# Experimental verification of SO<sub>2</sub> and S desorption contributing to defect formation in MoS<sub>2</sub> by thermal desorption spectroscopy†

Shuhong Li,<sup>ab</sup> Tomonori Nishimura,<sup>a</sup> Mina Maruyama,<sup>b</sup> Susumu Okada <sup>b</sup> and Kosuke Nagashio <sup>\*a</sup>

The defect-free surface of MoS<sub>2</sub> is of high importance for applications in electronic devices. Theoretical calculations have predicted that oxidative etching could be responsible for sulfur vacancy formation. No direct experimental evidence, however, points out the role of adsorbed oxygen on sulfur vacancy formation for MoS<sub>2</sub>, especially on an insulating SiO<sub>2</sub>/Si substrate. Herein, by applying thermal desorption spectroscopy, we found that sulfur loss can be tightly coupled to adsorbed oxygen, as confirmed by observation of SO<sub>2</sub> desorption. With annealing MoS<sub>2</sub>, even under ultrahigh vacuum, oxygen molecules adsorbed on MoS<sub>2</sub> assist the sulfur atom in dissociating from MoS<sub>2</sub>, and thus, defects are formed as the result of SO<sub>2</sub> desorption from 200 °C to 600 °C. At higher temperatures (over 800 °C), on the other hand, direct sulfur desorption becomes dominant. This finding can be well explained by combining the morphology investigation enabled by atomic layer deposition at defective sites and optical transitions observed by photoluminescence measurements. Moreover, a preannealing treatment prior to exfoliation was found to be an effective method to remove the adsorbed oxygen, thus preventing defect formation.

## 1. Introduction

MoS<sub>2</sub>, a two-dimensional (2D) layered material, is promising as a channel material for next-generation field-effect transistors (FETs) because a natural thin body can overcome the scaling limit for the Si gate length.<sup>1,2</sup> Although the dangling-bond-free surface of the layered MoS<sub>2</sub> channel is expected to ideally provide an electrically inert interface, sulfur vacancies in reality have been recognized as a dominant defect in MoS<sub>2</sub> due to the lowest formation energy of ~1.3–1.5 eV under S-poor conditions.<sup>3,4</sup> Moreover, sulfur vacancies are known to introduce defect states in the band gap, which degrades the FET performance.<sup>5–8</sup> Therefore, controlling sulfur vacancies has still been an critical issue due to the limited understanding of its formation mechanism, even though many healing processes based on various adsorbates or S vapor annealing have been proposed.<sup>9–12</sup>

The stability of MoS<sub>2</sub> has been intensively studied thus far.<sup>13,14</sup> The conventional mechanical exfoliation process for device fabrication leads to exposure to ambient air, which introduces adsorbates on the MoS<sub>2</sub> surface and edge. These adsorbates, such as oxygen and water, greatly affect chemical

stability, since thermodynamic calculations suggest that most 2D materials show oxidation tendencies.<sup>15</sup> The long-term exposure of MoS<sub>2</sub> flakes to ambient air has proven the gradual oxidation from the edges to the interior of MoS<sub>2</sub><sup>16</sup> because the coordinatively unsaturated edge is energetically more favorable for oxidation than the basal plane.<sup>17–20</sup> For intentional exposure to an oxygen environment,<sup>21</sup> the basal plane of MoS<sub>2</sub> is oxidized, and MoO<sub>3</sub> is formed during oxidation above 400 °C. This is further supported by the aggressive oxidation using oxygen plasma, where layer-by-layer oxidation was observed since MoO<sub>3</sub> formed on the MoS<sub>2</sub> surface prevented further oxidation.<sup>22</sup> Interestingly, for an oxygen/air environment at lower temperatures of 300–340 °C, however, layer-by-layer anisotropic etching of MoS<sub>2</sub> results in triangular pits, which are initiated *via* intrinsic defects on the basal plane of MoS<sub>2</sub>.<sup>21,23</sup> This oxidative etching is explained by the reaction of MoS<sub>2</sub> + O<sub>2</sub> → MoO<sub>3</sub>↑ + SO<sub>2</sub>↑,<sup>18,24</sup> where both MoO<sub>3</sub> and SO<sub>2</sub> are volatile. Thus, oxidative etching is considered to be an important process when MoS<sub>2</sub> is exposed to oxygen or air.

