Stimuli-responsive structure–property switchable polymer materials

Zhuang Mao Png,^a Chen-Gang Wang,^{†a} Jayven Chee Chuan Yeo,^{bc} Johnathan Joo Cheng Lee,^b Nayli Erdeanna Surat'man,^a Yee Lin Tan,^{bd} Hongfei Liu,^b Pei Wang,^b Beng Hoon Tan,^b Jian Wei Xu,^{id*abc} Xian Jun Loh^{id*ab} and Qiang Zhu^{id*abe}

The development of polymeric materials with switchable properties upon exposure to external stimuli such as light, heat, force, acids/bases, and chemicals has attracted much attention due to their potential applications in smart coatings, drug carriers, soft robotics, etc. Thus, a systematic understanding of the relationship between the chemical structures and stimuli-responsive properties as well as the corresponding mechanisms of switchable stimuli-responsive polymers is important to guide the sophisticated design of functional macromolecules for specific applications. In this review, we outline the representative chemical structures that enable reversible structural switching to be achieved under photo-, mechano-, CO₂- and chemo-stimuli, with a brief discussion on thermo- and pH-activation. Polymer materials containing these chemical moieties exhibit unique behaviours on changing their mechanical, thermal or photochemical property in a switchable manner, and their applications in healing materials, rewritable surfaces, drug delivery carriers, conductive hydrogels and luminescent materials are highlighted. Based on the comprehensive summary of structural switchable moieties and applications of polymer materials, this review gives insight into how bottom-up approaches can be used to inspire the future design of switchable multi-stimuli-responsive polymer materials.

Design, System, Application

Stimuli-responsive polymers are promising materials whose properties can be controllably and predictably changed by external stimuli and have a wide range of applications including molecular sensing, drug carriers, coatings, artificial muscles, and thermoelectric materials. At the heart of these materials are the moieties that alter their chemical structure in response to an external stimuli, resulting in a change in macroscopic properties such as colour, morphology, and phase transition temperature. This review covers the design of polymers responsive to six different stimuli (light, pH, thermal, force, CO₂, and redox), with a section regarding polymers responsive to multiple stimuli also included. This review is structured according to the key enabling functional groups and discusses tuning of the properties of polymers by changes in their position or chemical structure. We believe that this class of polymers will see greater utilization with the maturity of this field, with a more extensive library of stimuli-responsive moieties.

1 Introduction

In the past two decades, major efforts have been devoted to creating on-demand stimuli-responsive materials to mimic natural systems.^{1–4} Stimuli-responsive polymers are a class of promising “smart” materials that are capable of altering their properties when triggered by external stimuli in a controllable manner.^{1,5–8} Depending on the polymer structure, the triggering stimuli can be physical (temperature, light, mechanical force, magnetic field, electric interaction, etc.), chemical (pH, redox, molecules, supramolecular interaction, etc.) or biological (enzyme, etc.). Due to their versatile stimuli-responsive functions and cost-effective preparation, smart polymer materials, such as nanoparticles, films and hydrogels, are attracting great interest for extensive

[†] These authors contributed equally.

applications such as drug carriers, coatings, molecular sensing, artificial muscles, and thermoelectric materials.^{9–14}

Among the stimuli-responsive polymers, reversibly switchable smart polymer materials and surfaces can achieve reversible “on–off” switching to tune their structures and properties several times.^{9,15,16} In nature, several creatures, *e.g.*, cuttlefish, chameleon and gray treefrog, are masters at reversibly changing their appearance such as colour and pattern in response to their surrounding environment.^{17–19} These reversible transformation features can be attributed to pigment translocation or molecular switch in their chromatophores, allowing them to mimic their background environments. Additionally, biopolymers such as proteins and nucleic acids extensively exist in living organic systems and undergo conformational changes to modulate and maintain physiological parameters. Consequently, these stimuli-responsive creatures and biomacromolecules have inspired scientists to develop various synthetic polymeric materials to mimic their adaptive behaviours.^{20–22}

Although pigment translocation still lacks applications in materials science, molecular switching is a promising and effective approach to endow materials with switchable physical and chemical properties. Many reversibly switchable molecules, such as photochromic molecules, host–guest molecule pairs, and mechanically interlocked molecules, have been developed and found many applications.^{23–28} In recent years, design at the molecular level by exploiting reversibly switchable molecules has enabled the synthesis of functional monomers, and then polymers to produce novel polymeric materials with unique stimuli-responsive behaviors.^{9,10,16} Many applications of reversibly switchable polymers have been found to control the appearance of materials or serve as a release system.

Herein, we attempt to summarize the numerous stimuli-responsive building units and how they alter their conformation or geometry reversibly in a polymer chain, and subsequently used to construct switchable polymer materials with stimuli-responsive functional groups and their reversibly conformational or geometric changes in a polymer chain to construct smart materials with switchable properties. Beyond the well-studied reversible phase transition behaviors *via* intermolecular hydrophobic interactions (*e.g.*, lower critical solution temperature (LCST) and upper critical solution temperature (UCST)) or supramolecular interactions, polymers with reversibly switchable chemical structures through isomerization, cyclization, ionization and bond cleavage are highlighted. Furthermore, structure-switchable functional groups triggered by various stimuli, including photo, mechanical, carbon dioxide (CO₂) and redox, are catalogued to express their structure transformation mechanisms, while thermal- and acidic/basic (pH)-responsive polymers will be briefly discussed. Subsequently, polymeric materials containing switchable functional groups are introduced to demonstrate their state-of-the-art applications and structure–property relationships. Examples of the combination of different stimuli-responsive functional groups to develop dual- or multiple-stimuli-responsive polymeric materials and surfaces

are also introduced. Finally, we address the remaining challenges and outlook for the future development of reversibly switchable smart polymeric materials.

2 Polymers with switchable structures and their applications

2.1 Photo-responsive polymers

As representative polymers,^{29,30} photo-responsive polymers are polymers that can respond to light, leading to a reversible change in either their conformation or chemical structure. They have a variety of potential applications ranging from drug delivery to actuators and self-healing materials. Some of the key photo-responsive chemical structures include azobenzene, diarylethenes, spiropyrans and disulfides. These moieties impart different photo-responsive properties to polymers. For instance, *cis–trans* isomerism can modulate the crystallinity and glass transition temperature (T_g) of polymers. Meanwhile, diarylethenes and spiropyrans can change their colour and fluorescence. In this section, we review photo-responsive polymers with emphasis on how changes in their chemical structure modulate their properties.

2.1.1 Azobenzene. The most common light-responsive moiety is azobenzene. Its *cis* isomer and photo-induced conversion were reported in 1937,³¹ and subsequently extensive research has focused on its properties and applications.³² *Trans* azobenzene, the thermally favoured isomer, is converted to *cis* azobenzene upon exposure to UV irradiation, while the reverse can be mediated by exposure to either visible light or thermally in the dark (Fig. 1a).³³ It has been found that this process is highly sensitive, and both its rate and quantum yield can be influenced by the solvent, temperature, substituents on the phenyl ring, and irradiation wavelength. As many as four different mechanisms have been postulated (rotation, inversion, concerted inversion, and inversion-assisted rotation), with multiple pathways being used to explain empirical observations.³⁴ More recently, progress has also been made in achieving *trans* to *cis* conversion *via* visible light irradiation, either by direct functionalisation of the azobenzene ring,^{35,36} extended conjugation,³⁷ or photo upconversion strategies.³⁸ This has enabled photo isomerism to be achieved without exposure to harmful UV rays, which is particularly important in the case of biological applications. Azobenzene and its derivatives are also often used because they are stable and do not exhibit significant side reactions.³⁹ Some of the azo-benzene containing polymers are shown in Fig. 1b.

The *cis–trans* transition of azobenzene has been used to modulate the fluorescence of polymers. Kuehne's group reported the preparation of a series of light-modulated monodisperse conjugated polymer particles.⁴⁰ Azobenzene was conjugated with fluorene *via* Suzuki–Miyaura polymerisation and grafted on a poly(vinylpyrrolidone-*co*-vinyl acetate) (PVPVA) nucleus (**P2a–c**). In the case of **P2a**, given that the *trans* to *cis* switching occurs along the polymer backbone, large-scale motion is required. In contrast, for

Fig. 1 (a) *Cis* and *trans* isomers of azobenzene. (b) Examples of polymers containing azobenzene units.

both **P2b** and **P2c**, the *trans* to *cis* switching only resulted in movement of their side chain, while **P2c** is completely non-conjugated with the polymer backbone as the azobenzene moiety is separated from the polymer backbone by the alkyl chain. Upon exposure to UV, the fluorescence of all three polymers shifted from about 450 nm to 600 nm (Fig. 2a). This was attributed to the non-radiative decay in the *trans*-configuration, which is significantly reduced in the *cis*-configuration, although the mechanism was not fully understood.⁴¹ The fluorescence switching was significantly slower for **P2a** compared to **P2b** and **P2c** because the entire polymer backbone needed to move, which is due to the fact that the fluorescence switching of **P2a** is triggered by the conformation change of the entire **P2a** polymer backbone. Consequently, the *cis* to *trans* transition for **P2a** was not fully reversible. As another example, in the work by Ren and co-workers, they prepared an amphiphilic diblock copolymer, **P2d**.⁴² The fluorescence of the polymer was sensitive towards pH, temperature and UV. In its neutral and basic conditions, the fluorescence of the polymer increased upon exposure to UV light, corresponding to the photo-isomerism of the azobenzene from *trans* to *cis*. Alternatively, under acidic conditions, only a slight increase in fluorescence was observed. This was due to the highly aggregated structure under acidic conditions, which inhibited the *trans* to *cis* photo-isomerism.

In principle, the *cis*–*trans* transition can lead to a change in the melting point of azobenzene and the glass transition temperature (T_g) of polymers with azobenzene moieties. Although the melting points of the *cis* and *trans* isomers with unfunctionalized azobenzene only differed by 3 °C, (68 °C for

trans and 71 °C for *cis*),⁴³ polymers with azobenzene carrying long alkoxy chains can exhibit significantly higher differences

in melting point, with photo-induced liquefaction observable.⁴⁴ As early as the 1980s, the photo-responsive properties of azobenzene-containing polymers have been reported, and a change in viscosity upon irradiation was also noted upon exposure to UV light.⁴⁵ However, a change in T_g upon irradiation has only recently been reported.

