Intrinsic giant magnetoresistance due to exchange-bias-type effects at the surface of single-crystalline NiS₂ nanoflakes†

The coexistence of different properties in the same material often results in exciting physical effects. At low temperatures, the pyrite transition-metal disulphide NiS₂ hosts both antiferromagnetic and weak ferromagnetic orders, along with surface metallicity dominating its electronic transport. The interplay between such a complex magnetic structure and surface-dominated conduction in NiS₂, however, is still not understood. A possible reason for this limited understanding is that NiS₂ has been available primarily in bulk single-crystal form, which makes it difficult to perform studies combining magnetometry and transport measurements with high spatial resolution. Here, NiS₂ nanoflakes are produced *via* mechanical cleaving and exfoliation of NiS₂ single crystals and their properties are studied on a local (micron-size) scale. Strongly field-asymmetric magnetotransport features are found at low temperatures, which resemble those of more complex magnetic thin film heterostructures. Using nitrogen vacancy magnetometry, these magnetotransport features are related to exchange-bias-type effects between ferromagnetic and antiferromagnetic regions forming near step edges at the nanoflake surface. Nanoflakes with bigger steps exhibit giant magnetoresistance, which suggests a strong influence of magnetic spin textures at the NiS₂ surface on its electronic transport. These findings pave the way for the application of NiS₂ nanoflakes in van der Waals heterostructures for low-temperature spintronics and superconducting spintronics.

1. Introduction

Pyrite transition-metal disulfides (p-TMDs) are an interesting family of compounds, which have been investigated since the end of the 1960s in bulk single-crystalline form.^{1–6} Several p-TMDs also have magnetic properties,⁴ like CoS₂, NiS₂, and related compounds obtained from them, for example *via* substitutional doping of Fe for Co (*e.g.*, Fe_{1–x}Co_xS₂, for $x > 0.05$; ref. 3 and 4) or of Se for S (*e.g.*, NiS_{2–x}Se_x for $x < 1$ or CoS_{2–x}Se_x for $x < 0.6$; ref. 4 and 6). Amongst magnetic p-TMDs, NiS₂ is of particular interest for several reasons. First, the magnetic

ground state of NiS₂ is not fully understood, although this would be important also to understand the properties of other p-TMDs obtained, for example, from NiS₂ *via* substitutional doping. Second, several studies suggest that NiS₂ can host different types of magnetic orderings at low temperature (T). In this complex magnetic state, non-collinear magnetic spin textures may arise, which could find, for example, applications in spintronic devices operating at low T , also in combination with superconductors.

Unlike other transition-metal disulfides (TMDs) that are layered and can be exfoliated down to the monolayer limit, p-TMDs like NiS₂ feature strong covalent/ionic bonds between their crystallographic planes. As a result of these strong bonds, p-TMDs are not easy to exfoliate in the form of nanoflakes, *i.e.*, as samples with size in one dimension (typically the thickness) within the nanoscale range, and sizes along the other two dimensions in the micrometre range. This is one reason why most studies on p-TMDs to date have been carried out on p-TMDs in bulk single-crystalline form, which makes it difficult to obtain quantitative information about local variations in their physical properties using a combination of local electronic transport and magnetometry measurements, with high spatial resolution.

In addition to the coexistence of different types of magnetic ordering at low T , NiS₂, which is a Mott insulator in the bulk, also features a metallic behaviour at its surface in the same low- T regime. From this point of view, NiS₂ is a p-TMD that would be interesting to study as single-crystalline nanoflakes, to gain a better understanding of the interplay between magnetic textures and electronic transport in this material at the nanoscale.

In terms of its magnetic properties, NiS₂ hosts a Type-I anti-ferromagnetic (AF) phase with long-range ordering (LRO) and a Néel temperature (T_{N1}) typically of ~ 38 K.^{7–10} Above T_{N1} , NiS₂ is paramagnetic.⁸ In the Type-I AF phase, the spin lattice of NiS₂ consists of four sublattices with a unit cell equivalent to the chemical cell, with each of the four spins forming an angle $\theta = 12^\circ \pm 4^\circ$ with respect to the principal axis of the electric field gradient at the Ni sites.^{11,12} This Type-I AF ordering of NiS₂ on its face-centred cubic (fcc) lattice is also known as a triple-Q structure because the ground state of this AF phase is triply degenerate due to the fcc lattice symmetry.^{13–15} The triple-Q structure also exists in other materials, like γ -FeMn,¹³ γ -MnNi¹⁴ and NpO₂.¹⁵

