Recent progress in semiconductor/graphene photocatalysts: synthesis, photocatalytic applications, and challenges

Mahmoud A. Ahmed ^{†*} and Ashraf A. Mohamed [†]

The presence of an increasing number of organic pollutants in water now poses serious risks to both human health and ecological systems. Many of these pollutants are persistent and non-biodegradable. The contamination of fresh water by harmful substances has compelled researchers to develop innovative, efficient, and cost-effective water remediation techniques and materials. Thus, photocatalysis has long been recognized as a promising approach to tackle both environmental remediation and the energy crisis. However, semiconductor photocatalysts frequently suffer from defects such as photo-generated charge carrier recombination, poor visible light response, and slow surface reaction kinetics, which can be remedied by modifications with appropriate co-catalysts. Therefore, graphene and its derivatives have widely been used as supports for semiconductors and photocatalysts due to their distinctive optical, physicochemical, and electrical features. This critical review addresses the current progress in the design and synthesis of graphene/semiconductor photocatalysts, as well as their use in photocatalytic degradation of organic pollutants and hydrogen production. Several influencing parameters are addressed, including pH, photocatalyst loading, initial pollutant concentration, light wavelength, and oxidizing species, all of which could have a significant impact on the rate of organic pollutant's degradation. Furthermore, the recyclability of the catalyst and its photocatalytic activity mechanisms are thoroughly discussed. Numerous case studies are systematically presented. Moreover, future prospects and major challenges are highlighted.

Mahmoud Adel Ahmed is currently a doctorate student under the supervision of Prof. Ashraf A. Mohamed, in the Department of Chemistry, Faculty of Science, Ain Shams University, Cairo, Egypt. He earned his M. Sc. degree in 2019. He is actively engaged in the research for the past six years and his research focuses on synthesis, characterization, and environmental applications

of nanomaterials and their composites. He has been working for Veolia Environmental Services as a service engineer in water desalination and wastewater treatment for 10 years.

Ashraf A. Mohamed is a Professor of environmental analytical chemistry, in the Department of Chemistry, Faculty of Science, Ain Shams University, Cairo, Egypt. He earned his M. Sc. degree in 1991, PhD degree in 1995. He is actively engaged in the research for the past 35 years and his research interests include nano-materials, layered double hydroxides, molecularly imprinted

polymers, water treatment and analysis, optical sensors, and paper microfluidics.