Wu's group also reported the preparation of an azobenzene-containing polymer **P2e** via reversible addition-fragmentation chain-transfer (RAFT) polymerization.⁴⁶ **P2e** was a hard solid at room temperature with a T_g of about 48 °C. Upon exposure to UV light, the surface of the polymer liquefied despite remaining at a temperature of only 28.5 °C. The T_g of the generated *cis* isomer was measured to be around -10 °C. Upon illumination with 530 nm visible light, the liquid polymer turned back into a solid, corresponding to the *cis* to *trans* isomerism. These types of materials can possibly be useful for repairable coatings or photo-switchable adhesives. However, at present, the liquefaction of bulk materials is still difficult to achieve due to the limited penetration of UV light (molar absorptivity of azobenzene is about $2.0 \times 10^4 \text{ mol}^{-1} \text{ L cm}^{-1}$ at 365 nm).⁴⁷ These polymers were also found to exhibit actuation properties, bending towards a UV light source, but returning to their original shape upon exposure to blue light.⁴⁸

The *cis-trans* photo-isomerism of azobenzene can also produce mechanical responses. Koyama's group reported the preparation of a dodecyl glyceryl itaconate polymer crosslinked with a *meta*-methylazobenzene-containing moiety to form a liquid crystalline network, *i.e.*, **P2f**.⁴⁹ This polymer exhibited a T_g of 29 °C, which was reduced to 16 °C upon exposure to UV irradiation, with a corresponding decrease in

Young's modulus from 140 MPa to 65.6 MPa. However, exposure to visible light restored the T_g within 2–4 seconds, enabling efficient photomechanical actuation. Exposure to UV light (354 nm) resulted in film bending towards the light, while exposure to blue light (465 nm) restored its flatness (Fig. 2b). The light intensity was also correlated with the bending speed. The mechanism of this bending was postulated to be due to the differences in the degree of absorption of photons between the front surface of the polymer and the back surface, which resulted in a difference in T_g between the front and the back of the film, with the inner strain causing the bending. As another example, in the work by Zhao and Xia, they prepared dodecanedioic acid-based epoxy networks, **P2g**.⁵⁰ The networks were dynamic under high temperature in the presence of a catalyst, making them reprocessable and vitrimeric.⁵¹ The UV-induced torque could drive a cylinder and a "vehicle", with no apparent degradation even after 100 rotations. Hayward's group also reported the preparation of an acrylate-thiol based polymer, **P2h**.⁵² Actuation behaviour was observed upon illumination with UV light even at 25 °C, but was found to be reversible upon exposure to green light only at temperatures above 60 °C.

2.1.2 Diarylethenes. Photochromic diarylethenes (Fig. 3a), which were first reported in 1988,⁵⁵ are photochromic molecules that can undergo 6π -electron cyclisation upon exposure to UV light and reversibly return to the initial opening isomer upon irradiation with visible light.⁵⁶ Unlike azobenzene, this transition is usually thermally irreversible. The 2-aryl position is often substituted to prevent oxidative aromatisation. This transition often leads to significantly

different frontier molecular orbital levels, resulting in a change in colour, fluorescence, and even electrical conductivity and electroluminescence in the case of conjugated polymers with such diarylethene units.⁵⁷ Therefore, they have received significant attention in photo-tunable optoelectronics. Hetero-aryl groups, such as dithienylethenes, are also often used in place of phenyl rings to improve the stability of the closed ring form.⁵⁸

The thermal stability of diarylethenes was used to control the reversibility of the Diels–Alder reaction in an adhesive material.⁵⁹ Polymer **P2i** (Fig. 3b), was prepared by Diels–Alder reaction between the furan and the maleimide groups, forming a dithienylethene moiety. The Diels–Alder reaction was reversible by heating the polymer to 90 °C, resulting in a decrease in adhesion strength. However, upon exposure to 312 nm UV light, 6 π -electron cyclisation occurring, resulting in the disappearance of the double bond of the diarylethene and preventing the occurrence of the reverse Diels–Alder reaction. Consequently, even when the polymer was heated to 90 °C, the adhesion strength did not decrease. This also demonstrated the thermal stability of the closed-ring configuration. Upon exposure to visible light (>435 nm), the reverse open-ring reaction occurred, allowing the reverse Diels–Alder reaction to proceed when heated.

Another application of photochromic diarylethenes is in photochromic films. Gu's group prepared an dithienyl-containing polyimine as a conjugated polymer network (**P2j**).⁵³ The yellow polymer solid turned olive green upon exposure to UV light (365 nm) for 50 s, which was reversed by exposure to visible light (>500 nm) in about the same time. This is relatively fast compared to other polymers, which require more than 2 min to undergo the same change. Upon repeated cycling, a small amount of weight loss was observed (~5%), but the overall physical structure of the polymer film was found to be stable. The composite films prepared by dispersing **P2j** in a PMMA matrix were found to undergo the same transition as the neat polymer (Fig. 3c). Another example of photochromic polymers was demonstrated by Bianco's group.⁶⁰ Six different variations of diarylethenes were prepared to examine the effect of functionality, and combined with dicyclohexylmethane 4,4'-diisocyanate to form polyurethanes. Interestingly, a linear relationship was observed between the molar extinction coefficient and the peak wavelength of the closed-ring form. Recently, Yagai's group also demonstrated the potential of diarylethene to control the folding of polymers⁵⁴ by making use of the difference in π - π stacking between the ring-closed and ring-opened form of diarylethene. Supramolecular polymers of **P2k** were prepared by cooling hot methylcyclohexane solution to obtain randomly coiled polymers. However, polymer **P2k** adopted a helical structure, as evidenced by the AFM imaging when the polymer was irradiated with UV light (293 nm), while upon cooling, AFM imaging showed that helical structures were adopted (Fig. 3d). In contrast, the polymer preferred a random supramolecular structure when exposed to visible light (620–645 nm).

Stilbenes are another class of diarylethenes that exhibit photo-responsiveness (Fig. 3a), though their mechanism differs from that of dithienylethenes given that they undergo *trans* to *cis* photo-isomerism similar to azobenzene. One example of this is in Harada's work, where they installed stilbene into a “daisy chain” crosslink.⁶¹ The *trans* to *cis* transition resulted in a significant change in polymer length, allowing for muscle-like contraction and expansion of the polymer, mediated by selective photoirradiation.

2.1.3 Spiropyran. Photochromic spiropyrans, which were first reported by Fischer and Hirshberg in 1953,⁶² can cleave their C–O bond upon irradiation with UV to form a ring-opened merocyanine form (Fig. 4a).⁶³ Besides a change in colour, this reversible transition upon exposure to visible light also results in a change in dipole, polarity, and even molecular volume.⁶⁴ There is no conjugation between the two halves of the spiral given that they are orthogonal to each other. Consequently, the spiropyran form is neutral, non-polar and can absorb light typically in the UV region. Meanwhile, the merocyanine form is conjugated and has a significant dipole moment, which can be changed in

Fig. 4 (a) Light-driven conversion between spiropyran and merocyanine forms. (b) Light-responsive spiropyran-containing polymers. (c) Effect of pH, UV and elevated temperature on release of doxorubicin from polymer **P2k** micelles.⁷⁰ Reproduced from ref. 70 with permission. Copyright 2020, Elsevier.

response to pH. This merocyanine form is typically strongly coloured and can absorb light in the visible region.⁶⁵ In addition, spiropyrans can also be responsive to redox and temperature changes depending on whether they contain any specific functionality.⁶⁶

Exploiting the difference in molecular volume and charge between the two forms of spiropyran, the light-driven expansion of hydrogels has been explored by Stupp's group.⁶⁷ Sulfonate groups were included in spiropyran to increase its water solubility, while the methacrylate group was added to enable free radical polymerization. Subsequently, the spiropyran methacrylate was co-polymerized with oligo(ethylene glycol) methyl ether methacrylate and *N,N'*-methylenebis(acrylamide) as a crosslinker to form **P2I** (Fig. 4b). When irradiated with light, the charge density of the polymer increased, allowing water to enter the polymer network, and then swelled up to 30%. Other examples of spiropyran-based hydrogels demonstrating actuation include the work of Sumaru⁶⁸ and Florea.⁶⁹

Spiropyrans have also been explored in drug delivery systems. For instance, Salami-Kalajahi and Roghani-Mamaqani's group prepared a poly(methyl methacrylate)-*b*-poly(*N*-isopropylacrylamide) block copolymer with spiropyran as the end group (**P2m**).⁷⁰ Doxorubicin (DOX, a chemotherapy drug) was loaded in the self-assembled **P2m**, and its release was examined under different pH values and UV irradiation. Less than 30% doxorubicin release was observed in neutral conditions, while 60–85% of DOX was found to be released in acidic and elevated temperature conditions (Fig. 4c). Alternatively, under UV irradiation, DOX release was found to be the fastest, with almost 100% release after 2 days, demonstrating the potential of light control for drug release. However, in this case, UV light as the trigger is suboptimal due to its lack of penetrative power, cytotoxicity and mutagenic effects on cells. A more elegant solution is the use of NIR up-conversion to provide stimuli for the ring opening. Some efforts have been reported making use of lanthanides nanoparticles to facilitate the up-conversion.^{71,72}

2.1.4 C=C *cis-trans* photo-isomerisation. Stereochemical control of polymers is a well-established approach towards controlling their properties. For instance, Hirabayashi prepared a succinic anhydride–propylene oxide polymer comprising predominantly *Z* isomer.⁷³ When isomerised into the *E* form in the presence of morpholine, the polymer exhibited higher crystallinity, higher bio-degradability and higher *T_g*. However, unlike the well-documented *cis-trans* photo-isomerism of azobenzene, the corresponding *cis-trans* photo isomerism in C=C bonds is much less common. In this area, the common synthetic approach is co-polymerization and cyclization.^{74–76}

In 2019, Lu's group reported an example of *cis-trans* photo isomerism in polymers (Fig. 5).⁷⁷ Ethylene oxide and maleic anhydride were co-polymerized to form **P2n** predominantly in the amorphous *cis* form. Upon treatment with diethylamine, the double bond isomerised to the more thermodynamically stable *trans* form, which was crystalline

Fig. 5 (a) Photo *cis-trans* isomerisation of polymers with corresponding modulation of their crystallinity.⁷⁷ (b) Ring-opening polymerisation to form **P2o**, which could be photo-isomerised into the *trans* form. in nature. Subsequently, irradiation with UV light in the presence of benzophenone for 5 h resulted in about 30% conversion from the *trans* to *cis* isomer, accompanied by the corresponding loss of crystallinity. Another example in the same year is the work by Buchard's group.⁷⁸ Polycarbonate **P2o** was prepared by ring-opening polymerization to obtain the predominantly *cis* form. This was isomerised into the more thermodynamically stable *trans*-form (52% after 68 h) upon exposure to UV light at room temperature in the presence of CuI. The *trans* isomer was a viscoelastic solid, while the *cis* isomer was a powder, demonstrating a practical approach to changing the properties of polymers by exposure to UV light. However, unlike the other polymers discussed, this isomerism has not been reported to be reversible.

2.1.5 Anthracene and coumarins. Another mechanism of photo-responsive moieties is photodimerization such as that exhibited by anthracenes [4 + 4], and coumarins [2 + 2] (Fig. 5c). This mechanism is useful for controllable crosslinking of polymeric networks, such as in the work by Saito *et al.*,⁷⁹ where they made use of anthracene to reversibly crosslink epoxy networks, enabling light-mediated healability. He's group also achieved similar results using coumarin as a photocrosslinker.⁸⁰ Pleasingly, these photodimerization reactions can often be controlled by modulating the wavelength of the incident light, with longwave UV (~355 nm) promoting the dimerization, while shortwave UV (~265 nm) promotes bond cleavage.

2.1.6 Disulfide linkage. Disulfides bonds are known to undergo homolytic photocleavage to form sulfenyl radicals, which is commonly exploited in dynamic covalent networks. Kessler's group prepared an epoxy network comprising 4,4-diglycidylazobenzene, sebacic acid and 4,4-dithiodibutryic acid (**P2p**, Fig. 8).⁸¹ The resultant polymer exhibited a smectic liquid crystalline structure. The number of disulfide bonds was limited to just 10% to prevent the polymer from being over-dynamic, which reduced the stability of the liquid crystalline phase. The azobenzene moiety imparted photo-induced shape memory and actuation properties, while the disulfide bonds enabled photo-induced

Fig. 6 Disulfide-mediated self-healing of P2m. Reproduced from ref. 81 with permission. Copyright 2017, The Royal Society of Chemistry.

self-healing within 3 min (Fig. 8). In another example reported by Gautrot, disulfide bonds were used as a crosslinker to prepare a hyaluronic acid-based hydrogel.⁸² Similar to P2p, the polymer exhibited photo-induced self-healing, showing that the broken sample could be welded by adding a photo-initiator, followed by irradiation with UV light

for 2 min. Some weakening of the material was observed compared to the pristine sample although the polymer was strong enough to be handled without special precautions (Fig. 6).