As T is lowered below T_{N1} , a Type-II LRO AF phase also appears in NiS₂ with a Néel temperature T_{N2} of ~ 30 K.^{7,10,16–18} Although Type-I and Type-II AF phases should be incompatible in the fcc lattice of NiS₂, they coexist over a certain temperature range as the result of a first-order phase transition accompanied, it has been proposed, by a small but finite distortion of the fcc lattice.^{19,20} This lattice distortion has been suggested to lift the degeneracy of the two AF phases,¹⁷ leading to a change in θ for the Type-I AF phase.¹¹ A canting in the spin direction towards the [100] axis due to the lattice distortion also induces weak ferromagnetic (WF) ordering^{8–11} with onset temperature T_{WF} coinciding with T_{N2} . The precise origins of this WF phase, however, remains a matter of debate.^{10,21}

Even more interesting is the fact that the coexistence of AF and WF orderings in NiS₂ also occurs along with an enhancement in its surface electrical conduction at low T . Several experiments based on photoemission spectroscopy²² and on magnetotransport measurements^{23–25} (the latter also with NiS₂ polycrystalline samples²⁵) have shown that the NiS₂ surface is more conductive than the bulk. As T is decreased, electronic transport in NiS₂ thus becomes effectively two-dimensional (2D), meaning that transport is completely shunted by the NiS₂ surface. Evidence for this is also provided by the fact that the contribution of the surface metallic conduction to the overall sample conductance at low T increases as the NiS₂ thickness is reduced.^{23,24} Measurements of the magnetic susceptibility χ also show an increase of the contribution of the WF phase to the total magnetic moment,⁸ when this is normalised to the sample volume, as the thickness of the NiS₂ single crystals decreases. Although those magnetic results were not confirmed in recent studies,²⁴ the combination of the above observations suggests the possibility of a correlation between the surface conduction and the WF ordering at low T in ultrathin NiS₂ crystals.

To reach a better understanding of the physical properties of NiS₂ at low T , and of the interplay between electronic transport and magnetic spin textures, here we study NiS₂ in the form of nanoflakes. These nanoflakes allow us to investigate electronic transport properties in NiS₂ using local electrical contacts to NiS₂, which we pattern with electron-beam lithography (EBL). We also apply a magnetometry technique with high spatial resolution – diamond quantum magnetometry (DQM) with nitrogen vacancy (NV) centres – to probe any spatial variations in the magnetic spin texture of NiS₂, which is essential to interpret the magnetotransport measurements that we carry out on the same nanoflakes. We note here that magnetotransport measurements on NiS₂ single crystals have been reported, but only down to $T \approx 35$ K.²⁴ On our NiS₂ nanoflakes, we instead study magnetotransport down to $T \approx 1.5$ K, and hence also below T_{WF} , where the interplay between magnetism and electronic transport could trigger unusual phenomena due to the coexistence of AF and WF phases with 2D surface conduction.

2. Results and discussion

We produce NiS₂ nanoflakes using a technique we have recently developed, which allows for the production of nanoflakes of any covalently or ionically bonded material in single-crystalline form, *via* subsequent cleaving and mechanical exfoliation of the same crystals.

In particular, the fabrication starts by cleaving a NiS₂ single crystal with a ceramic ZrO₂ blade to prevent contamination of the smaller pieces of crystal obtained during this process. The cleaving is carried out in a glovebox in inert (N₂) atmosphere directly on a piece of strong adhesive tape so that the smaller NiS₂ crystals obtained at the end of this step are on the tape ready to be exfoliated. The smaller crystal pieces are then broken into nanoflakes by mechanical exfoliation and transferred onto a SiO₂ (300 nm)/Si substrate with pre-patterned Au/Ti markers used as reference to locate the nanoflakes (Fig. 1a). The substrates are then mapped with an optical microscope inside the glovebox to detect those flakes which are likely NiS₂. This is done because several other flakes of different materials (also from residues present in the tape) can be found on the substrate after exfoliation. The composition of the identified NiS₂ flakes is confirmed by energy-dispersive X-ray (EDX) analysis, which is usually done after the measurements to avoid contamination of the interface between the contact electrodes and the NiS₂ surface, or oxidation of the NiS₂ surface before device fabrication.