a major threat as a result of globalization, urbanization, and anthropogenic activities.^{1,2} Water pollution is defined as any change in the biological, physical, or chemical characteristics of water in lakes, rivers, oceans, and/or groundwater. The three most common types of water pollutants are organic pollutants (*e.g.*, hydrocarbons, dyes, pesticides, pharmaceuticals, phenols), biological pollutants (*e.g.*, microorganisms), and inorganic pollutants (*e.g.*, heavy metals).^{3–5} An appreciable fraction of dyes contain known carcinogenic moieties such as naphthalene, benzidine, or quinonoid structures.^{6,7} Various types of dyes are available commercially, and they are used in various industrial dyeing processes, *e.g.*, in rubber, textile, paper, paint, printing, plastic, pharmaceutical, cosmetics, food, and leather sectors.^{6,8} The world consumes over 800 000 tons of organic dyes annually, where approximately 20% of the total dyes production is wasted during various industrial dyeing processes.^{9–11} Effluents resulting from the textile and dyeing industries process usually contain mixtures of dyes, metal ions, and other pollutants, as well as to its elevated levels of biochemical oxygen demand, pH, suspended solids, chemical oxygen demand, salts, and colors.⁶ The discharge of these pollutants into bodies of water without proper treatment can have serious consequences, such as toxicity to mammals, fish, and aquatic microorganisms, and can even obstruct the photosynthesis of aquatic plants, resulting in the destruction of the aquatic ecosystem.^{12,13} As a result, innovative, cost-effective, recyclable, and environmentally friendly approaches are required to eliminate these dangerous threats. Several approaches have been widely employed in industrial sectors to eliminate organic pollutants, and heavy metals from real wastewater; *e.g.*, reverse osmosis, ion exchange, coagulation–flocculation, ultrafiltration, electrodialysis, adsorption, chemical precipitation, and solvent extraction.^{6,14,15} Due to the renewability of solar light, sustainability, and the global energy crisis, photocatalytic process has emerged as a desirable green solution to deal with the worsening environmental problem and energy crisis and through degradation of organic contaminants and generation of hydrogen, respectively.^{16,17} With ever-increasing energy consumption that exceeds its supply, the globe is edging closer to a grave energy catastrophe. We take it for granted while always knowing that the energy we consume on a daily basis is finite. Water, oil, gas, and power are all scarce resources. Hydrogen is considered a renewable power resource due to near-zero-emission operation and has great energy density as well as provides high-quality energy services in a wide range of applications.^{3,4} As a result, there has recently been a lot of interest in the development of photocatalytic processes based on semiconductors due to their ease of use, high stability, low cost, suitable band positions, and nontoxic nature.^{18,19} Furthermore, some semiconductor-based materials can conduct electrons in the presence of light even at room temperature. With incident radiation of proper energy ($h\nu$) that is equal to or greater than the bandgap energy of a photocatalyst, an electron in the valence band (VB) is transferred into the conduction band (CB) level, with the formation of a hole in the VB.^{20–22} The excited electron and photogenerated holes play a critical role in photocatalytic degradation of organic

pollutants, as well as solar energy conversions such as solar photovoltaics and hydrogen production.^{23–27} However, there are some drawbacks that limit the widespread use of photocatalysts in practical applications; *e.g.*, the high bandgap energy, the poor visible light absorption, and the ease of electron–hole recombination that waste energy as heat and result in poor photocatalytic activity.^{28,29} Therefore, several strategies have been used over the last decade to improve the photocatalytic behavior of semiconductor photocatalysts; *e.g.*, by proper textural design, noble metal doping, and tailoring of proper composites. In particular, several studies have incorporated graphene-based materials with semiconductors to improve their photocatalytic performance. Graphene is a single 2D nanosheet with sp^2 hybridization that has a honeycomb-like structure, zero bandgap energy, possessing distinctive electrical features such as ballistic electronic transport, massless fermions, and extremely high electron mobility ($200\,000\text{ cm}^2\text{ V}^{-1}\text{ s}^{-1}$). Moreover, graphene has a large surface area ($2630\text{ m}^2\text{ g}^{-1}$), a highly flexible structure, high thermal conductivity ($\approx 5000\text{ W m}^{-1}\text{ K}^{-1}$), and high transparency (optical transmittance is 97.7%).^{6,8,30–33} Graphene is hydrophobic and chemically inert due to the absence of undesirable functional groups. Reduced graphene oxide (rGO) and graphene oxide (GO) are two common counterparts of graphene. GO is commonly synthesized by the oxidation of pristine graphite. GO contains an abundance of groups on both sides of its sheet, namely hydroxyl epoxy on the basal plane, and carboxyl and carbonyl at the layer boundaries, which in turn enables GO to form stable suspensions in solutions, and also work as sites for semiconductors nucleation and growth. However, an excess of groups in non-conducting σ states may lead to the insulation of GO, which reduces the separation and transport of charge carriers.^{34–36} The number of groups generated on the GO layers depends on the type of used graphite and the oxidation conditions. The miniature form of GO is rGO, which can be made from chemical/thermal reduction or direct growth of GO. Thus, rGO has fewer surface groups and an excessive amount of defects, which makes it more chemically stable and has higher electrical conductivity compared to its parent GO. Due to these distinctive features, graphene and its counterparts (GO and rGO) have drawn great interest in photocatalytic applications.^{37,38} The scientific works published on graphene-based photocatalysis over the period 2006 to 2022_11 are illustrated in Fig. 1. A total of 4630 publications have been incorporated into the Scopus database under the keywords “photocatalysis and graphene”. These papers have been categorized as; 86% journal articles, 5% conference papers and book chapters, and 8% reviews, this illustrates the importance of reviews devoted to the topic.