2.2 Force-responsive structure

In recent years, there has been a growing interest in polymers that can transduce mechanical inputs into specific chemical transformations. The resultant chemical responses can be categorised as either scissile (*i.e.*, covalent bond-breaking reactions) or non-scissile (*i.e.*, non-covalent bond disruptions and conformational changes) transformations.⁸³ By tailoring the composition, types and positions of mechanophores (mechanically activated chemical groups) on the polymer chain, the mechanoresponsive behaviour of these materials can be programmed at a molecular level. In addition, the mechanochromic behaviour displayed by many mechanophores further highlights their potential to be used for the accurate detection of stress.⁸⁴ In this section, we elaborate on the force-induced structural transformations of different chemical structures, including pyran derivatives, supramolecular assemblies, and other emerging structures.

2.2.1 Pyran derivatives. Pyran derivatives, such as spiropyran and naphthopyran, are some of the most studied mechanophores. Through a 6-electron electrocyclic ring-

opening reaction, the weak C–O bond in the pyran ring can be broken. This transforms the ring-closed pyrans to the ring-opened merocyanine, displaying mechanochromic behaviour in the process.⁸⁷ Depending on the combination of the polymer chain attachment points and the nature of the substituents, the threshold force required to induce this transformation can be altered.⁸⁸

Qiu *et al.* fabricated 6-nitro-spiropyran mechanophores with different attachment points (Fig. 7a).⁸⁵ The threshold activations were found to occur at ~60% strain and 4–7 MPa stress (Fig. 7b). This activation resulted in the appearance of absorption peaks at 500–650 nm, corresponding to the formation of merocyanine. A rapid decrease in absorption strength was recorded as the unloading of compressive strain gradually increased from 62%, showing that the polymers possessed a reversible mechanochromic response (Fig. 7c). Although both electronic and geometric effects influenced the mechanochromic behaviour of the mechanophores, the latter was found to be the dominant factor. Osler and co-workers investigated the mechanochemical reactivity of isomeric 2*H*-

and 3*H*-naphthopyran mechanophores using solution-phase ultrasonication experiments and in crosslinked polydimethylsiloxane (PDMS) elastomers (Fig. 7d).⁸⁹ The ring-opening reaction of the 2*H*-naphthopyran substrate was found to produce a red merocyanine dye ($\lambda_{\text{max}} = 485$ nm), while the 3*H*-naphthopyran formed a yellow merocyanine ($\lambda_{\text{max}} = 440$ nm) upon mechanical activation. The yellow dye in the 3*H*-naphthopyran polymer faded completely after 10 min of force removal, returning to the original colourless state. In contrast, the reddish colouration in the 2*H*-naphthopyran polymer was more persistent, taking a longer time to fade after the stress relaxation and still being visible in the pristine film (Fig. 7e), showing the greater stability of the merocyanine compound formed from the 2*H*-naphthopyran.

2.2.2 Supramolecular assemblies. Supramolecular assemblies, which consist of self-organising complexes held together by non-covalent bonds, often exhibit superior mechanoresponsive behaviour, with a high level of sensitivity to mechanical forces. In these assemblies, the breakage of the weak non-covalent bonds, *e.g.*, van der Waals

interactions, hydrogen bonding, and π -stacking interactions, between complexes triggers a structural transformation. Compared to other mechanoresponsive polymers, which rely on the breakage of covalent bonds in the mechanophores, supramolecular assemblies are advantageous in being more sensitive due to their lower activation energy as well as having generally higher reversibility.^{88,90–93}

Sagara's group investigated the mechanoresponsive behaviour of rotaxane-based supramolecular mechanophores.⁹⁴ The rotaxane mechanophores were composed of a luminophore-containing ring, which was threaded onto an axle with a matching quencher and two stoppers (Fig. 8a). Reversible fluorescence changes were observed even after 50 loading and unloading cycles due to the molecular shuttling of the mechanophores. An increase in fluorescent intensity was measured under the uniaxial deformation, but immediately reversed when the deformation was released (Fig. 8b). However, when excessive force was applied at the strain of 600%, the ring with the luminophore slipped past the stoppers, permanently breaking the mechanical bond. This dethreading resulted in an irreversible fluorescence change. The same group recently reported the fabrication of a cyclophane-based mechanophore containing two fluorescent 1,6-bis(phenylethynyl)pyrene moieties (Fig. 8c).⁹⁵ The pyrene moieties could form an excimer with an emission around the wavelength of 530 nm, whereas the pyrene monomer emission was at 470 nm, which a induced colour change based on the mechanophore assembly structures. Excimer emission dominated the emission spectra of the dilute solutions with a low composition of cyclophane mechanophore (0.8 wt%) and polyurethane elastomers. Upon deformation, conformational changes occurred in the polymer, leading to a greater monomer emission. This phenomenon was observed when the mechanophore was covalently embedded in a linear, segmented polyurethane elastomer, and the film produced exhibited a distinct colour change from cyan to blue at a strain of 600%.

Imato and co-workers developed mechanoresponsive supramolecular polymers using fluorescent pyrene and naphthalene diimides incorporated in the mid-chain of poly(ϵ -caprolactone)s.⁹⁶ With no mechanical stimuli, fluorescence quenching occurred as the pyrene formed an intramolecular charge transfer complex with the naphthalene diimides. The application of force triggered the dissociation of the complex, leading to strong fluorescent emission.

Tetraarylsuccinonitrile is the another mechanoluminescent moiety that can generate colored radicals using mechanical stimuli. Otsuka's group introduced a tetraarylsuccinonitrile moiety at the crosslinking points of a polymer gel.⁹⁷ After freezing the polymer gel, the swelled solvent induced homolytic dissociation of the central carbon-carbon bond of the tetraarylsuccinonitrile skeleton, resulting in not only a color change but also light emission of the gel (Fig. 9b). The structure change and mechanoluminescence were reversible upon heating and freezing the gel. The same

group also introduced tetraarylsuccinonitrile functions into polystyrene and silsesquioxane composite elastomers, which allowed the materials to display reversible mechanofluorescence upon grinding.^{98,99}

Lin *et al.* incorporated a cyclobutane mechanophore on a polymer backbone as a mechanical gate to regulate an acid-sensitive ketal.¹⁰⁰ Given that both the mechanical load and chemical trigger are required to achieve significant molecular weight degradation, this allowed the polymer to retain its degradable properties, while building resistance to unintended degradation (Fig. 9c). The integrity of the polymer backbone was maintained in the presence of only a chemical trigger using trifluoroacetic acid. However, upon the application of a mechanical load through ultrasonication,

polymer degradation occurred to an apparent limiting molecular weight of 28 kDa. When the two stimuli were combined, an 11-fold decrease in molecular weight to 2.5 kDa was achieved. Although the bond cleavage was not reversible, the design and introduction of a mechanophore enabled the polymer chains to exhibit unique degradation functions.

2.2.3 Other force-responsive polymers. Recent developments have led to the emergence of other novel mechanoresponsive structures. Qian *et al.* employed an oxazine-based mechanophore scaffold to create a fast and reversible force-responsive material.¹⁰¹ Unlike conventional spiropyran and naphthopyran mechanophores, oxazine undergoes a purely ring-opening reaction with no double-bond isomerism involved during its mechanical activation. This process formed coloured zwitterion species, which reverted to the initial state orders of magnitude faster than the merocyanine to spiropyran and naphthopyran transformation (Fig. 9a). The threshold activation strain of the oxazine mechanophore in the bulk polydimethylsiloxane varied in the range of ~90–125%. No phase lag or response fatigue was observed even after 8 continuous loading–unloading cycles.

2.3 CO₂-responsive structure

Carbon dioxide-switchable polymers are stimuli-responsive polymers that employ CO₂ as the primary triggering mechanism to alter and reversibly switch the polymer properties. For instance, controlling the degree of hydrophobicity in the presence of CO₂ (hydrophilic) or the absence of CO₂ (hydrophobic). Incorporating CO₂-switchable

components has gained much attention in recent years due to their unique advantages including abundance, non-toxic and environmentally friendly nature with no accumulation of chemical species, rapid response, good penetration depth and low cost.^{102,103} Most importantly, the excellent precision to control and manipulate the polymer chain structure allows great versatility and autonomy. Generally, this strategy revolves around the design and tailoring of the polymer chain structure of CO₂-responsive materials in terms of their functionalities, as shown in Fig. 16. The various types of CO₂-responsive functionalities are composed of copolymers of various compositions, as well as hybridized with functional nanomaterials to form composites.^{102,104}

Among the polymerisation strategies, atom transfer radical polymerisation (ATRP) is typically preferred due to its low impurities, simplicity, and controlled polymer growth. Generally, this polymerization involves chemical functionalization of the precursor and polymerization of the CO₂-responsive monomer to form a CO₂-responsive copolymer. CO₂-responsive copolymers have huge potential for application in catalysis, nanoreactors, switchable surfactant/stabilizers, drug delivery, and separation.¹⁰⁵ Alternatively, hypoxia-responsive polymers are also highly relevant in biomedical applications such as tumor treatment.¹⁰⁶ In this section, we discuss the most recent development of CO₂-responsive polymers, their mechanism, and their applications.

2.3.1 Guanidine. Guanidine is an amine derivative that contains three nitrogen groups (two ‘amides’ and one

stability of its conjugated acids. Generally, guanidines undergo a protonation reaction upon CO₂ simulation and are converted into guanidinium species. However, the deprotonation reaction can only be achieved by heating instead of inert gas bubbling (Ar or N₂) due to their high pK_a value.¹⁰⁷ For instance, Lowe and co-workers developed a polyarginine homopolymer and block copolymer *via* a two-step modification including RAFT polymerization and post-polymerization modification. Interestingly, the copolymer reversibly formed micelles under N₂ and dissociated into a linear chain under CO₂ exposure in an aqueous medium.¹⁰⁸ In another work, Theato and Schattling synthesized a random copolymer of various L-arginine and acrylamide using a similar two-step modification and discovered its dual temperature and CO₂-responsive behaviors. The copolymer exhibited a reversible hydrophilic/hydrophobic performance under CO₂ or Ar exposure, which can be utilized in drug delivery systems, sensors, and even as “smart” CO₂ trapping surfaces.¹⁰⁹

2.3.2 Amidine. Amidine contains two nitrogen atoms in the ‘amide’ and ‘imine’ functional groups in its structure, which resembles carboxylic acids and has an average pK_a value of ~9.0 (in the range of 5–12). As shown in Fig. 10, the protonation reaction converts the imino nitrogen to a symmetrical amidinium ion, which can be stabilized by resonance. In general, the stronger basicity of amidine groups causes the equilibrium constant between CO₂ and amidine to be substantial ($K_{\text{IE}} = 102\text{--}105$), leading to higher CO₂ sensitivity and responsivity. Jessop and co-workers first reported the preparation of CO₂-responsive aliphatic amidine-containing surfactants in 2005.¹¹⁰ Subsequent work by Yan *et al.* synthesized an amidine-based copolymer *via* ATRP of the difunctional monomer (*N*-amidino)dodecyl acrylamide (AD). These tuneable drug delivery vesicles exhibited smart expansion and contraction cycles upon CO₂ stimulation with controlled-release capability.¹¹¹ Guo and co-workers adopted a post-polymerization modification strategy, converting poly(4-chloromethyl styrene) (PCMS) into poly(pazidomethyl styrene) (PAMS) with high amidine functionalities *via* a Cu(I)-catalyzed cycloaddition “click”

reaction. The resultant homopolymers displayed a reversible hydrophobic-hydrophilic evolution in CHCl₃/water when

Fig. 16 Functional groups and chemical changes involved in redox-responsive polymers.

exposed to CO₂ and N₂ in an aqueous medium, showing potential application in sensors, “smart” surfaces, and drug delivery.¹¹¹ However, amidine is highly susceptible to hydrolysis in the absence of a CO₂ environment, which disrupts its self-assembly. Moreover, the complex synthesis of amidines makes them a less preferred choice.