Unlike other NiS₂ nanoflakes reported in the literature, which are prepared *via* chemical synthesis methods, mostly for water splitting applications,^{26,27} our NiS₂ nanoflakes are single-crystalline because they are obtained from NiS₂ single crystals, from which they must retain certain physical properties. The NiS₂ nanoflakes reported in this study have a thickness ranging between ~ 200 nm and 800 nm, which makes them about three orders of magnitude thinner than the

Fig. 1 Structural characterisation and elemental composition analysis of the NiS₂ nanoflakes. (e) Elemental composition analysis of the nanoflake in (d) based on energy-dispersive X-ray (EDX) spectroscopy.

thinnest NiS₂ single-crystalline samples reported to date, which were produced by mechanical polishing.²⁴ This reduced thickness of our NiS₂ nanoflakes compared to single crystals should increase any surface-related contributions to charge transport, and in turn amplify any effects derived from the interplay between surface states and magnetic spin textures at low T .

Fig. 1a shows a typical NiS₂ nanoflake that we obtain from a NiS₂ single crystal (see ref. 24 for a description of the relevant single-crystal growth) on SiO₂(300 nm)/Si with pre-patterned Au/Ti markers. In addition to being helpful for the location of the nanoflakes under an optical microscope, the markers are also used for alignment of the electron beam during the patterning of electrical contacts to the nanoflakes by EBL. The EBL patterning is then followed by magnetron sputtering of the electrode materials and removal of the EBL resist. We use sputtering of the contacts to get better coverage of the electrodes' material along the nanoflake edges.

X-ray diffraction (XRD) measurements carried out with a micro-XRD (μ -XRD) setup show that our NiS₂ nanoflakes always exfoliate along the same crystallographic axis, as they are all (200)-oriented (Fig. 1b). We can differentiate the diffraction peaks of the NiS₂ nanoflakes from those generated by the Au/Ti markers and the substrate by performing μ -XRD measurements on substrate areas with markers but without nanoflakes (Fig. 1b; inset). The (200) orientation of our NiS₂ nanoflakes is also confirmed by surface electron back-scattered

diffraction (EBSD) measurements (Fig. 1c), which we carry out in a scanning electron microscope (SEM).

The EBSD data show that the NiS₂ nanoflakes exfoliate with the a - and b -axis of the cubic unit cell oriented along the nanoflake edges (Fig. 1d). We also carried out EDX spectroscopy on all NiS₂ nanoflakes investigated to confirm that their stoichiometry corresponds to the nominal stoichiometry of the NiS₂ crystals from which the nanoflakes are obtained (Fig. 1e). The elemental analysis based on the EDX pattern of a NiS₂ nanoflake reported in Fig. 1e, for example, confirms the stoichiometric 2 : 1 ratio of S to Ni within experimental uncertainty.

Using electrical contacts to the nanoflakes fabricated by EBL (Fig. 2a), we first characterise their electronic transport properties down to low T . The resistivity *versus* temperature, $\rho(T)$, curves show different trends in the range 50 K < T < 150 K, depending on the material from which the electrical contacts to the NiS₂ nanoflakes are made. When Au/Ti contacts are used, we sometimes measure non-linear current *versus* voltage curves, $I(V)$, likely characteristic of poor transparency (*i.e.*, high contact resistance) at the contact/nanoflake interface. With such Au/Ti contacts, $\rho(T)$ monotonically increases from room T all the way down to low T (Fig. 2b). When Au/Pd contacts are used, however, for which linear $I(V)$ curves are always measured, a decrease in $\rho(T)$ occurs at 50 K < T < 150 K, before $\rho(T)$ increases again for T < 50 K (Fig. 2c). We therefore relate the metallic behaviour shown in Fig. 2c for 50 K < T < 150 K to a better interface transparency (lower contact resistance) when we employ Au/Pd rather than Au/Ti contacts.

The better interface transparency obtained with a Pd wetting layer may well be due to the larger molar enthalpy of formation of TiS₂ (from -400 to -600 kJ mol⁻¹; ref. 28) and other Ti sulfides, compared to that of PdS and other Pd sulfides (from -70 to -96 kJ mol⁻¹; ref. 29). This likely favors interfacial metal/sulfide reactions (forming poorly-conducting TiS₂, for example) when Au/Ti contacts are deposited, but not in the Au/Pd case. The transport data reported in the remaining part of this manuscript are thus collected on NiS₂ nanoflakes with Au/Pd contacts, unless otherwise specified.