Herein, we provide a critical and comprehensive review of the use of graphene-based semiconductors in photocatalytic degradation of organic pollutants and hydrogen production. The methods of synthesis, physicochemical characterization, and photocatalytic activity are thoroughly reviewed, in a chronological order, with numerous representative examples. The operating parameter, the recyclability, and the mechanisms of the photocatalytic processes are also discussed. In addition, we attempted to present challenges for improving the

Fig. 1 Number of publications in Scopus database reporting graphene/semiconductors materials for photocatalytic reaction (keywords: graphene AND photocatalysis).

photocatalytic performance of graphene-based semiconductors for industrial applications. We believe this review will benefit researchers in the fields of photocatalysis, graphene and semiconductors-based nanomaterials.

2. Preparation of graphene/semiconductors composites

Various semiconductor materials have been utilized for the production of graphene-based photocatalysts. These include metal oxides, metal sulfides, silver/silver halides, salts, and metal-free polymers like graphitic carbon nitride, as well as others.^{39–41} There are two basic methods of preparation: (1) *in situ* crystallization, in which nanocrystals form and grow on graphene-based material surfaces, and (2) *ex situ* crystallization, in which pre-fabricated nanomaterials are mixed with graphene-based material surfaces.⁴² The *in situ* method results in a homogeneous distribution of semiconductors on 2D nanosheets of the graphene material; moreover, the functional groups present on GO can be used to control the crystallinity, size, and morphology of the *in situ* grown semiconductor crystals. In addition, the direct contact of graphene sheets with semiconductor nanoparticles promotes the electron's transfer among them.^{43,44} On the other hand, the *ex situ* hybridization approach is good at overcoming any incompatibility between compounds and enables to co-assembly of nanoparticles of various textures, sizes, and shapes on sheets of graphene or its derivatives.^{45,46} However, the *ex situ* approach suffers from non-uniform distribution and low density of semiconductors on the surface of graphene or its derivatives.^{46,47} There are several methods utilized to synthesize semiconductors/graphene photocatalysis including solvo/hydrothermal, microwave-assisted deposition, sol-gel, and solution mixing.^{48–51}

Hydro/solvothermal methods are widely utilized to synthesize graphene/semiconductor photocatalysts due to its low cost, simplicity, effectiveness, environmental friendliness and the uniform distribution of semiconductor nanomaterials on graphene sheets' surfaces.⁵² However, these methods are very sensitive to the operating conditions such as temperature, pH, and time. Often methanol, ethanol or water is used as a solvent and the nanoparticles are grown under high pressure and temperature.⁷ For example, ZnS/graphene nanoplatelets were synthesized by a solvothermal route, wherein a mixture of graphene nanoplatelets and zinc acetate in ethylene glycol were ultrasonicated for an hour, and sodium sulfide solution was added into the mixture that was then transferred into an autoclave and heated to 1600 °C for 15 h.⁵³ The obtained ZnS/graphene nanoplatelets composite was then characterized by SEM, Raman, AFM, XRD, and DRS studies.⁵³ Further, a series of Cu₂O-rGO was synthesized through solvothermal method for the photocatalytic degradation Rhodamine B dye.⁵⁴ The SEM and FTIR data confirmed the reduction of GO and the successful fabrication of Cu₂O/rGO_x composites with various wt% of rGO to Cu₂O, where x (0, 0.05, 0.1, 0.2 and 0.5 wt%), respectively; Fig. 2a and c. Moreover, the BET analysis showed that all composites have greater surface areas than pure Cu₂O (Fig. 2d).⁵⁴ Further, rGO/Fe₃O₄ nanocomposites with various mass ratios were synthesized through the solvothermal method, where SEM analysis revealed that Fe₃O₄ particles, with average diameter in the range of 131–237 nm, were densely distributed on both sides of rGO sheets preventing the restacking of rGO sheets.⁵⁵ Moreover, rGO/TiO₂ nanocomposites with various ratios of GO were synthesized *via* solvothermal method.⁵⁶ On the other hand, a graphene/CdS composite photocatalyst for the efficient H₂-production was fabricated through a solvothermal route where CdS uniformly decorated the graphene sheets.⁵⁷ The observed high