2.3.3 Amine-based copolymers. All amine-based copolymers can react with CO₂ to form the corresponding bicarbonate salts in water, including the bulky primary and secondary amines, and tertiary amines, as shown in Fig. 10. Among them, tertiary amines possess the best CO₂ reversibility and switchability, which is attributed to their weak alkalinity (pK_a = 6.7–8.0).¹¹² The protonation reaction by the bicarbonate anion (pH = 4.0–5.0) can easily occur at ambient temperature, whereas heat is required for primary and secondary amines. Polymers containing tertiary amines can be fully separated in water/THF co-solvent due to their exceptional ionic conversion capability in water. Moreover, the simple manufacturing process and commercial availability of tertiary amines make them the prime choice.¹¹³ Functional monomers with tertiary amines include 2-(dimethylamino)ethyl methacrylate (DMAEMA), 2-(diethylamino)ethyl methacrylate (DEAEMA), and melamine derivative [N²,N⁴,N⁶-tris(3-(dimethylamino)propyl)-1,3,5-triazine-2,4,6-triamine] (MET) and others. These monomers offer great possibility to design CO₂-responsive chain structures by varying their composition/sequence (homopolymers, block, random, alternating, gradient and statistical copolymers), and topologies (graft polymer, hyperbranched, and polymer network). They demonstrated great utilization as catalysts,¹¹⁴ nanoreactors,¹¹⁵ switchable surfactants/stabilizers,^{104,116–121} and membrane separators.^{113,122,123}

2.3.3.1 Poly(*N,N*-dimethylaminoethyl methacrylate) (PDMAEMA). To date, poly(*N,N*-dimethylaminoethyl methacrylate) PDMAEMA and poly(*N,N*-diethylaminoethyl methacrylate) PDEAEMA have been labeled as the perfect

CO₂-switchable moieties and are significantly utilized in many applications. The comparable pK_a value of the amine copolymers to the aqueous medium allows rapid and reversible protonation/deprotonation under alternating CO₂/inert gas stimulations.¹¹³ Despite their small structural difference, Zhao and Yin found that the graphene oxide (GO)/pyrene end-functionalized PDMAEMA (Py-PDMAEMA) nanofiltration membrane performed better than the GO/Py-PDEAEMA nanofiltration membrane. They assembled Py-PDMAEMA on GO sheets through π - π stacking and electrostatic interaction and fabricated the membranes *via* vacuum filtration on a PVDF microfiltration membrane. The hydrophilic PDMAEMA displayed good solubility and extended chain conformation in an aqueous medium regardless of the alternate CO₂/Ar bubbling, which maintained an excellent size exclusion effect and charge property, as shown in Fig. 11. On the contrary, the hydrophobic PDEAEMA collapsed after eliminating CO₂ and covered the GO surface, which resulted in a reduction in the charge property and size exclusion effect of the membranes.¹²³ Zhao and Fan synthesized a random copolymer of poly((*N,N*-dimethyl aminoethylmethacrylate)-*co*-4-methyl-[7-(methacryloyl)oxy-ethyl-oxy]coumarin) (P(DMAEMA-*co*-CMA)) and an amphiphilic diblock copolymer of PS-*b*-P(DMAEMA-*co*-CMA) (PS is hydrophobic polystyrene). The CO₂-responsive single-chain polymeric nanoparticles aggregated and self-assembled into core-shell micelles in water. The reversible protonation/deprotonation reaction of the tertiary amine groups made the SCNPs swell and shrink reversibly under CO₂/N₂ stimulation, showing great potential as effective gas-tuneable nanoreactors.¹¹⁵ Recently, block and random copolymers of DMAEMA and poly(methyl methacrylate) (PMMA) were synthesized through RAFT solution polymerization. The team obtained latexes that could coagulate and re-disperse under alternating N₂ and CO₂ bubbling. They found that the optimum protonation could be achieved by randomizing the MMA content over blocks of MMA. The rapid protonation was contributed by the larger gap between the nitrogen atoms, making them a promising CO₂-switchable stabilizer.¹¹⁶

2.3.3.2 Poly(*N,N*-diethylaminoethyl methacrylate) (PDEAEMA). In addition to the typical applications of amine-based copolymers, gas-enabled self-cleaning membranes have gained immense popularity. For instance, Zhang and co-workers¹²² developed a blend comprised of the CO₂-responsive copolymer polyacrylonitrile-*co*-poly(*N,N*-diethylaminoethyl methacrylate) (PAN-*co*-PDEAEMA) with PAN matrix *via* a phase inversion process. The controllable hydrophilicity/hydrophobicity of the membrane surface dictated its self-cleaning efficiency. Upon CO₂ stimulation, the collapsed hydrophobic PDEAEMA segments instantly transformed into a chain-extended state due to the protonation of the tertiary amine groups. The reaction induced hydrophilicity, which deterred the adsorption of proteins on the membrane surface. Deprotonation of the tertiary amine groups by N₂ bubbling returned them to the hydrophobic state. Remarkably, the cleaning efficiency of this

green strategy is comparable to that of the traditional acid and alkaline cleaning.¹²²

In their recent work, Feng and Jiang¹¹⁸ studied the effects of the chemical structure and segment composition on the topological effect and tendency of the CO₂ response by evaluating the properties of self-assembled micelles, as shown in Fig. 12. They synthesized three types of amphiphilic copolymers based on poly(ethylene oxide) (PEO, hydrophilic component) and DEAEMA (hydrophobic component) in the form of di-block, tri-block, and a novel cyclic structure *via* ATRP polymerization. As illustrated in Fig. 12b, the cyclic copolymer (copolymer 1) possessed the largest particle given that it promoted micelle formation and increased the aggregation of the micelles. A plot of particle size for the different copolymers are also depicted in Fig. 12c corresponding to their treatment times showing that copolymer 1 exhibits the largest particle size.

The same group developed a new strategy to generate lightly crosslinked poly(diethylaminoethyl methacrylate-styrene) [P(DEA-St)] latexes with different PDEA contents *via* one-pot emulsion copolymerization, as displayed in Fig. 13.¹¹⁷ At a high DEA content (98.05 wt%), the latexes switched steadily between swelling and deswelling, which was attributed to the CO₂-reversible protonation/deprotonation reaction of their PDEA portions. On the contrary, a low DEA content (below 13.74 wt%) made the latexes CO₂-insensitive due to the insignificant electrostatic interactions. This crosslinked structure proved to be a promising strategy for other common latexes such as PMMA and PS.^{120,121}

2.3.3.3 Melamine derivative [*N*²,*N*⁴,*N*⁶-tris(3-(dimethylamino)propyl)-1,3,5-triazine-2,4,6-triamine]. Yin and Feng¹²⁴ reported the preparation of a CO₂-stimulated reversible graphene dispersion by non-covalently functionalizing reduced graphene oxide with a CO₂-sensitive melamine derivative, *N*², *N*⁴, *N*⁶-tris(3-(dimethylamino)propyl)-1,3,5-triazine-2,4,6-triamine (MET). They found that the excellent graphene dispersion is attributed to the strong van der Waals interaction between MET and the graphene surface. Reversible aggregation/dispersion could be easily realized by interchanging CO₂ and N₂ bubbling, which manipulated the desorption/adsorption of MET on the graphene surface. This novel gas-triggered aggregation/dispersion smart graphene with controllable stimuli-responsive dispersity demonstrates great potential in the medical and biochemical fields. Recently, the same group developed a biocompatible polylactic acid (PLA) bioinspired honeycomb-like porous film with ON/OFF CO₂ gas-triggered switchable wettability.¹²⁵⁻¹²⁷ This group employed the breath figure method to prepare the non-responsive PLA and CO₂-sensitive MET. The film displayed noticeable hydrophobic-hydrophilic conversion, as shown in Fig. 14. By tuning the PLA/MET ratio, they could precisely position the hydrophilic CO₂-sensitive groups in the inner surface and control the water penetration and wettability of the pore. Consequently, the enhanced surface wettability improved the cell-film interaction and the subsequent cell attachment. The combination of a biocompatible polymer and natural gas trigger allows the

Fig. 17 Schematic representation of synthesis and reduction-induced degradation of S-propranolol molecularly imprinted polymers for drug delivery. Adapted with permission from ref. 146 Copyright 2020, The Royal Society of Chemistry.

preparation of future intelligent materials for biomedical and bioengineering applications.

2.3.4 Carboxyl-based copolymers. Generally, carboxyl has a relatively low pK_a value of ~ 5.0 to 9.0 . It undergoes a protonation reaction upon CO_2 simulation and converts the sodium salt of acid from anionic surfactants to non-ionized erucic acid, as shown in Fig. 10. For instance, Zhang and Feng developed a CO_2 -responsive anionic worm-like micellar system based on sodium erucate.¹²⁸ The protonation/

deprotonation process interchanged between the worm-like micelles and low-viscosity emulsion particles, which is attributed to the reversible conversion of the sodium salt of the erucic acid (anionic surfactant) into the non-ionized erucic acid. In another work, Fischer and co-workers reported the preparation of carboxyl functionalized, CO_2 -switchable nanoparticles *via* surfactant-free mini-emulsion polymerization by employing a reactive surfactant known as surfmer, *i.e.*, *N*-methacryloyl-11-aminoundecanoic acid (treated equimolarly with NaOH).¹²⁹ The obtained latex had a size of about 100 nm with good dispersion. The protonation reaction was carried out *via* CO_2 bubbling to instantly form carbonic acid, which covalently attached onto the surface of the colloid, and could be deprotonated by ultrasonic treatment. In another work by Wang and Zhu, they fabricated zwitterionic crosslinked polymer particles comprising DEAEMA and sodium methacrylate (SMA).¹³⁰ These particles possessed CO_2/N_2 -adjustable isoelectric points in the pH range of 7.5–8.0, and subsequently were used as an emulsifier for Pickering emulsions. The optimization of the cationic amine group and the anionic carboxyl group provides insight for the preparation of future CO_2 -responsive polymer materials.

2.3.5 Lewis acid–base pair copolymers. The most common approach and strategy for the preparation of CO_2 -responsive polymers is by modifying the polymer chain functionalities, as shown in the earlier sections. There has been an increase in the development of innovative dual CO_2 -responsive polymer systems based on the frustrated Lewis pair (FLP) theory in recent years. Stephan and co-workers first introduced this theory in 2006,¹³² where the Lewis acid and base offer latent interactions to connect small molecules such as dihydrogen (H_2) and carbon dioxide (CO_2) to create a connecting (bridging) structure that possesses reversible

Fig. 18 Schematic illustration of the preparation of mPEG-b-PCPT/DOX nanomedicine and the “drug release promoting release strategy” of mPEG-b-PCPT/DOX for synergistic cancer chemotherapy. Adapted with permission from ref. 147 Copyright 2019, The Royal Society of Chemistry.