In a recent study,²⁴ it has been shown that $\rho(T)$ for NiS₂ single crystals can change significantly depending on the surface preparation and thickness. For NiS₂ single crystals that are thinned by mechanical polishing, for example, an enhancement in surface conduction is observed, which results in a flattening of $\rho(T)$ at T < 150 K.²⁴ Although our NiS₂ nanoflakes are thinner by almost a factor of 10³ than the thinnest NiS₂ single crystals obtained by mechanical polishing in ref. 24, the $\rho(T)$ curves that we measure (Fig. 2b and c) show similar trends to those reported for NiS₂ single crystals without surface polishing,^{30,31} with a typical kink in $\rho(T)$ around T_{WF} . Nonetheless, the $\rho(T)$ that we measure at low T (Fig. 2b and c) is smaller than that reported in ref. 24, consistent, significantly, with an increase in the contribution of surface metallic states to the electronic conduction in our ultrathin NiS₂ nanoflakes.

To study the effect of magnetic spin textures in NiS₂ on the electronic transport, we also carried out magnetotransport

Fig. 2 Electronic transport measurements on NiS₂ nanoflakes. (a) Pseudo-colour scanning electron micrograph of a 550 nm-thick NiS₂ nanoflake (light blue area) with Au/Pd electrical contacts (yellow areas) fabricated on top of the nanoflake. (b and c) Resistivity *versus* temperature, $\rho(T)$, curves measured for a 380 nm-thick NiS₂ nanoflake with Au/Ti contacts (b) and for a 400 nm-thick NiS₂ nanoflake with Au/Pd contacts (c).

measurements on NiS₂ nanoflakes. To the best of our knowledge, resistivity *versus* applied magnetic field, $\rho(H)$, curves for NiS₂ single crystals have only been reported for $T > 35$ K (*i.e.*, above T_{WF}),²⁴ and measured with contact geometries much less local (*i.e.*, on far bigger scales) than those of our nanoscale devices. Measurements on bulk crystals with wire-bonded contacts other than with local EBL-patterned contacts as in our study, for example, make it difficult to study electronic transport due to edge states, or to investigate the effect of few magnetic domains on electronic transport properties.

Here, we perform magnetotransport measurements as T is progressively lowered below T_{N1} and T_{WF} to better understand the influence of both AF and WF order on electronic transport. The most striking magnetotransport features that we report are measured below T_{WF} , *i.e.*, at a T where the WF and AF orders coexist in NiS₂. In this state, *field-asymmetric* features in the magnetoresistance (MR) are found (Fig. 3), meaning different values of $\rho(H)$ for opposite H polarities. We define $MR(H) = 100 \times ((\rho(H) - \rho(0))/\rho(0))$ here. A list of the devices for which we have performed MR measurements is reported in Table S1 of the ESI† together with some device parameters (*e.g.*, direction of applied H , ρ at $T = 300$ K *etc.*). In Table S1,† we also identify each device with a number, which we also use to refer to a specific device in this manuscript.

Fig. 3 (where the applied H is in the plane of the flake) shows that for device 1 in the paramagnetic state of NiS₂ ($T > T_{N1}$), or in the Type-I AF state ($T_{WF} < T < T_{N1}$), we only measure field-symmetric MR(H) in agreement with other studies.²⁴ As T is lowered below T_{WF} , however, for all the devices investigated here, MR(H) assumes different values at the limits of the applied H range (*i.e.*, $[-7$ Tesla, 7 Tesla]), meaning that it becomes strongly asymmetric with respect to H polarity. This asymmetric MR behaviour for opposite H directions at $T < T_{WF}$ occurs with both in-plane and out-of-plane H , and it is independent of the type of contacts used (Fig. 4). In addition, MR(H) also changes sign, going from negative to positive values in the intermediate range of the H that we apply (see, *e.g.*, curves measured at 5 K and 18 K in Fig. 3 at negative H values between -3 T and 0 T). Lastly, we note that for some devices,

Fig. 3 Magnetotransport measurements on NiS₂ nanoflakes (device 1). Variation in magnetoresistance (MR) defined as $MR(H) = 100 \times (\rho(H) - \rho(H = 0))/\rho(H = 0)$ for a 380 nm-thick NiS₂ nanoflake as a function of T with an in-plane applied H . Ascending and descending H sweeps are shown in blue and red, respectively, with the measurement T indicated in the top right corner of each panel. $\mu_0 = 1.657 \times 10^{-6}$ N A⁻² is the vacuum permeability. Gray dashed lines indicate the MR measured at $H = 0$, whilst green arrows show the hysteretic MR loops that are shifted with respect to $H = 0$.

at $T < T_{WF}$, MR(H) also exhibited hysteretic loops that are shifted in H with respect to $H = 0$ (see Fig. 3 at 5 K and 18 K).