Recently, atomic-resolution scanning tunneling microscopy (STM) suggested that the O<sub>2</sub> adsorbed on the basal plane of MoS<sub>2</sub> volatilized as SO<sub>2</sub> by removing S, leaving S vacancies with O saturation on the basal plane.<sup>10</sup> This O<sub>2</sub>-assisted S vacancy formation in ambient air at room temperature (RT) is estimated to be energetically spontaneous with −0.49 eV by first principles calculation. On the other hand, in a high vacuum environment, the creation of S vacancies has been confirmed not at 127 °C but at elevated temperatures >627 °C by atomic-resolution STM<sup>25</sup>

† Electronic supplementary information (ESI) available. See DOI: <https://doi.org/10.1039/d2na00636g>

and transmission electron microscopy (TEM).<sup>26</sup> These results indicate that the formation of S vacancies at RT cannot be fully explained without the existence of oxygen adsorbed on the basal plane of MoS<sub>2</sub>, suggesting the importance of O<sub>2</sub> adsorption and reaction mechanism. Therefore, further theoretical studies on the initial step of oxidative etching have been conducted in detail.<sup>27</sup> However, direct experimental evidence of SO<sub>2</sub> desorption as well as direct S desorption has not yet been proven.

Here, thermal desorption mass spectrometry (TDS) is used to study the surface reaction and desorption kinetics in Si<sup>28,29</sup>, Ge,<sup>30</sup> and HOPG<sup>31</sup> by detecting a small amount of desorption species using a quadrupole mass spectrometer (QMS). By using this TDS system, it may be possible to detect SO<sub>2</sub> and/or S desorption from MoS<sub>2</sub> flakes transferred onto SiO<sub>2</sub>/Si substrates in ambient air. Although no measurement method to observe S vacancies with atomic resolution is available for MoS<sub>2</sub> on an insulating substrate, it is well known that Al<sub>2</sub>O<sub>3</sub> during atomic layer deposition (ALD) is adsorbed only at the defect sites;<sup>32–35</sup> this will allow us to visualize the defect evolution with the assistance of surface topology observed macroscopically by atomic force microscopy (AFM). In this research, a quantitative characterization of the defect evolution mechanism of MoS<sub>2</sub> on SiO<sub>2</sub> at elevated temperatures up to ~1000 °C is realized by combining TDS and ALD.

## 2. Experimental

2H-MoS<sub>2</sub> crystals purchased from SPI supplies were used in this study. First, a 110 nm SiO<sub>2</sub>/n<sup>+</sup>-Si substrate was sonicated by acetone and isopropyl alcohol for 10 min in laboratory air. After a few exfoliations by metallic tweezers, the bulk MoS<sub>2</sub> flakes were directly transferred to the SiO<sub>2</sub>/n<sup>+</sup>-Si substrate. This procedure provides a sufficiently large surface area of MoS<sub>2</sub> for the TDS measurements, while it prevents any tape residue on the substrate since the tape is not used. Other 2H-bulk transition metal dichalcogenides (WS<sub>2</sub>, WSe<sub>2</sub>, MoSe<sub>2</sub> and MoTe<sub>2</sub>) were grown by chemical vapor transport method<sup>36</sup> and treated by the same method applied for MoS<sub>2</sub>. Alternatively, MoS<sub>2</sub> flakes were

clashed into powders using a mortar to further increase the surface area of MoS<sub>2</sub>. Then, the MoS<sub>2</sub> powders were placed on the SiO<sub>2</sub>/Si substrate. Fig. 1a illustrates the TDS apparatus, which allows selective heating of only the Si substrate *via* infrared radiation from the underlying power-operated lamp under ultrahigh vacuum (UHV) conditions of  $\sim 4 \times 10^{-8}$  Pa. Since this TDS is cold wall system, the desorption from the inner chamber wall can be avoided during the sample heating. The QMS functions by manipulating the electric field between four orthogonal rods to collect ionized desorbed molecules and atoms and thus enables distinguishing the desorbed species according to its atomic/molecular mass-to-charge ratio. The bulk MoS<sub>2</sub> flakes were heated from room temperature to ~1000 °C with a heating rate of 20 °C min<sup>-1</sup>, and TDS spectra were detected in multi-ion detection mode with a sensitivity up to 10<sup>-15</sup> A.

