light information from outside can be gathered, processed into electrical signals, and transmitted into the brain by retina, majorly composed of retinal ganglion cells (RGCs).[136,137] Recent studies showed that patients with CNS disorders including AD and PD suffer from ophthalmologic symptoms at high frequency.[138,139] To support the hypothesis on the eye–brain axis contributing to CNS disorders, microfluidics have been employed. Some initial studies enabled the culture of RGCs in the microfluidics. For instance, Wu *et al.* cultured RGCs in the microfluidics, which were connected to a 3D pressure-applying adaptor, designed to impose the same pressure on RGCs, and investigated how the RGCs respond to different hydrostatic pressures.[140] Later, Chen *et al.* established a microfluidic chip to co-culture human retinal pigmental epithelial cells (ARPE-19) and human umbilical vein endothelial cells (HUVEC) (Fig. 7e).[127] Utilizing this platform, more VEGFs can be secreted under the low glucose and hypoxia conditions, in turn causing the directional migration of HUVEC. Arik *et al.* further modified this device to develop an outer blood–retinal barrier (oBRB) chip which evidenced that exposure to reactive oxygen species (ROS) may lead to vascular hyperpermeability and induce wet AMD. These microfluidic devices can be applied to study complex eye disease pathology and even utilized for treatment evaluation with precision medicine.

4.-6. Skin–brain axis

Psychological hyperstress can cause and aggravate neurogenic inflammation, which may further trigger skin diseases such as atopic dermatitis and psoriasis.[141] Meanwhile, the skin can also affect the brain through the transmission of hormones or cytokines to the brain region.[141,142] Given the correlation between the skin and brain, there is an increasing demand on the development of skin–brain axis on chips. Wufuer *et al.* successfully developed a human skin-BBB chip on which human immortalized keratinocytes (HaCaT), fibroblasts, and human umbilical vein endothelial cells (HUVEC) were cultured (Fig. 7f).[128] They induced inflammation and edema conditions of the human skin *in vitro via* perfusing TNFα into the device. Afterward, they validated that dexamethasone, a well-known anti-inflammatory compound, alleviated the skin inflammation and its transmission to the blood vessel. Although no skin–brain microfluidic device has been developed yet, the advance of the cell culture technique and its biomaterials would contribute to the development of skin–brain disease models in the near future.

5. Perspectives

Herein, we overview the current state-of-art techniques for developing a multicellular brain organoid on a chip, which precisely represents the pathological conditions of CNS diseases. Microfluidics are powerful platforms to reconstitute CNS diseases due to the following reasons. Firstly, the microfluidic platform can culture cells in long-term periods allowing the development of chronic status found in most CNS diseases as it could supply nutrient and remove waste continuously by modulating the flow of aqueous solution and gas in the device.[17] For instance, the perfusion system enables not only continuous supplement of essential factors for cell culture but also exchange of buffers and reagents for multiple analyses. Secondly, capillary channels forming stable gradients for chemotaxis could be applied for the study of infiltrating innate immune cells observed in neuroinflammation, a common signature found in CNS disorders.[19] The capillary structures can be further employed to guide the neuronal growth and control the connectivity of neural networks.[143] Thirdly, the compartmentalized system having multiple chambers connected through several microchannels could divide a mini-brain into multi-compartments having specific functions and structures.[17] This compartmental system further enables the development of multi-organ models, which can expand the scope of the study from the brain to other organs. In this way, the

Published on 16 January 2023. Downloaded on 2/15/2026 2:40:59 AM.

microfluidic-based brain organoid can simplify the complex aspects of the human brain compared to *in vivo* models while keeping sophisticated aspects. Lastly, microfluidic devices are very thin and optically transparent, allowing multiple robust and high-throughput analyses in parallel compared to other *in vitro* and *in vivo* models.[17]

Despite the multiple benefits of using the microfluidic system, there are some limitations on the miniaturized brain models in the chip compared to other types of *in vitro* models and animal models. The minute amounts of cells in the models limit some analyses requiring at least 1×10^5 cells per sample, such as western blotting, immunoprecipitation, exosome purification, fluorescence-activated cell sorting (FACS), and others. In addition, random absorption of biological molecules on the device surface, commonly composed of PDMS or other polymers, occurs which would reduce the detection power of biomarkers in the models. This would further reduce the delivery efficacy of nutrients or other drug candidates to be tested. We believe that continuous advances in the cell culture technique and biomaterials would resolve such issues in the near future. We also propose future directions to improve microfluidic-based CNS disease models as follows:

- Alzheimer's disease-on-chip: current AD models, adopting the overexpression of Aβ mutants or their precursors to promote Aβ depositions in the chip, have elucidated the underlying mechanisms of FAD-associated cases well, but not SAD.[17,144] Recently the advent of AD patient-derived iPSCs could reconstitute pathological signatures driven by risk factors found in SAD such as age, gender, and other environmental factor-driven neurodegeneration;[145] however, the standardization of SAD models on chips remains to be solved in the future.
- Parkinson disease-on-chip: here, we introduced examples of microfluidic-based PD models allowing the simplification of intricate biological parameters in the study of PD progression. The risk factors simulated in current PD models on chips are limited to the promotion of α-syn depositions, leading to inflammation and neurodegeneration. Other risk factors such as age, gender, and other disorder conditions increasing the PD incidents should be considered and described in future directions.[146]
- Traumatic brain injury-on-chip: microfluidic platforms enabled the sophisticated control over mechanical stress on neurons and precisely reconstitute the axonal degeneration followed by damage transmission through neuron-to-neuron networks. Given the fact that dysfunctions in other cellular components such as glial cells maintaining homeostasis in the brain can affect TBI conditions,[56,58–60] further improvement such as multi-cellular culture is required to construct pathologically-relevant TBI models for the next generation.
- Neurovascular units-on-chip: VD models on chips have demonstrated the transport of risk factors to the brain region and clarified their contributions to the development of CNS disorders. The use of patient iPSC-derived cells, retaining the inherent pathological conditions, could further improve VD models.[147] In addition, the dysfunction in neurovascular coupling, the bi-directional crosstalk between neurons and vessels, should be considered in future VD models.[148,149] Other risk factors leading to the dysregulation of cerebral blood flow and neurovascular coupling, such as hypertension, atherosclerosis, and stroke, are needed to be accomplished in the next generation of VD models.[150–152]
- Environmental risk factor-driven dementia-on-chip: here, we described a few examples of microfluidic platforms for the study of ERFDs. Further studies are needed to develop chip-based platforms connecting the brain to other organs reconstituting not only the entry pathways but also neurodegeneration driven by the external risk factors. In the previous section, we introduced a few examples of promising multi-organ systems providing the entry pathways of external risk factors.

Overall, we envision that brain chips would offer versatile platforms to simulate physio-pathologically relevant CNS disorder conditions and powerful model systems to analyse the underling mechanism of complex disease progression; otherwise, such applications are limited by using conventional *in vitro* or *in vivo* models.