The latter type of feature resembles the magnetotransport behaviour observed, for example, in spin valves based on thin film heterostructures with a ferromagnetic (F) layer exchange-biased by an AF layer exchange coupled to it. Critically, these asymmetric MR behaviours were observed in several devices not only for out-of-plane H (Fig. 4; devices 2 and 3), but also in-plane H (Fig. 4; device 1), ruling out that this MR behaviour is due to contamination of the MR signal by some anomalous Hall effect. A planar version of the latter might be envisioned also, but the behaviour of the MR asymmetry is essentially the

Fig. 4 MR change at $H = \pm 7$ Tesla for different devices made on NiS₂ nanoflakes with thicknesses of 380 nm (device 1; top panel), 790 nm (device 2; middle panel) and 400 nm (device 3; bottom panel). H is applied in plane for device 1 and out of plane for devices 2 and 3.

same for out-of-plane and in-plane H (Fig. 4), making us confident that the observed asymmetry is not due to contamination of the typically field-even MR by field-odd Hall effects.

The MR curves for devices 2 and 3 are reported in Fig. S1 and S2 of the ESI file.† We observe that the $MR(H)$ curves show a negative background above T_{WF} when H is applied out of plane (device 1 in Fig. 3) and a positive background when H is within the plane (devices 2 and 3 in Fig. S1 and S2†).

The asymmetric and hysteretic $MR(H)$ features shown above, and the fact that their onset T corresponds to T_{WF} , also suggest that these features originate from the interplay between WF and AF orders, which coexist in NiS₂ at $T < T_{WF}$. One possible explanation for these MR features would be that the WF regions in NiS₂ form adjacent to AF regions, resulting in exchange-coupled areas with different coupling strength that are sensitive to the applied H and strongly affect the local magnetotransport measurements. Exchange-bias-type effects at these WF/AF interfaces may then lead to asymmetric MR with hysteretic features like those that we report in Fig. 3.

To probe the above hypothesis and resolve the types of magnetic spin texture forming locally in NiS₂, we also carried out DQM using commercially available diamond probes with a single NV centre at the apex of a diamond tip (Fig. 5f). The NV

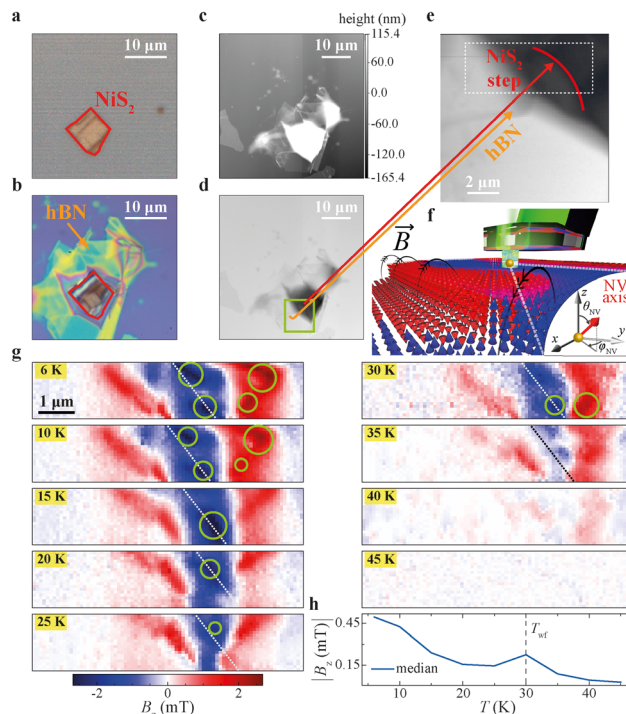

Fig. 5 Diamond quantum magnetometry (DQM) measurements on NiS₂ nanoflakes. (a–e) Optical microscope image of a NiS₂ nanoflake before (a) and after capping with hBN (b) with atomic force microscopy image after capping in (c) and with inverted colour bar in (d). Panel (e) is a zoom in on the area in the green box of (d), with the white box highlighting where the DQM is done. (f) Schematic of the DQM setup. (g) Magnetic field B_z measured by DQM at different temperatures T_s (specified in the yellow boxes) on the NiS₂ area corresponding to (e) showing regions with stronger B_z (green circles) close to a nanoflake step edge (dashed line). (h) Median value of B_z versus T over the nanoflake areas in (g).