Fig. 19 Schematic illustration of utilizing selenium-containing nanoparticles to implement combined chemotherapy, radiotherapy, and immunotherapy. Adapted with permission from ref. 155 Copyright 2020, Wiley.

cleavage and re-bonding feature, as illustrated in Fig. 15. For instance, Yan and co-workers demonstrated this theory by adding Lewis acid–base pairs to a polymer, and successfully developed a recyclable nano-catalyst with good activity and recyclability, showing great potential as a wastewater treatment membrane.¹³³

Subsequently, they adopted the same theory and developed a novel polymer system exhibiting ultrafast response, self-healing capability, reversibility, and excellent mechanical robustness. As shown in Fig. 15, this is due to

the bridging of CO₂ in the polymer segment, which subsequently induced assembly in organic solvent systems, demonstrating potential in future gas-sensitive smart materials.¹³¹ In their most recent work, they developed a gel material with a double-crosslinked FLP network comprised of dynamic CO₂ gas-bridged connections and permanent chemical crosslinks by reacting triaryl borane (TB), triarylphosphine (TPP), and CO₂. Notably, the strength and toughness of the gel could be tuned by adjusting the CO₂ content, which dictated the density of supramolecular nodes

Fig. 20 Illustration of the preparation, biodegradable behavior and dual redox-responsive drug release of P(MPC-Se-Se-MPC) nanogels. Adapted with permission from ref. 160 Copyright 2020, Wiley.

in the network. Furthermore, the excellent self-healing stimulated by CO₂ *via* dynamic covalent network reconstruction allows these innovative soft materials to be potentially applied as sensors, actuators, and biomedical devices.¹³⁴

2.4 Redox-induced structure switch

The development of redox-responsive polymeric materials has been dramatically researched over the years to optimize and regulate the delivery and release of encapsulated therapeutic agents, such as doxorubicin (DOX), camptothecin (CPT), and paclitaxel (PTX), especially for tumour treatment. Their environment displays many redox activities involving biological reductants and oxidants, making redox-responsive materials a suitable material for the preparation of drug delivery systems.¹³⁵ The typical redox-responsive species include (i) reactive oxygen species (ROS), (ii) glutathione species (GSH), (iii) ROS + GSH species, and the recent (iv) hydrogen sulphide (H₂S)-based species, as displayed in Fig. 16.¹³⁶ Generally, there are two approaches to incorporate drugs in delivery systems. The first approach involves loading a drug in an amphiphilic micelle assembly, where hydrophobic-hydrophilic conversion is the primary responsive mechanism. The second approach involves incorporating the drug in a polymer chain integrated with a responsive species, where bond cleavage is the main responsive mechanism.¹³⁷

ROS is a highly reactive species made up of a group of oxygen-containing molecules. It is categorized into two types, *i.e.*, the radical type comprised of hydroxyl radical (HO[•]) and superoxide (O₂^{•-}) and the non-radical type comprised of hydrogen peroxide (H₂O₂), HOCl, and singlet oxygen (¹O₂). Among them, H₂O₂ is a popular ROS-responsive material due to its relative stability and longer half-life. A low concentration of these species makes them a useful biological signal in living organisms, while excessive amounts can lead to an imbalance between ROS and antioxidants, which is known as oxidative stress. This oxidative stress damages lipids, proteins, and DNA, adversely leading to physical harm.¹³⁸ Examples of ROS-based species include chalcogen ethers, thioketals, aryl boronic esters, and many others.

Alternatively, GSH is a reduction-responsive tripeptide containing cysteine, glycine, and glutamate. The huge redox potential difference between the intracellular (~10 mM) and extracellular environments (~10 μM) at any concentration make GSH a proper biological signal for intracellular delivery. Most importantly, GSH production maintains the redox equilibrium by balancing the oxidative stress produced by ROS.¹³⁹ Ideally, the employment of both ROS and GSH will be favourable because of the versatility and performance. Besides the typical species, H₂S, the simplest gaseous thiol, has gained attention lately. H₂S exists in deprotonated anion form due to its acidic nature and has demonstrated positive physiological and

pathological effects, especially in encapsulated therapeutics.^{140–142}

2.4.1 Disulfide linkage. A widely used GSH-responsive species, disulfide, is comprised of a sulfur-sulfur (S-S) linkage with a bond energy of 240 kJ mol⁻¹. In the presence of GSH, the disulfide linkage undergoes oxidative cleavage to form thiols, as shown in Fig. 16, contributing to successive drug release. The similarity between the thiol-disulfide exchange reaction to the biological system makes it an ideal drug delivery capsule.¹³⁹ Generally, the disulfide linkage is incorporated *via* various strategies. The first strategy is integrating the disulfide linkage into the main chain, as demonstrated in the recent studies by Ghosh and co-workers.¹⁴³ Their group incorporated a disulfide group into the supramolecular assembly of a protein, bovine serum albumin (BSA), which underwent disulfide linkage cleavage upon GSH exposure. Subsequently, the protein was released, leading to enzymatic activity. In another work, Ju and He designed and fabricated a reduction-sensitive amphiphilic triblock copolymer poly(ethyl ethylene phosphate)-*b*-poly(disulfide)-*b*-poly(ethyl ethylene phosphate) (PEEP-PDS-PEEP) through thiol-disulfide polycondensation and ring-opening polymerization (ROP).¹⁴⁴ The copolymer demonstrated good self-assembly and profoundly released the DOX hydrophobic drug upon reduction-trigger *via* poly(disulfide) scission and dissociation. Recently, Wang *et al.* introduced a disulfide bond into the conjugates of oxaliplatin(IV) and oleic acid (OA) to form a reduction-responsive nanoscale assembly.¹⁴⁵ Similar to previous work, the self-assembly structure underwent disulfide bond cleavage and displayed high anticancer potency and drug efficiency.

The second strategy is by pendant group integration, where a disulfide-containing component is attached to the main backbone of the polymer. For instance, Shen *et al.* attached the disulfide-containing cleavable prodrug monomer camptothecin (CPT) to a methoxy poly(ethylene glycol) (mPEG)-based polymer chain by RAFT living polymerization and developed an amphiphilic copolymer.¹⁴⁷ Besides CPT, doxorubicin (DOX) was encapsulated *via* hydrophobic and π-π stacking interactions. In their work, the co-release of both anticancer drugs was well controlled and demonstrated a synergetic effect with enhanced anticancer efficacy, as illustrated in Fig. 18.

The last strategy is by crosslinking with a cleavable disulfide-containing crosslinker. Bhattacharya and co-workers covalently crosslinked the disulfide group on a polymer chain and reported an excellent drug release profile.¹⁴⁸ In 2020, Zhao *et al.* directly polymerized methacrylic acid with the reductive-sensitive crosslinker bis(2-methacryloyloxyethyl) disulfide (DSDMA) or *N,N'*-bis(acryloyl) cystamine (BAC) using *S*-propranolol as a model template to form a degradable molecularly imprinted polymer (MIP).¹⁴⁶ As shown in Fig. 17, the team found that the MIP-disulfide could readily degrade *via* bond cleavage in a reductive environment and had a better release performance than the traditional ethylene

glycol dimethacrylate (EDMA)-based MIP. This approach can be effectively adopted as an intracellular controlled drug delivery system.

2.4.2 Chalcogen linkage. Chalcogens are chemical elements found in group XIV of the periodic table, which are comprised of sulfur (S), selenium (Se), and tellurium (Te). These three common chalcogens possess similar chemical reactivities and readily undergo oxidation, as illustrated in Fig. 16. However, the difference in their electronegativity and atomic radius influences their oxidation sensitivity and reactivity. The one with the lowest electronegativity, tellurium, has the highest sensitivity, followed by selenium (Se), and lastly sulfur (S). These elements are typically integrated into the main chain and/or within the pendant groups to form various ether-based copolymers such as thioether (S-based), selenoether (Se-based), and telluroether (Te-based), which are activated based on the hydrophilicity of the ether group.

Similarly, telluroether has the highest sensitivity, followed by selenoether, and lastly thioether. For instance, Lee *et al.* developed three ROS-responsive amphiphilic block copolymers based on polycaprolactone (PCL) with selenide and sulfide pendent.¹⁴⁹ As expected, PCL-*co*-selenide demonstrated faster oxidation compared to PCL-*co*-sulfide due to the high sensitivity of selenide. However, it transformed back to its amphiphilic nature after the β -elimination reaction, leading to a poor disassociation and drug release performance. Their result showed that α -ethylthio caprolactone displayed an excellent H₂O₂-induced hydrophobic-hydrophilic transition from ethyl thioether to its sulfoxide. This event resulted in excellent disassembly, demonstrating a promising vesicle for photodynamic therapy.¹⁵⁰

Xu and group intensively researched selenoether-based copolymers. In their recent high-impact work, they successfully developed selenium-containing nanoparticles combining various cancer treatments (radiotherapy, immunotherapy, and chemotherapy), as illustrated in Fig. 19. Seleninic acid was formed upon the cleavage of the diselenide bonds under γ -radiation, which exhibited anticancer activity by upregulating the reROS levels in cancer cells, paving a promising path for simultaneous cancer treatment.^{113,151} The tumor-targeting peptide-modified nanoparticles could actively accumulate in cancer cells through systemic administration. Following radiotherapy, the diselenide portion in the polymer was oxidized to seleninic acid, and the loaded drug DOX was released in the nucleus, realizing its chemotherapy function. The seleninic acid blocked HLA-E expression, and further enhanced the NK cell-mediated immunotherapy by releasing cytokines and lytic molecule (granzyme). Recently, Xu and team employed the hydrothermal process to fabricate carbon-dots with selenium-sulfur dynamic covalent bonds. The Se-S-CDs increased the thioredoxin reductase (TrxR) activity and enhanced the cell viability, demonstrating promising biological applications such as cell culturing.^{27,152,153}

2.4.3 Thioketal linkage. Thioketal is a sulfur-based ROS-responsive group that undergoes an oxidative backbone cleavage mechanism to produce two thiols and a ketone product. Hence, polymers containing this linkage will degrade and dissociate in the presence of ROS, as shown in Fig. 16, and are widely used in drug delivery systems.^{154–157} Wang *et al.* employed the thioketal linkage to develop a pathologically responsive mitochondrial gene delivery vector. Their recent work demonstrated the thioketal-based polymer dissociation by high mitochondrial ROS exposure to release functional DNA genes that improve the gene transfection efficiency and correct genetic abnormalities, showing great discovery in *in situ* mitochondrial gene therapy.¹⁵⁴ In a recent study, Li and Chen developed a thioketal-gated mesoporous silica nanoparticle by grafting ROS-sensitive mPEG on the particle surface. The vancomycin-loaded MSP displayed an excellent controlled release profile through thioketal cleavage. Besides, the antibacterial properties and non-cytotoxicity show its capability as an antibacterial material for wound treatment.¹⁵⁷