For ALD, Al<sub>2</sub>O<sub>3</sub> was deposited on MoS<sub>2</sub> flakes in a hot wall chamber at 200 °C with trimethylaluminum (TMA), water, and nitrogen as the precursor, oxidant, and purge gas, respectively.<sup>32</sup> The pulse time for TMA/water is 0.1 s/0.5 s, respectively. Ten cycles were performed to obtain ~2 nm-thick Al<sub>2</sub>O<sub>3</sub>. The surface morphology was measured with dynamic force mode by AFM. The Raman and photoluminescence (PL) spectra were measured at RT in ambient air using a 488 nm excitation laser with a power of 0.06 mW to avoid the degradation of MoS<sub>2</sub> owing to laser heating.

## 3. Results and discussion

First, the desorption of adsorbates on the SiO<sub>2</sub>/Si substrate without MoS<sub>2</sub> flakes should be examined. As shown in Fig. S1a,<sup>†</sup> in addition to the small amount of H<sub>2</sub>, CO<sub>2</sub> and N<sub>2</sub>, H<sub>2</sub>O physisorbed on the SiO<sub>2</sub>/Si substrate was clearly detected in the temperature range of 100–300 °C because the SiO<sub>2</sub> surface is hydrophilic.<sup>37</sup> After transferring MoS<sub>2</sub> flakes onto the SiO<sub>2</sub>/Si substrate, the desorption of H<sub>2</sub>O and CO<sub>2</sub> was enhanced, as shown in Fig. S1b.<sup>†</sup> This indicates that many kinds of gas

Fig. 1 (a) Illustration of thermal desorption spectroscopy applied in this experiment. (b) TDS spectra with  $m/z = 32$  (O<sub>2</sub> or S) and  $m/z = 64$  (SO<sub>2</sub>) for bulk MoS<sub>2</sub> flakes on the SiO<sub>2</sub>/Si substrate. (c) Comparison of the TDS spectra for  $m/z = 32$  between the first annealing and second annealing.

species are adsorbed on MoS<sub>2</sub> flakes when MoS<sub>2</sub> flakes are mechanically transferred in ambient air.

The desorption of sulfur and sulfur-related compounds is of the highest interest. Fig. 1b shows the TDS spectra for mass-to-charge ratios of  $m/z = 32$  and 64. S and O<sub>2</sub> can be assigned for the same mass-to-charge ratio of  $m/z = 32$  because QMS can only filter substances by mass-to-charge ratio. To separate them, the second annealing experiments were successively carried out without removing the sample, as shown in Fig. 1c and S1c.† The broad peak from 200 to 600 °C for  $m/z = 32$  is totally removed in the second annealing experiment, with the sharp intensity tail remaining at ~800 °C. It can be expected that direct S desorption is observable even in the second annealing, while O<sub>2</sub> is not detected once it has totally desorbed in the first annealing experiment. Therefore, the broad peak from 200 to 600 °C in Fig. 1b is assigned as the contribution from O<sub>2</sub>. Here, it should be noted that the contribution from water adsorbed to the sample was excluded in this discussion, even though the water desorption was observed in Fig. S1.† According to the recent paper,<sup>38</sup> no degradation of monolayer MoS<sub>2</sub> was observed after two weeks exposure to the environment of both N<sub>2</sub> and N<sub>2</sub> with the 75% humidity, suggesting that water itself have no dominant contribution for oxidation. Moreover, the desorption tails observed for all species at a high temperature of ~800 °C in Fig. S1† basically resulted from the inner pressure enhancement in the TDS chamber, not from the real increase in desorption. Nevertheless, the TDS spectrum of  $m/z = 32$  in the second annealing experiment is greatly enhanced when the surface area of MoS<sub>2</sub> increases by preparing the MoS<sub>2</sub> powder, which is reflected as a threshold temperature shift to the lower side in Fig. S2a.† This indicates that the desorption tail for  $m/z = 32$  contains real desorption, that is, the contribution from S. Moreover, Fig. S2b† compares the TDS spectra of chalcogens (S, Se and Te) for various transition metal dichalcogenides. The direct Te ( $m/z = 128$ ) desorption from MoTe<sub>2</sub> is stronger than others, which is consistent with the common understanding of the stability of 2D materials.