axis direction is defined by the angles (φ_{NV} and θ_{NV}), as shown by the schematic illustration of the DQM setup shown in Fig. 5f. The values of φ_{NV} , θ_{NV} and the distance of the NV centre from the sample surface (d_{NV}) have been determined *via* independent measurements,³² as reported in the ESI.† The NV centre measures the projection of the stray field coming from the sample along the NV axis. The out-of-plane component of the magnetic field (B_z) at the sample is then reconstructed *via* the Fourier method.³³

We note that, only for the DQM measurements, we used a hexagonal boron nitride (hBN) flake as capping layer to prevent the oxidation of the NiS₂ nanoflakes (see ESI†). We performed DQM measurements as a function of T , whilst progressively reducing T below T_{N1} and T_{WF} , to correlate possible changes in the magnetic signal probed by the NV spins with the onsets of the AF and WF orders. The results of the DQM measurements are shown in Fig. 5g for a representative NiS₂ nanoflake. The measurement data show the absence of any significant B_z originating from the NiS₂ nanoflakes at $T > T_{N1}$, which agrees with the absence of any type of magnetic ordering in NiS₂.

As T is reduced below T_{N1} , however, an increase in the stray magnetic field signal probed by the NV spin is clearly observed. In particular, we detect regions of the nanoflakes that generate magnetic field with opposite direction (red and blue areas in Fig. 5g measured for $T < T_{N1} \approx 35$ K). These regions likely correspond to areas with uncompensated moments on the NiS_2 surface.

Characterisation of the surface topography of our NiS_2 nanoflakes *via* atomic force microscopy indeed shows that they have a stepped surface (see, *e.g.*, Fig. 5c–e). Such a stepped surface in the AF state of NiS_2 could lead to the formation of areas with uncompensated magnetic moments,³⁴ which would generate a non-null B_z for $T < T_{N1}$. This B_z can also change polarity when moving from one terrace to another depending on the step height, which is consistent with the DQM data in Fig. 5g.

As T is reduced below T_{WF} , we then detect additional regions with stronger B_z , which we associate with the WF order in NiS_2 , since they appear around $T_{WF} \sim 30$ K. The increase in B_z below T_{WF} is also shown in Fig. 5h, where we report the median absolute value of B_z originating from the sample as a function of T . Our DQM data in Fig. 5h confirm that areas with stronger B_z (green circles in Fig. 5g), which we ascribe to the WF phase, emerge in proximity to AF regions with uncompensated moments that we resolve at the NiS_2 surface at $T_{WF} < T < T_{N1}$. Since exchange coupling is known to arise at the interface between F regions and AF regions with uncompensated moments,^{35,36} exchange bias effects can account for the exchange-bias-like MR features observed at temperatures where AF and WF coexist (Fig. 3 and 4).

We also note that the regions with B_z that we associate with the WF phase are mostly localised near step edges on the NiS_2 nanoflakes (see the dashed line in Fig. 5g), where the formation of AF areas with uncompensated moments is more likely. It is therefore reasonable to assume that near step edges the concentration of non-collinear magnetic textures and exchange-bias regions increases. This means that nanoflakes with steeper edges should exhibit more asymmetric MR features and larger MR ratios than those we measure for NiS_2 nanoflakes with a mostly flat surface (Fig. 3). To verify this, we selected NiS_2 nanoflakes with higher steps and wider terraces and measured their $\text{MR}(H)$ using contacts made to opposite sides of the nanoflake, across a step edge.

The results of these magnetotransport measurements are reported in Fig. 6 and Fig. S3† for two different NiS_2 nanoflakes. For both nanoflakes, we measure a significant increase of the $\text{MR}(H)$, which reaches values as high as 1370% for one of these nanoflakes at the limits of the applied H range (at $T \sim 26.6$ K in Fig. 6b). More strongly asymmetric behaviour in MR for positive and negative H , and more pronounced exchange-biased-like features than those shown in Fig. 3 are also measured.