2.4.4 Aryl boronic ester. Aryl boronic ester is an ROS-responsive functional group, which is widely utilized in the preparation of H₂O₂-responsive materials due to its selectivity and sensitivity towards H₂O₂. The linkage is usually attached as a pendant group and reacts with H₂O₂ by the backbone breakage or hydrophilicity switch. For instance, Hsu and co-workers synthesized a PCL bearing pendant aryl boronic esters. Exposure to H₂O₂ induced the migration of the aryl group to the oxygen atom, known as nucleophilic addition, followed by the hydrolysis of the borate ester to release phenol, which underwent 1,6-rearrangement. Subsequently, this rearrangement exposed the active phenol group. The copolymer showed high sensitivity to H₂O₂ and good hydrolytic stability, allowing it to be used as a drug delivery carrier. Garcia *et al.* synthesized a diblock copolymer based on a hydrophilic PEG segment and an aryl boronic ester-functionalized hydrophobic polycarbonate segment. They systematically studied the oxidation of nanoparticles and found that the dissociation of aryl boronic ester was highly dependent on the polymer concentration, while the amount of H₂O₂ could control the drug release amount.¹⁵⁸ In recent work, Jager prepared a novel ROS-responsive amphiphilic block copolymer comprised of a hydrophobic boronic ester-based ROS in the hydrophilic backbone. The copolymer yielded either the hydrophilic carboxylic acid or an amphiphilic phenol upon exposure to H₂O₂ and displayed a hydrophilic switch before the controlled drug release.¹⁵⁹

2.4.5 Diselenide linkage. Both oxidation responsiveness and reduction responsiveness can be found in diselenide-based copolymers due to the similar chemical properties of selenium and sulfur. The dual-responsive capability allows diverse applications in both physiological and pathological environments. In addition, the bond energy of diselenide (Se-Se 172 kJ mol⁻¹) is much lower than that of the carbon-selenium bond, C-Se (244 kJ mol⁻¹), and disulfide bonds (S-S, 240 kJ mol⁻¹), making it more reactive to an external

stimulus. These findings were evinced in the work by Luo and Zhang, where (mPEG-PCL-Se)₂ tri-block copolymer micelles showed faster DOX release than the (mPEG-PCL-S)₂ tri-block copolymer micelles.¹⁶¹ In another work, Tsai and co-workers developed a diselenide-linked polymeric nanogel (PEG-Se-Se). They performed the redox-responsive drug release study using 0.1% H₂O₂ and 0.1 mg mL⁻¹ of GSH in PBS buffer with pH of 7.4 at 37 °C. The drug-loaded diselenide nanogel underwent bond cleavage under stimuli (H₂O₂ and GSH), resulting in the release of the encapsulated DOX. The nanogel exhibited good DOX release profiles in the presence of both GSH (reductive) and H₂O₂ (oxidative).¹⁶²

Recently, Tian and co-workers designed 2-methacryloyloxyethyl phosphorylcholine (MPC) with a diselenide bond-containing crosslinker (*N,N'*-bis(methacryloyl) selenocystamine (BMASC)). Copolymerization resulted in the formation of a novel zwitterionic nanogel with an exceptional dual redox-labile property. As illustrated in Fig. 20, the diselenide linkage of the drug-loaded nanogel cleaved and dissociated in the reducing (GSH) and oxidative (H₂O₂) environments. Subsequently, the disintegrated nanogel released the drug effectively. In addition to its excellent release profile, the low leakage and non-cytotoxicity of the nanogel make it a suitable drug delivery carrier.¹⁶⁰

2.4.6 Azide-based linkage. Currently, the bio-orthogonal azido group has been identified as a potential H₂S-responsive copolymer due to its high H₂S-responses, where azide reduction is the primary mechanism. For instance, Zhang and Lin prepared a series of H₂S-trigger *N*-(2-hydroxyethyl)-4-azide-1,8-naphthalimide-ended amphiphilic diblock copolymers, poly(2-hydroxyethyl methacrylate)-*block*-poly(methyl methacrylate) (N₃-Nap-PHEMA-*b*-PMMA-N₃). Upon the introduction of H₂S, the DOX-loaded micelles underwent charge reversal from negative to positive as the

azido functional group reduced. The cellular uptake of DOX-loaded micelles was improved by employing an electrostatic attraction, contributing to the fast DOX release rate for potential tumor diagnosis and therapy.¹⁴⁰

In another work, Yan and Sang created a novel *O*-azido methyl benzoate (AzMB)-containing block copolymer that is highly responsive to H₂S stimulus. As shown in Fig. 21, the cleavage of the AzMB functional group changed the amphiphilicity, leading to controlled dissociation of the self-assembled nanocapsule.¹⁴¹ Similarly, Almutairi and Kawasaki developed a self-assembled H₂S-responsive cholesterol-modified dextran (SC-Dex) nanogel in their recent work. In the presence of H₂S, cholesterol dissociated from the main dextran chain *via* reduction and arrangement of the aryl azide functional group. Subsequently, the nanogel swelled and released the encapsulated protein controllably.¹⁴²

2.4.7 Other redox-responsive polymers. Besides the several linkages mentioned above, other redox-sensitive bonds such as ferrocene-based and polyoxalate-based bonds were incorporated to create redox-responsive polymer delivery systems. Ferrocene is an organometallic chemical compound that is comprised of two coplanar cyclopentadienyl rings bound on opposite sides of a central iron (Fe) atom. These metallocenes are usually ROS responsive, stable, and have an excellent reversible redox property. Hydrophobic-hydrophilic conversion is the primary responsive mechanism, where the hydrophobic ferrocene groups are oxidized into hydrophilic ferricenium upon exposure to ROS. For instance, Xu and co-workers designed a ferrocene-containing amphiphilic block polymer (PACMO-*b*-PAEFC) *via* ATRP, with poly(2-acryloyl oxyethyl ferrocenecarboxylate) (PAEFC) as the hydrophobic component and poly(*N*-acryloyl morpholine) (PACMO) as the hydrophilic component. Under ROS triggering, the reductive ferrocene groups of the PACMO-*b*-PAEFC micelles were converted into the hydrophilic ferricenium, resulting in swelling and releasing the encapsulated drugs. In addition, the oxidative micelles could reversibly convert back upon

reduction by vitamin C, as shown in Fig. 22.¹⁶³ In another work, Höcherl and Jäger¹⁶⁴ synthesized a novel self-immolating H_2O_2 -sensitive biodegradable polyoxalate prodrug *via* a simple one-pot synthesis. The drug molecules were integrated into the backbone of the polymer with responsive polyoxalate bonds. The linkage underwent rapid chain-cleavage in an oxidative environment and effectively released the drugs as required.

2.5 pH-responsive polymers

pH-responsive polymers have great potential to be applied in fields such as drug delivery, although at present, significant limitations in polymer encapsulation-based delivery systems have been observed in clinical trials.^{90,165,166} By carefully strategizing and tailoring the side chains of the polymer, the pH-responsive behaviours of these polymers can be manipulated *via* the bottom-up approach, achieving the appropriate response from the polymer at the chemical environment of the active site.^{9,90,167–171} In this section, the pH-induced structural transformation of several responsive polymers including acid-labile polymers, crosslinking polymers, and zwitterionic polymers will be discussed. Given that there are a myriad of examples of pH-responsive polymers, we aim to highlight a few works and applications. The interested reader is referred to other comprehensive reviews in the literature regarding these polymers.^{172,173}

2.5.1 Boronic acid linkage. Boronic acid-functionalised polymers pose a great advantage of structural reversibility in detection and sensor applications due to their reversible dynamic covalent bonds formed upon complexation with diol/catechol moieties.¹⁷⁴ The pH sensitivity of the complexation and dissociation from crosslinking of the polymer chains allows adverse changes in the physical properties of the polymer, resulting in a response to a change in the chemical environment.¹⁷⁵ In the following section, several examples of boronic acid polymers are highlighted to emphasize their efficiency as pH-responsive polymers for several loading and release responses on various substrates.

Ju *et al.* prepared a pH-responsive cellulose/4-vinyl-phenylboronic acid (VPBA) composite bio-hydrogel using electron-beam irradiation at room temperature for the polymerisation of VPBA to poly VPBA.¹⁷⁶ The novel composite bio-hydrogel was believed to have potential application in the biomedical field due to the incorporation of the biocompatible cellulose matrix.¹⁷⁷ They made use of the concept of reversibility of the complex formed between glucose monomers in cellulose and the phenylboronic acid in VPBA.¹⁷⁸ They also highlighted that the equilibrium established in aqueous medium between the neutral and anionic form of the borate was a crucial factor for the formation of covalent complexes, as shown in Fig. 23a. The complex formed between anionic boronic acid and glucose was stable, whereas the complex of neutral phenylboronic acid and glucose was unstable. The resulting ionisation equilibrium shifted towards the anionic phenylboronic acid.

Fig. 23 (a) Equilibria of poly-4-vinyl-phenylboronic acid between neutral and anionic form and complexation with glucose. (b) Release profiles of FITC-insulin from cellulose/VPBA hydrogels at 28 °C, pH = 9.0, under various glucose concentrations: 0 g L⁻¹ (a), 1.0 g L⁻¹ (b), 3.0 g L⁻¹ (c) and 5.0 g L⁻¹ (d). Reproduced from ref. 176 with permission. Copyright 2018, Elsevier.

This demonstrates that two factors, *i.e.*, pH and glucose concentration, affect the equilibrium position between the charged and uncharged phenylboronic acid. Thus, the polymer characteristics such as hydrophilicity can be drastically affected upon regulation of the glucose level. Lastly, they demonstrated the responsive properties of the novel composite bio-hydrogel through the self-regulated release of insulin from the composite hydrogel through various concentrations of glucose solution. The release of the insulin was labelled *via* fluorescein isothiocyanate (FITC) for the tracking of fluorescence intensity of the external milieu. It was believed that a threshold concentration of glucose was responsible for triggering the spike in the release between 3.0–5.0 g L⁻¹, as shown in Fig. 23b.

2.5.2 Zwitterionic polymers. Zwitterionic polymeric materials have attracted great interest due to their outstanding anti-fouling properties such as protein resistance^{179,180} and slowing the growth of microorganisms.^{181,182} However, currently, several limitations of zwitterionic materials such as their fragile and rigid nature, which limit their biocompatibility and utility in flexible medical devices,^{183,184} need to be circumvented before the potentials of these materials can be fully realised. The examples illustrated in this section aim to address the limitations of zwitterionic polymers and highlight their potential as biomedical materials.