In addition to direct S desorption, the sulfur oxidation product, that is, SO<sub>2</sub>, was also observed and expressed as  $m/z = 64$  in Fig. 1b, where two peaks are observed at ~400 °C and ~650 °C. It should be noted that the  $m/z = 64$  was assigned to be the SO<sub>2</sub> rather than S<sub>2</sub> based on the isotope method.<sup>39</sup> Sulfur mainly has stable four isotopes: <sup>32</sup>S (95.02%), <sup>33</sup>S (0.5%), <sup>34</sup>S (4.21%), and <sup>36</sup>S (0.02%). The second abundant <sup>34</sup>S ( $m = 34$ ) was used to distinguish S<sub>2</sub> ( $m/z = 68$ ) and SO<sub>2</sub> ( $m/z = 66$ ), as shown in Fig. S3(b).† The desorption signal of  $m/z = 66$  well follows  $m/z = 64$ , while no clear feature was observed for  $m/z = 68$ . Moreover, from the viewpoint of activation energy of S<sub>2</sub> desorption, the higher temperature is expected. Therefore,  $m/z = 64$  was assigned to SO<sub>2</sub> rather than S<sub>2</sub>. Furthermore, in the second annealing experiment in Fig. 1c, both peaks disappeared, suggesting that oxygen that constitutes SO<sub>2</sub> comes from adsorbates on the MoS<sub>2</sub> flakes not from inside of the MoS<sub>2</sub> flakes. Therefore, it is considered that adsorbed O<sub>2</sub> reacted with S in MoS<sub>2</sub> and desorbed as SO<sub>2</sub> at ~400 °C and ~650 °C. That is, it is suggested that sulfur vacancy formation at relatively low temperature (~400 °C & 650 °C) is caused by SO<sub>2</sub> desorption

assisted by oxygen adsorption on the MoS<sub>2</sub> basal plane, while it is caused by direct S desorption at high temperature (over 800 °C). Although the theoretical simulation<sup>10</sup> has suggested SO<sub>2</sub> desorption instead of direct S desorption for S vacancy formation, this is the first experimental observation.

The origin of the two SO<sub>2</sub> peaks in Fig. 1b may be related to different intermediates for the final SO<sub>2</sub> formation, as suggested in the theoretical calculation.<sup>27</sup> The formation of the intermediate “OSOMo”, in which one oxygen atom is inserted into the Mo–S bond, leads to the desorption of SO<sub>2</sub> with an energy barrier of 1.49 eV. On the other hand, the formation of the intermediate “Mo–OSO”, which can be seen as the SO<sub>2</sub> molecule with one oxygen atom bonded to two adjacent Mo atoms, leads to the desorption of SO and SO<sub>2</sub> with energy barriers of 0.41 eV and 0.78 eV, respectively. Interestingly, in the reproduced TDS experiment in Fig. S3,† it is found that the SO signal highly overlaps with the SO<sub>2</sub> signal in the low-temperature region, where the first peak is observed in Fig. 1b. The overlapping feature suggests that the formation of SO and SO<sub>2</sub> at relatively low temperatures is simultaneous. The slight intense peak for SO at 650 °C can be attributed to the decomposition of SO<sub>2</sub> to SO and O due to the ionization in QMS.<sup>39</sup> Although the rigorous separation of SO and SO<sub>2</sub> is difficult at present, two SO<sub>2</sub> peaks may result from the different intermediates for the final SO<sub>2</sub> desorption.