The largest MR measured for the flake with a step edge in Fig. 6 at $T \sim 26.6$ K occurs around the same T at which we also observe a peak-like feature in the B_z (mT) measured by DQM near the step edges of NiS_2 nanoflakes (Fig. 5). The combi-

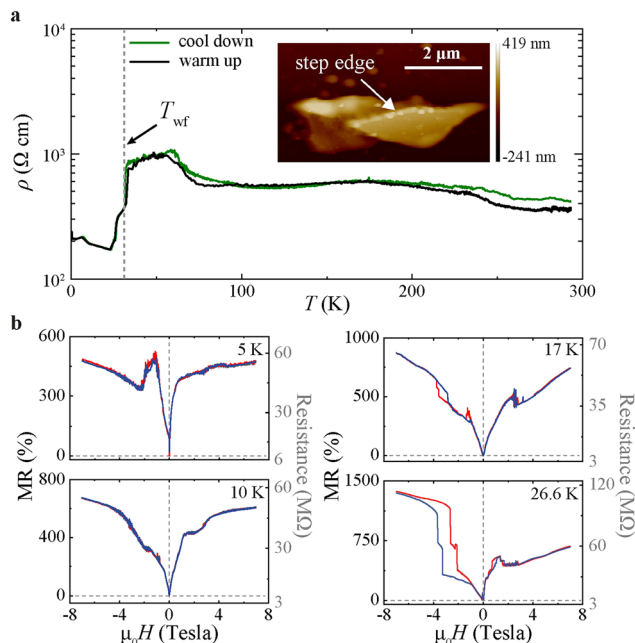

Fig. 6 Magnetotransport measurements on a NiS_2 nanoflake with high step edges (device 4). (a) Resistivity versus temperature, $\rho(T)$, curves measured for a 280 nm-thick nanoflake. Atomic force microscopy image highlighting the step edges of the nanoflakes is shown as inset panel (a). The dashed line in panel (a) marks T_{WF} . (b) MR change as a function of the applied field H , $\text{MR}(H)$, at a few representative temperatures (left axes) and corresponding resistance values (right axes) measured for the NiS_2 nanoflake in (a). Ascending and descending H sweeps are shown in blue and red, respectively.

nation of these results suggests that the onset of the WF phase in NiS_2 can indeed be the physical mechanism responsible for the large MR measured near step edges.

We note here that the expression ‘giant magnetoresistance’ has been originally introduced in the literature for spin valve devices based on thin film multilayers consisting of magnetic layers separated by non-magnetic ones.³⁸ After its introduction, the same expression has been also used to describe changes in MR in magnetic thin film multilayers with exchange-bias effects at their interfaces.^{39,40} We therefore refer to the very large changes in MR that we measure in our NiS_2 devices as giant magnetoresistance because the effects that we observe arise across interfaces between regions with different magnetic orders/spin textures, making them close to the effects observed for magnetic multilayer systems, for which the expression giant MR is routinely used.

For the two devices with step edges that we have measured (device 4 in Fig. 6 and device 5 in Fig. S3†), we find that the MR background is always positive, independent of the direction of H . For device 4, for example, where H is applied in plane, the MR background is positive at $T > T_{WF}$. Similarly, for device 5 in Fig. S3† the MR background remains positive, although H is applied out of plane. We believe that the positive MR background in devices with step edges is not a deterministic property, as the MR in such devices depends on a variety of

factors, which makes its sign difficult to predict. First, the voltage signal that we measure in devices with step edges has both in-plane and an out-of-plane contributions from the bias current. Also, spin textures forming in these devices can exhibit complex patterns near step edges, as confirmed by the DQM data in Fig. 5, that can be randomly distributed with respect to the measurement electrodes every time a device with step edges is made. All these factors make it difficult to understand the origin and predict the sign of the MR background in such devices.