Cheng's group designed and synthesized an all-in-one tunable zwitterionic material (poly2-((2-hydroxyethyl)(2-methacrylamidoethyl)(methyl)ammonio)acetate (pCBMAA-1))

Review

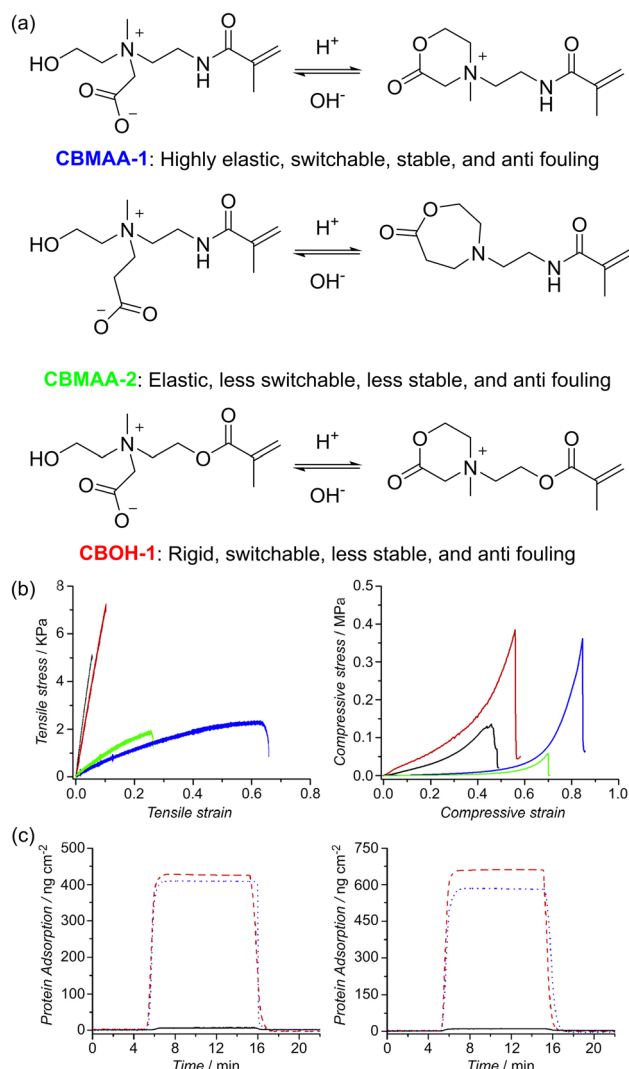

Fig. 24 (a) Chemical structure and characteristics of carboxybetaine derivatives. All listed carboxybetaine derivatives show excellent antifouling properties. (b) Tensile (left) and compression (right) results for pCBMAA-1 (blue), pCBMAA-2 (green), pCBOH-1 (red), and pCBMA-2 (black) hydrogels prepared at 1.5 M (c) SPR sensorgrams showing ultralow fouling properties of zwitterionic pCBMAA-1 (left) and pCBMAA-2 (right) polymer brushes against the adsorption of 1 mg mL⁻¹ fibrinogen (black solid line), undiluted human plasma (red dash line) and undiluted human blood serum (blue dotted line). encompassing elasticity, switchable antimicrobial-antifouling properties and stability.¹⁸⁵ In their design, a hydroxy group was introduced on one of the side chains of the quaternary ammonium to enable switchability from the cationic antimicrobial form to the zwitterionic antifouling form, as shown in Fig. 24a. CBMAA-2 is a variation of their original zwitterionic polymer CBMAA-1, with a seven-membered ring structure in the cationic form rather than the six-membered ring in CBMAA-1. The initial synthesis of the two polymers is illustrated in Fig. 24b. The physical properties of the two polymers were examined. As shown in Fig. 24c, both PCMAA-1 (blue) and PCMAA-2 (green) could

Fig. 25 Fluorescence images of polymer brushes functionalized with BODIPY-maleimide (a) after Diels-Alder, (b) after retro-Diels-Alder and (c) after a second Diels-Alder reaction. Reproduced from ref. 203 with permission. Copyright 2017, the American Chemical Society.

withstand higher tensile and compressive strain than the methacrylate-based polymer pCBMOH-H. This was attributed to the higher hydrophilicity and stronger hydrogen bonds of methacrylamide compared to methacrylate, resulting in a softer and more elastic material. Surface plasmon resonance (SPR) results also showed that both pCBMAA-1 and pCBMAA-2 displayed excellent antifouling properties as the amount of protein adsorbed was below the detection limit (0.3 ng cm⁻²) of the SPR sensor.

2.6 Thermal-induced structure switch

Heat is a common stimulus that changes the physical properties of polymers,¹⁸⁶ in some cases due to the change in chemical structure *via* breaking or forming bonds, leading to even more significant changes such as changes in polymer solubility. These polymers are useful in some applications such as drug delivery,^{187,188} thermoelectric generators,^{189,190} thermal energy storage^{191–193} and liquid chromatography.^{194,195} In this section, we discuss polymers with thermal-induced chemical structural changes, with particular focus on reversible chemical transformation and phase transitions, which can act as a new type of phase-change material.^{196,197} Also, we only give a brief overview of this topic, and the interested reader is referred to other comprehensive reviews.^{198,199}

2.6.1 Diels-Alder cycloaddition. One of the most well-established reversible temperature-dependent reactions is the Diels-Alder (DA) cycloaddition. Briefly, cycloaddition typically occurs between electron-rich dienes, such as furans and pyrroles, with electron-deficient dienophiles, such as maleimides. These classical building blocks have been widely utilized in the synthesis of a variety of self-healing polymeric materials^{200,201} and nanogels.²⁰² Some examples of these polymers that are capable of undergoing reversible DA and retro-DA reactions will be discussed.

Sanyal and co-workers reported the first example of utilizing DA cycloaddition to conjugate maleimide-containing molecules on furan-containing polymer brushes under mild and reagent-free conditions.²⁰³ The reaction was found to be highly efficient, functionalising all the polymer brushes at 60 °C (Fig. 25). The reaction was also found to be reversible at 110 °C *via* the retro-DA pathway. As a proof of concept, a fluorescent boron-dipyrromethene (BODIPY)-maleimide dye and a protein binding ligand were prepared and conjugated on the polymer brush. Green fluorescence was clearly observed after the reaction (Fig. 25b), which was completely quenched after the retro-DA (Fig. 25c).

Another example of reversible DA reaction was demonstrated by Du Prez and co-workers.²⁰⁴ Triazolinodione (TAD) reversible click chemistry was combined with microcontact interactions to print, erase and reprint polymer brushes on a surface. The polymer brushes were first fabricated *via* ATRP of a TAD bearing-initiator on the surface of an alkene-modified substrate; in this case, glass or silicone-supported 10-undecenyl trichlorosilane self-assembled membrane (SAM) was used. Subsequent surface-induced ATRP produced substrates functionalised with micropatterned polymethylacrylate brushes. The indole-TAD

click reaction occurred at room temperature, while the reverse reaction was observed at a higher temperature of 120 °C. Upon covalent immobilization of the indole derivative on the substrate *via* ATRP, the desired imprinted micropattern could be observed by introducing fluorophores and examined using fluorescence microscopy. Erasure of TAD from the substrate could be achieved through an irreversible *trans*-click reaction by immersing the substrate in a solution of 2,4-hexadien-1-ol, regenerating the indole on the substrate. Fig. 26 illustrates the general rewritable process of the polymer brush and the substrate.

2.6.2 Lower critical solution temperature (LCST)/upper critical solution temperature (UCST) polymers. Reversibility in chemical bonds can also translate into drastic physical changes in the properties of polymers, such as solubility and miscibility of the polymer in aqueous medium. LCST refers to temperature below which polymers are fully miscible, while UCST refers to the temperature above which they are fully miscible. The presence of an LCST is often driven by unfavorable entropy changes upon mixing due to strong solvent-solute interactions. To date, the most explored polymer exhibiting LCST is poly(*N*-isopropylacrylamide) (PNIPAM), which exhibits an LCST with water of around 32

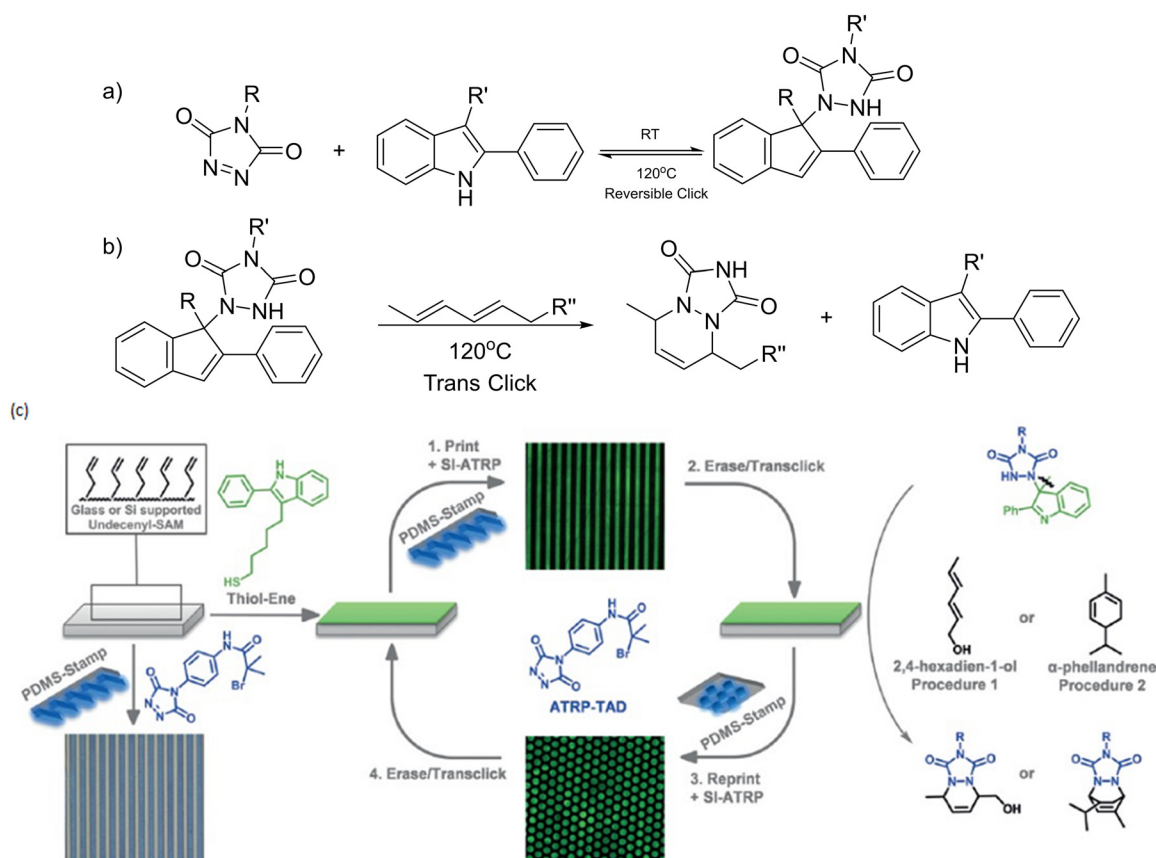

Fig. 26 (a) TAD click reaction with an indole derivative, which is reversible at higher temperatures. (b) Example of a *trans*-click reaction: after the TAD-indole adduct is cleaved, the indole derivative is regenerated. Fig. 27 Illustration of sol-gel transition of electrolyte that slows the migration of conductive ions between the electrodes. Upon increasing the temperature, the electrolyte solution transforms to a hydrogel through hydrophobic association. Reproduced from ref. 215 with permission. Copyright 2015, Wiley.

°C depending on the conditions. This thermal-responsive polymer is used to efficiently inhibit thermal runaways in devices such as lithium-ion batteries or supercapacitors^{205–210} and building applications.²¹¹ Some further examples of the applications of LCST/UCST polymers are presented in this section, although a full discussion is beyond the scope of this review, which has been thoroughly discussed elsewhere.^{212–214}

In 2015, Chen and co-workers fabricated a thermal copolymer, poly(*N*-isopropylacrylamide-*co*-acrylamide) (PNIPAM/AM), using free radical polymerization with *N*-isopropylacrylamide (NIPAM) and acrylamide (AM) as monomers and bisacrylamide as a crosslinking reagent and AIBN as the polymerization initiator.²¹⁵ The copolymer was soluble in aqueous solutions below 32–34 °C given that it was hydrophilic.^{216,217} The PNIPAM/AM solution was transformed into white hydrogels due to the disruption of the hydrogen bonds between the *N*-isopropyl groups and water, as shown in Fig. 27. Interestingly, the transition temperature for the phase change of the sol-gel process could be controlled by the adjusting the ratio of the monomers, *i.e.*, PNIPAM and AM, in the copolymer mix. They utilized the polymer as an electrolyte in supercapacitors and showcased the sol-gel process of the polymer to allow suppression or migration of conductive ions in the device upon an increase or reduction of the temperature, hence regulating the overall specific capacitance and impedance of the device.