To confirm whether defects form as a result of desorption during TDS annealing, 2 nm Al<sub>2</sub>O<sub>3</sub> was deposited by ALD since Al<sub>2</sub>O<sub>3</sub> is formed selectively on defect sites due to the dangling-bond free inert surface of the 2D material.<sup>32–35</sup> For the present ALD-assisted morphology characterization, bulk MoS<sub>2</sub> were intentionally selected to avoid strain-enhanced ALD growth on monolayer MoS<sub>2</sub> due to the transfer process. To show the importance of ALD, the surface topography of MoS<sub>2</sub> annealed up to 835 °C in the TDS chamber without ALD was examined to assess the resolution of AFM. As shown in Fig. S4,† no clear defects could be identified. The situation was inverted when ALD was applied to the MoS<sub>2</sub> flake after TDS annealing. As shown in Fig. 2b, for the MoS<sub>2</sub> flake annealed up to 200 °C in the TDS chamber, the growth of Al<sub>2</sub>O<sub>3</sub> is distributed in dots on the MoS<sub>2</sub> surface with a greater concentration at the step edge. It should be noted that 200 °C was selected as the starting temperature for defect characterization since the Al<sub>2</sub>O<sub>3</sub> growth temperature in ALD was 200 °C. As the TDS annealing temperature increases, Al<sub>2</sub>O<sub>3</sub> growth is enhanced, occupying more surface area of MoS<sub>2</sub> (Fig. 2b–e). For the MoS<sub>2</sub> flake annealed up to 630 °C, the growth of Al<sub>2</sub>O<sub>3</sub> is no longer preferential at the grain boundaries and the step edges but uniformly covers the entire MoS<sub>2</sub> surface. The morphology evolution is schematically illustrated below the AFM images.

Next, the Al<sub>2</sub>O<sub>3</sub> coverage was extracted from the AFM images and plotted as a function of annealing temperature in Fig. 2a. The coverage rate is relatively slow in the temperature range from 350 to 500 °C, where the first peak of SO<sub>2</sub> desorption is observed in Fig. 1b. In contrast, there was a significant increase in the coverage rate from 550 to 630 °C. This temperature interval matches the second peak of SO<sub>2</sub> desorption. These results suggest that the evolution of the Al<sub>2</sub>O<sub>3</sub> coverage is correlated to SO<sub>2</sub> desorption. However, further quantitative

Fig. 2 (a) Coverage estimation of ALD- $\text{Al}_2\text{O}_3$  on TDS-annealed bulk  $\text{MoS}_2$  flakes with varying annealing temperatures. The gray point represents the coverage extracted from different AFM images. The red dashed line is an eye guide to reflect the coverage evolution rate. (b)–(e) Representative AFM images for  $\text{Al}_2\text{O}_3/\text{MoS}_2$  at annealing temperatures of 200 °C, 425 °C, 565 °C, and 630 °C, respectively. In addition, the  $\text{Al}_2\text{O}_3$  coverage evolution with increasing annealing temperature is schematically illustrated. The yellow particles represent deposited  $\text{Al}_2\text{O}_3$ .

estimation of the defect density is not possible here since the  $\text{Al}_2\text{O}_3$  particle density does not form a one-to-one correspondence with the defect density. That is, new  $\text{Al}_2\text{O}_3$  growth occurs not only at the defect site but also on the  $\text{Al}_2\text{O}_3$  that has already been grown. However, the importance of ALD-assisted AFM characterization is to provide clear evidence that the formation of defects on the basal plane of  $\text{MoS}_2$  flakes does arise when  $\text{SO}_2$  desorption occurs.

To reveal the structural change in  $\text{MoS}_2$  after TDS annealing, Raman measurements were conducted. Fig. 3a shows the Raman spectra of monolayer  $\text{MoS}_2$  at different TDS annealing temperatures. The frequency difference of  $\text{E}_{2g}^1$  and  $\text{A}_{1g}$  is  $\sim 19.4 \text{ cm}^{-1}$ , which matches well with the characteristics of