Fig. 2 (a) FT-IR spectra of as-prepared Cu₂O/rGO_{x%} samples with various wt% of rGO, (b and c) FESEM image of Cu₂O/rGO 0.05, and 0.5% (wt%), respectively, and (d) N₂-adsorption isotherms of Cu₂O/rGO_{0%} and Cu₂O/rGO_{0.5%} (wt) reprinted with permission from ref. 54. Copyright 2022 Elsevier.

photocatalytic H₂-production activity was attributed predominantly to the presence of graphene that served as an electron collector and transporter to efficiently lengthen the lifetime of the photogenerated charge carriers from CdS nanoparticles.⁵⁷

The sol-gel method is a multistep wet chemical process for the engineering and synthesis of photocatalysts that involves sequentially hydrolyzing molecular precursors such as metal chlorides, metal alkoxides, or organometallic compounds followed by instant polycondensation to form a sol-gel.⁵⁸ This method has several advantages, including low cost, high product homogeneity and purity, ease of manufacture, and low procedure temperatures. Furthermore, surface groups in rGO/GO serve as semiconductor nucleation sites for attachment with the produced metal oxides. Thus, rGO/ZnO with various mass ratios of rGO was synthesized through the sol-gel method and was used to generate a photocurrent. The TEM images revealed a 19 ± 2 nm particle size of ZnO dispersed on the surfaces of rGO sheets; whereas HRTEM images revealed that the weight ratio of rGO affected the crystallinity of the NPs.⁵⁹ Further, GO/TiO₂ thin films were prepared through a sol-gel route where GO markedly enhanced the photocatalytic activity of TiO₂.⁵⁰ Moreover, mesoporous G/TiO₂/SiO₂ nanocomposites were synthesized by the direct sol-gel co-condensation combined with hydrothermal treatment, where graphene similarly exerted a pronounced enhancement of the photocatalytic activity of TiO₂.⁶⁰ Further, rGO/TiO₂ hybrid nanocomposites with various rGO ratios were synthesized by sol-gel route followed by calcination and were applied to photocatalytic hydrogen production; where, a 0.25 wt% rGO gave 10 fold enhancement of the photocatalytic activity of bare TiO₂, and

thus suggested rGO as a competitive cocatalyst to replace noble metals cocatalysts.⁶¹

Microwave irradiation has recently been regarded as a promising tool for the preparation of a wide range of nanomaterials, including bimetallic alloys, metal oxides, semiconductors, and organic compounds, with controlled shape and size and without the need for high pressure or high temperature. Crystalline growth can be controlled during this process by varying the concentrations of different surfactants and the time of the process. Thus, TiO₂/graphene nanocomposite was synthesized through microwave-assisted method that offered a uniform coating and excellent interactions between graphene sheets and TiO₂ semiconductor.⁶² Further, GO/ZnO nanostructures of various ZnO dimensions (3D, 2D and 1D) were prepared through the microwave exfoliation synthesis under different irradiation times; with the schematic procedure for the preparation of various GO-ZnO nanostructures as shown in Fig. 3.⁶³ Moreover, graphene/ZnS nanocomposite was synthesized, in aqueous medium, by microwave-assisted approach during which the GO was converted to graphene; where after photoluminescence studied revealed an electron transfer between graphene nanosheets and ZnS.⁶⁴