Another example of a PNIPAM-based thermo-responsive polymer was reported by Chen and co-workers.²¹⁸ PNIPAM was dissolved in an ionic liquid solvent (1-methyl-3-methylimidazolium-bis(trifluoromethylsulfonyl)imide) to form an ionogel. At room temperature, this ionogel was plastic-like and rigid with an elastic modulus of 62.5 MPa. However, when heated above the UCST (~60.5 °C), the ionogel became transparent and soft with an elastic modulus of 0.66 kPa, representing a change in stiffness ratio by a

factor of 10^5 with a mild temperature change. The use of the phase transition to improve mechanical properties was also demonstrated by Marcellan's group.²¹⁹ Hong and Wu's group further exploited PNIPAM to prepare muscle-like hydrogels, which could be steered by light.²²⁰ This was achieved by incorporating gold nanoparticles in the polymer to enhance the photo-thermal effect. Consequently, the robot could be driven by using green laser irradiation.

2.7 Multi-stimuli-responsive structure switch

The abovementioned functional groups can be incorporated into a polymer chain to achieve dual or multi-stimuli-responsive polymer materials.^{7,8,221} These polymer materials enable reversible switching of their structures and properties *via* different stimuli for drug release, molecule sensing, healable materials, and smart surface applications. In this section, a few examples of polymer materials with a single type of multi-stimuli-responsive group or with multiple functional groups will be introduced.

Spiropyran is one of the most widely used photochromic compounds for multi-stimuli applications, boasting high responsivity to a multitude of environmental factors, such as light, pH, temperature and the presence of ions. As a distinct color change occurs during the reversible ring-opening formation of merocyanine from spiropyran, this makes it ideal to be used in the development of optical sensors.²²² Zhang *et al.* fabricated spiropyran-modified poly(*N*-isopropylacrylamide)-based multi-stimuli responsive microgels.²²³ The microgel-based optical devices (etalons) showed reversible responsiveness to light, pH, temperature and copper(II) cation (Cu^{2+}) concentrations. The microgels also exhibited two-photon fluorescence, highlighting their potential for applications in bioimaging. Similarly, Nhien and coworkers synthesized a novel multi-stimuli responsive amphiphilic aggregation-induced emission (AIE) copolymer using tetraphenylethylene-spiropyran monomers.²²⁴ The polymer exhibited photo-switchable properties, with ratiometric fluorescence between the green tetraphenylethylene (517 nm) and red merocyanine emissions (627 nm) the Förster resonance energy transfer (FRET) process. In the ring-opened merocyanine form, the emission of the material showed a strong dependence on pH, temperature, and cyanide anion (CN^-) concentration. Furthermore, due to its good biocompatibility coupled with low limit of detection (LOD = 0.26 μM) for aqueous CN^- , this material is a promising FRET sensor for the detection of CN^- in living cells.

Supramolecular polymer systems are popular components in the design of multi-stimuli responsive polymers. Through the use of multiple non-covalent binding motifs, these polymers are often capable of exhibiting reversible responsiveness to a myriad of stimuli.^{227–229} For example, Jiang *et al.* reported the preparation of a stable supramolecular polymer containing tripodal pillar[5]arene tails. This supramolecular polymer could undergo a

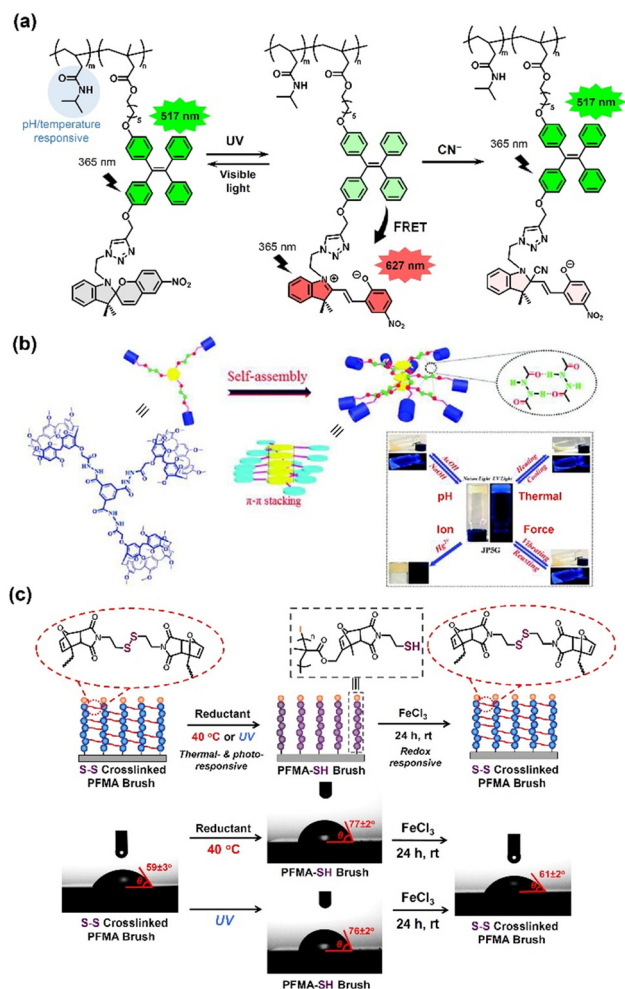

Fig. 28 (a) Chemical structures of AIE-containing copolymers and their reversible energy transfer *via* the FRET process. The structure switch can be quenched by adding CN^- ions. reversible gel-sol transition *via* pH, thermal, and force stimuli and demonstrated strong AIE after gelation (Fig. 28b).²²⁵ Moreover, the polymer also displayed strong interaction with mercuric cation (Hg^{2+}) to form a gel, indicating its potential application to remove Hg^{2+} from water. Hatai and coworkers used coumarin moieties together with a central 1,3,5-trisubstituted benzene core and poly(ethylene glycol) linkers to create a multi-stimuli responsive supramolecular polymer.^{230,231} The material was found to be light and pH sensitive, owing to the photodimerization of coumarin and the cleavage of the hydrazone bonds, respectively. The addition of Cu^{2+} ions was

found to induce disassembly of the nanoaggregates. By controlling the 3 stimuli (light, pH and Cu^{2+} concentration), the aggregation behavior of the polymer could be controlled. This allowed the polymer to successfully achieve the encapsulation and targeted release of hydrophobic molecules, such as drugs and dyes. Xiong and coworkers employed a novel AIE luminogen to design an organic multi-stimuli-responsive fluorescent material.^{228,232} Consisting of vinylpyridine motifs on a tetraphenylethene backbone, the AIE luminogen displayed reversible fluorescence under varying force, pH, and temperature stimuli. Due to the supramolecular intermolecular interactions and presence of a shrinkable space in the packing structure of the polymer, this material could sustain fluorescence emission even under external pressure as high as 11.25 GPa.

The Diels-Alder mechanism conjugates double-bond systems by reacting diene bonds with a single double bond, which is typically reversible by light and heat. This multi-stimulus-responsive conjugation has been used to impart reversibility to functional polymers. Yamamoto and coworkers demonstrated a multi-responsive reversible topologically converting polymers using anthracene and coumarin derivatives.²³³ Exploiting the Diels-Alder mechanism, the polymers reversibly dimerized from a linear to cyclic structure and cleaved the anthryl groups by light or heat stimuli. Poly(ethylene oxide) with electron-donating and electron-withdrawing substituted anthryl end groups was irradiated at 365 nm for photo-dimerisation. Afterwards, linearization of the polymers was successfully achieved by heating at 150 °C. Sim *et al.* also employed the Diels-Alder mechanism and disulfide linkage to create multi-stimuli-responsive polymer brushes.²²⁶ The authors uniquely applied bis(2-maleimidoethyl) disulfide to form a crosslinked poly(furfuryl methacrylate) (PFMA) brush gel *via* a Diels-Alder reaction. The disulfide bond (S-S) could cleave upon thermal or photo stimulus and rebridge under oxidative stimulus. The combination of Diels-Alder moieties and disulfide bonds allowed the polymer brush gels to be crosslinked and decrosslinked with thermal, photo and oxidative stimuli. The surface wettability and patterns could be precisely and spatially modulated and potentially applied for adsorptive/desorptive interfaces and rewritable interfaces.

The combination of functional groups and/or polymers with different stimuli-responsive properties also provide an effective method to prepare multi-stimuli responsive polymers. For example, Gebeyehu *et al.* developed a dual thermo- and photo-responsive supramolecular polymer based on uracil and oligomeric polypropylene glycol.²³⁴ The thermo-sensitive polypropylene backbone was end-capped with photo-sensitive uracil moieties using a one-step Michael addition reaction and self-assembly of the oligomers was initiated by double hydrogen bonding interactions between the uracil moieties upon immersion in aqueous conditions. This polymer could self-assemble to form micelles and exhibit reversible phase transition behavior in aqueous solutions. By manipulating the concentration and duration of

UV irradiation and aqueous solution temperature, these micelles displayed tunable and reversible hydrophilic/hydrophobic properties, which could potentially mimic biological processes for applications in drug delivery and gene transport. Jiang and the co-workers reported the preparation of triple-stimuli-responsive polymers by incorporating a redox-responsive ferrocene unit and a pH/CO₂-responsive *N,N*-diethylamino ethyl group.²³⁵ These polymers exhibited unique reversible phase transition behavior in an aqueous solution. For example, in an acidic environment, the polymers formed spherical particles, where the size and morphology of their aggregates changed upon oxidative stimuli given that the ferrocene segment switches their hydrophobic/hydrophilic properties.

3 Conclusions and outlook

The field of stimuli-responsive switchable polymers has progressed tremendously in the past two decades. Many of the stimuli-responsive moieties such as azobenzenes, spiropyranes, disulfide groups, and amidine groups have seen new applications, focusing on tuning their properties and their incorporation in new polymers. The fundamental understanding of the chemistry, structure, geometry and conformation of stimuli-responsive moieties as well as how these factors modulate the switchable functions and properties of the corresponding switchable stimuli-responsive polymers have also been significantly realized, allowing us to appropriately predict the properties of the polymers based on their chemical structure (as summarized in Table 1). Besides these well-known stimuli-responsive moieties, new stimuli-responsive structures have also been designed and developed, such as rotaxanes and some supramolecular polymers. The discovery of these stimuli-responsive species opens new opportunities for the development of advanced materials with desirable properties. Multi-stimuli-responsive polymer materials consisting of different stimuli-responsive moieties or a single stimuli-responsive moiety and capable of responding to different stimuli represent another interesting area to be explored. With the advancement of stimuli-

responsive polymers, we envision that they will continue to find new applications beyond the drug delivery, molecular sensing and self-healing functions emphasized in this review, while other applications such as artificial muscles and chameleon-like materials have also seen significant advances. We also believe that their current limitations such as rate of response, reversibility, and selectivity will be overcome with further research. Overall, we believe that the field of stimuli-responsive polymer materials will continue to advance and play an important role in future emerging smart materials.