monolayer  $\text{MoS}_2$ .<sup>40</sup> No detectable shifts of the  $\text{E}_{2g}^1$  and  $\text{A}_{1g}$  peaks were found for any temperature range. On the other hand, the full width at half maximum (FWHM) of these two peaks shown in Fig. 3b is slightly broadened when the annealing temperature was elevated to 835 °C; at this temperature, direct S desorption becomes dominant in the TDS spectra of Fig. 1b. This indicates that some damage to the crystallinity is induced by considerable direct S desorption. The change in Raman spectra at temperatures above 800 °C has also been reported.<sup>41</sup> Although Raman spectra are found to be insensitive to temperatures below 630 °C, this is not consistent with Fig. 2a, where a clear  $\text{Al}_2\text{O}_3$  coverage evolution is observed. In Fig. S3,<sup>†</sup> the desorption of  $\text{SO}_2$  and S was detected but not for  $\text{MoO}$ ,  $\text{MoO}_2$ , and  $\text{MoO}_3$ ,

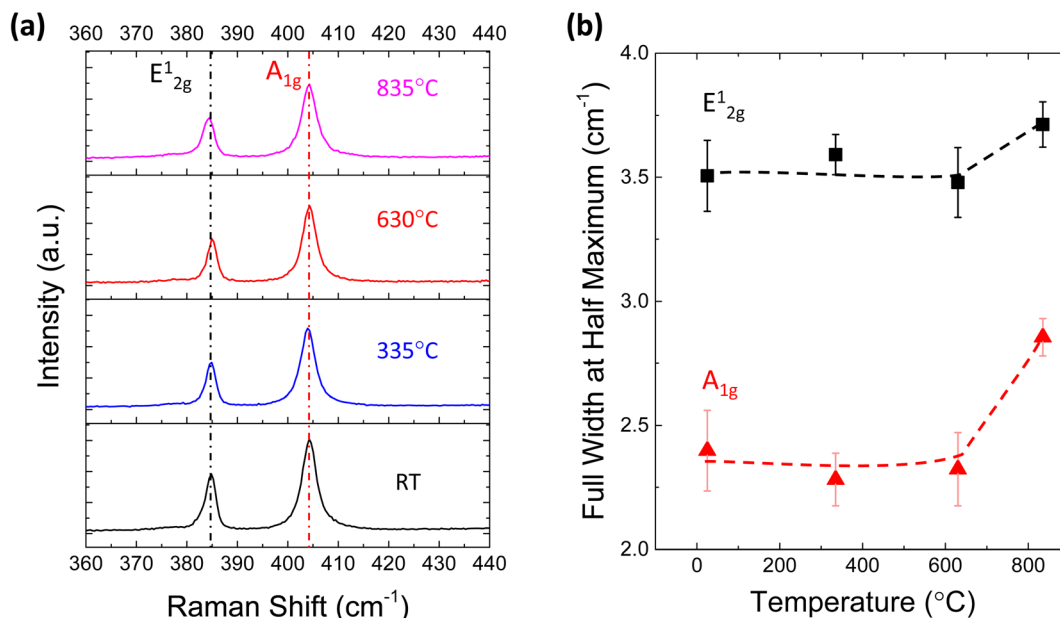

Fig. 3 (a) Raman spectra for monolayer  $\text{MoS}_2$  annealed at different temperatures in the TDS chamber. (b) Full width at half maximum (FWHM) of the Raman peaks at different temperatures.

**Fig. 4** (a) Photoluminescence spectra for monolayer MoS<sub>2</sub> annealed at different temperatures in the TDS chamber without preannealing in Ar. X, X<sup>-</sup> and X<sub>B</sub> represent exciton, trion and defect-induced bound exciton, respectively. The red arrow indicates the intensity enhancement with increasing annealing temperature from RT to 630 °C, while the blue arrow indicates the transition from exciton to defect-induced bound exciton due to high-temperature annealing at 835 °C. (b) Photoluminescence spectra for monolayer MoS<sub>2</sub> annealed at different temperatures in the TDS chamber with preannealing in Ar.

suggesting that the original MoS<sub>2</sub> crystal lattice can be retained since Mo is located at the center of the MoS<sub>2</sub> crystal structure. Therefore, Raman spectra could be insensitive to the relatively small change in crystallinity due to S vacancy formation accompanied by SO<sub>2</sub> desorption.