Ultrasonic synthesis involves the mixing of graphene or its derivatives with the semiconductor precursors under ultrasonic agitation and mixing where the semiconductors uniformly distribute themselves on surface of graphene sheets and interconnect with them when the liquid is evaporated, to produce the photocatalyst composite. For instance, ZnO/rGO composite was synthesized through a simple ultrasound mixing approach and characterized by various techniques, Fig. 4a-e.⁶⁵ The synthesized ZnO/rGO composite had a band gap of less than

3.03 eV, compared to 3.13 eV for the pure ZnO (Fig. 5c) and FESEM images (Fig. 4d and e) showed the ZnO densely decorating the surfaces of the rGO sheets.⁶⁵ Moreover, a graphene/

TiO₂ photocatalyst was synthesized by ultrasonically mixing graphene oxide with titanium tetrachloride (TiCl₄) in an ethanol-water, followed by reducing by hydrazine.⁶⁶ Further,

two composites of TiO_2 nanoparticles/GO and TiO_2 nanorods/GO were synthesized by ultrasonic mixing of suspensions of GO and TiO_2 nanoparticles or nanorods.⁶⁷ The HRTEM images of TiO_2 nanorods and both composites was illustrated in (Fig. 5a and f).⁶⁷

3. Mechanisms of photocatalysis

Semiconductors usually have a high photosensitivity and crystallinity, a large bandgap, and a low absorption capacity. However, when combined with graphene or its derivatives, semiconductors demonstrated improved photocatalytic activity *via* variety of mechanisms:

3.1 Increasing light absorption harvesting

The fabrication of composites of graphene-based materials and semiconductors, under optimum conditions, usually involve bond formations between the surfaces of graphene materials and the semiconductor that can enhance light harvesting by increasing the light absorption intensity and edge. For instance, diffuse reflectance spectrometric (DRS) analysis showed increased light absorption and edge of ZnS/G composite in visible region compared to pure ZnS due to the black color of graphene, and the band gap decreased from 3.58 eV for ZnS to 3.27 eV for the ZnS/G nanocomposite, Fig. 6a–d.⁵³ Similarly, introducing rGO into ZnO improved its photocatalytic activity by enhancing the light absorption range and intensity.⁶⁸ Furthermore, the synthesized ZnS/rGO photocatalyst, with various ratios of rGO, exhibited a red shift in the absorption edge of the synthesized composites while also improving its light-harvesting capability.⁶⁹

3.2 Enhancement the adsorptive ability of semiconductors

Adsorption of pollutants on the photocatalysis plays an important role in the photo-degradation process because this process mainly occurs on the surface of the photocatalysts. Graphene has a high surface area and an abundance of π electrons, whereas GO and rGO have plenty of $-\text{C}=\text{O}$, $-\text{C}-\text{O}-\text{C}$, $-\text{C}-\text{OH}$, $-\text{COOH}$, among other fruitful functional groups that lead to improved adsorption ability of photocatalysts towards various pollutants by increasing active adsorption sites *via* electrostatic interactions, hydrogen bonding, and $\pi-\pi$, $n-\pi$ and van der Waals interaction mechanisms. However, an excess amount of the graphene material can lead to an increased collisions holes and electrons and thus dramatically reduce the catalytic efficiency of the composites. As a result, the ratio of graphene material plays a critical role in the performance of synthesized composites and must be carefully optimized. For example, the presence of GO improved the removal efficiency of MB by rGO/ TiO_2 because of the abundance of active removal sites, which extremely enhanced the $\pi-\pi$ interaction between the graphitic skeleton of rGO and aromatic rings of methylene blue (MB), in addition to the electrostatic interaction between the residual functional groups of rGO and cationic centers of MB molecules.⁵⁶ Similarly, the incorporation of rGO onto CuI enhanced the overall removal of Rhodamine-B dye.⁷⁰