We further observe that the resistivity $\rho(T)$ measured with the configuration of the electrical contacts across step edges shown in Fig. 6a and S3[†] takes on much larger values compared to those measured on nanoflakes with a flat surface (Fig. 3), but still in line with the ρ values reported in other studies of single crystals.²⁴

The larger ρ measured on nanoflakes with higher steps (Fig. 6 and S3) is consistent with an increase in the current component that flows along the NiS₂ out-of-plane direction, meaning across the bulk of the nanoflake, which is known to be less conductive than the surface. Also, the interplay between WF and AF phases is more strongly probed in this transport configuration, and it results in $\rho(T)$ with sharp jumps and/or instabilities near the onset temperatures (T_{WF} and T_{N1}) of the two magnetic orders (Fig. 6 and S3). We also note that the MR curves show a host of very complex behaviours at low T , both in nanoflakes with and without step edges (Fig. 3a, 6 and S3[†]). Further studies, possibly with the support of micromagnetic simulations, will be needed to understand the complex T evolution of these MR features below T_{WF} , parts of which we ascribe to the interplay between WF and AF phases in NiS₂ nanoflakes. Also, magnetotransport measurements on bulk single crystals below T_{WF} will have to be carried out to compare the low- T magnetotransport properties of bulk single crystals to those which we have measured for NiS₂ nanoflakes.

3. Conclusions

In conclusion, we have fabricated NiS₂ nanoflakes by exfoliating NiS₂ single crystals, characterised their low- T magnetotransport properties, and correlated the magnetotransport data with the magnetic spin textures existing in the material by NV magnetometry. Nanoflakes with a flat surface show surface-dominated electronic transport at low T and field-asymmetric MR with hysteretic features that resemble those usually observed in more complex magnetic thin-film heterostructures. Based on our NV results, we correlate these MR features to exchange-bias-type effects originating at the interface between the WF regions and uncompensated moments of the Type-I AF regions at the NiS₂ surface, which has a step-and-terrace topography. When nanoflakes with higher steps are tested, an extremely large increase in MR asymmetry and more pronounced exchange-bias-like features are measured. These results suggest that NiS₂ nanoflakes host intrinsic exchange

bias effects due to the coupling of surface regions with different types of magnetic orders at low T . As a result of the good surface metallicity of NiS₂, exchange-coupled surface regions then have a strong effect on the magnetotransport properties of the NiS₂ nanoflakes.

One implication of our findings is that NiS₂ nanoflakes could potentially be used as an alternative to more complex thin-film heterostructures for a variety of spintronic and device applications based on MR effects. The good metallicity of the flat nanoflakes, in combination with exchange-coupled spin textures, could also be exploited for the realisation of superconducting spintronic devices by coupling NiS₂ nanoflakes to superconducting materials.³⁷ In such systems, the magnetic spin textures at the metallic surface of NiS₂ could be tested for the generation of long-range spin-triplet correlations.

Although the resistivity ρ of our NiS₂ nanoflakes is three orders of magnitude lower than that of NiS₂ single crystals,²⁴ we also note that it increases at low T , which can in principle be a problem when coupling NiS₂ nanoflakes to superconductors. Nonetheless, the absolute value of ρ at low T ($\sim 1.0 \Omega \text{ cm}$ at $T \sim 4.2 \text{ K}$ for nanoflakes with a flat surface; Fig. 2) is still lower than that of other TMDs like MoS₂ (ref. 41 and 42) for which proximity-induced superconductivity has been observed.^{43,44} These results on other TMDs are therefore very encouraging with respect to coupling NiS₂ to superconductors, which may result in an even stronger proximity effect due to the relatively low ρ of the NiS₂ surface at low T .

Finally, we note that NiS₂ nanoflakes can be picked up *via* the same dry-transfer technique used for other van der Waals (vdW) materials. This implies that the exchange-bias-type effects intrinsic to NiS₂ nanoflakes could potentially be used for the realisation of novel exotic phases and quantum effects obtained by coupling NiS₂ nanoflakes to other vdW materials.

Author contributions

A. D. B. conceived the project. R. H. exfoliated the NiS₂ nanoflakes with some help from D. L. The nanoflakes were exfoliated from single crystals grown and characterised by C. L. and B. D., also with some support from S. E. K. and M. E. The fabrication of devices on NiS₂ nanoflakes was done by R. H. and low-temperature magnetotransport measurements were carried out by R. H. and A. D. B, with some help from M. Am. The analysis of the magnetotransport data was done by R. H., E. S. and A. D. B. Diamond quantum magnetometry data were collected and analysed by M. H., A. K. C. T., and M. At. The manuscript was written by A. D. B. and R. H. with contributions to the text and comments on the results from all authors.