To further investigate the effect of defect formation more sensitively, PL measurements were performed for monolayer MoS<sub>2</sub> annealed at different temperatures in the TDS chamber. As shown in Fig. 4a, the conventional broad PL peak mixed with exciton (X, ~1.9 eV) and trion (X<sup>-</sup>, ~1.85 eV) was observed.<sup>42–44</sup> As the TDS annealing temperature increased from RT to 630 °C, the intensity of the exciton peak drastically increased. Since the MoS<sub>2</sub> flakes were exposed to ambient air during the PL measurement after removing the sample from the TDS chamber, the exciton intensity enhancement is attributed to the oxygen chemical adsorption on S vacancies created by SO<sub>2</sub> desorption during TDS annealing.<sup>43</sup> As shown in Fig. S5,† the trion contribution was reduced at elevated temperature, while the exciton component became dominant. This indicates the p-type doping by oxygen passivation at the defect site.<sup>45</sup> Moreover, when the annealing temperature increased to 835 °C, the defect-induced bound exciton peak (X<sub>B</sub>, ~1.75 eV) became dominant.<sup>46–49</sup> Although SO<sub>2</sub> formation at relatively low temperatures is limited by the amount of oxygen adsorbed initially on MoS<sub>2</sub> flakes, direct S desorption at high temperatures depends only on the temperature. Therefore, a much broader X<sub>B</sub> peak implies a significant amount of S vacancy formation and clustering due to the enhanced direct S desorption, which is also supported by the broadening of the FWHM in the Raman peaks (Fig. 3b).

Four different types of experiments, namely, of TDS, AFM, Raman and PL, surprisingly, can be well explained by the two

common kinds of defect formation mechanisms in the low and high annealing temperature regions. That is, at a low annealing temperature, the oxygen adsorbed on the basal plane of MoS<sub>2</sub> flakes is the key factor, and it volatilizes as SO<sub>2</sub> by removing S from MoS<sub>2</sub>, leaving S vacancies. Then, at a high annealing temperature, direct S desorption becomes dominant. Here, it is reasonable to consider that defect formation at low annealing temperatures could be suppressed by removing oxygen adsorbed on MoS<sub>2</sub> flakes before TDS annealing. To verify this idea, the MoS<sub>2</sub> crystals were preannealed at 500 °C for one hour in an Ar gas flow to remove oxygen adsorbed on the MoS<sub>2</sub> surface. Then, MoS<sub>2</sub> flakes were transferred onto the SiO<sub>2</sub>/Si substrate by mechanical exfoliation in ambient air, followed by TDS annealing. The PL spectra of preannealed monolayer MoS<sub>2</sub> are shown in Fig. 4b. The PL intensity enhancement at temperatures below 630 °C is greatly suppressed, which strongly indicates that S vacancy formation due to SO<sub>2</sub> desorption was hindered due to the great reduction in oxygen adsorbed on the MoS<sub>2</sub> surface. On the other hand, at a high temperature of 835 °C, the X<sub>B</sub> peak was almost the same, which is also evidence for direct S desorption. These results clearly support the two kinds of defect formation mechanisms in the low and high annealing temperature regions. To date, S vacancies have been experimentally observed and recognized as dominant defects because they have the lowest formation energy of ~1.3–1.5 eV compared with other types of defects.<sup>3,4</sup> However, this large formation energy could not explain the high S vacancy concentration of ~10<sup>13</sup> cm<sup>-2</sup>.<sup>50</sup> The present study experimentally proves that oxygen adsorbed on MoS<sub>2</sub> assists S vacancy formation by desorbing as SO<sub>2</sub> since this O<sub>2</sub>-assisted S vacancy formation is energetically spontaneous at -0.49 eV.<sup>10</sup>

## 4. Conclusions

Through this experimental desorption study using TDS in combination with ALD, Raman, and PL, two kinds of S vacancy formation mechanisms are realized, that is, O<sub>2</sub>-assisted SO<sub>2</sub> desorption at low annealing temperatures (400 °C to 650 °C) and direct S desorption at high annealing temperatures (over 800 °C). The key finding is that the initially adsorbed oxygen causes S vacancy formation through SO<sub>2</sub> desorption. As a solution, the removal of oxygen is quite effective for preventing the formation of defects and further oxidation.