3.3 Transport of excited electrons from synthesized semiconductors

A semiconductor has an electron-occupied valence band (VB) and an unoccupied conduction band (CB), and the difference between them is known as the band gap. When light with

Fig. 6 Band gaps of ZnS/G NPs (a) and ZnS (b); and diffuse reflectance spectra of ZnS/G NPs (c) and ZnS (d), respectively.⁵³

energy greater than a semiconductor's band gap (E_g) is incident on it, electrons in the VB are transported to the CB, resulting in the formation of positive holes (h^+) in the VB and photo-excited electrons (e^-). The suffering of semiconductor photocatalysts is caused by the rapid recombination of e^- and h^+ , in which photogenerated electrons recombine within 10 nanoseconds. Photocatalytic processes are severely limited in their efficiency due to the rapid recombination of positive holes and excited electrons. Graphene-based materials are used as electronic accumulators, which can transport electrons over their 2D structures and effectively promote the separation of photo-generated electron-hole pairs while inhibiting electron-hole recombination. The Fermi level of graphene materials is typically lower than the CB of most semiconductors, allowing excited electrons to be transported to graphene or its derivatives. The increased electron path length and decreased recombination of holes and photogenerated electrons improve the graphenes/semiconductor photocatalytic efficiency. For example, rGO enhanced the photocatalytic efficiency of WO_3 , where DRS and PL optical measurements; Fig. 7a, revealed that the recombination of electron-hole pair of WO_3 photocatalyst was highly prohibited after rGO incorporation, at the four different rGO wt% studied.⁷¹ Further, incorporation of graphene into In_2S_3 significantly improved the photo-electrochemical characteristics of pure In_2S_3 , as shown in Fig. 7b.⁷² The photocurrent density of graphene/ In_2S_3 was the

highest, demonstrating that the separation and transfer of photogenerated electron-hole pair had been greatly improved over bare In_2S_3 .⁷² Moreover, CB electrons of the NiS semiconductor were transferred to the rGO sheets of rGO/NiS composite reducing the extent of electron-hole recombination in NiS and thus leading to enhanced photocatalytic activity of the rGO/NiS catalyst.⁷³ The general mechanisms of photocatalytic activity of semiconductor-graphene based binary and ternary composites are illustrated in Fig. 7c and d, respectively.^{27,74} For the binary system (Fig. 7c) when the radiation source hits the photocatalyst, photo-excited electrons (e^-) are transferred from VB to CB in the PC and leaves holes (h^+) behind. Subsequently, the excited electron moves from the conduction band to the graphene sheets which results in enhanced charge separation. Then, the excited electron are react with oxygen dissolved in system or adsorbed onto the surface of photocatalyst to produce superoxide radical anion ($\cdot O_2^-$), which then reacts with water producing hydroxyl radicals. In addition, the holes react with OH^- ions or water to generate the powerful oxidant, hydroxyl radicals. These radicals enrich the nanocomposite surfaces, protracted by the more stable carbon free radicals derived from GO/RGO nanosheets and effectively degrades the organic pollutants. In the ternary system, Fig. 7d, extra steps occur; namely, the incident light leads to the formation of electron/hole pairs in both photocatalysts (PC-I & PC-II). The interface between semiconductors

Fig. 7 (a) Photoluminescence spectra of WO_3 and WO_3/rGO composites reprinted with permission from ref. 71, (b) transient photocurrent response of In_2S_3 and $\text{In}_2\text{S}_3/\text{graphene}$ composites under visible light irradiation reprinted with permission from ref. 72, (c) mechanism of radicals generation using photocatalyst (PC)-doped GO/RGO binary nanocomposites, and (d) mechanism of radicals generation using dual-semiconductor (PC-I and PC-II)-doped GO/RGO ternary nanocomposites reprinted with permission from ref. 27. Copyright 2022 Elsevier.

materials (PC-I & PC-II) could enhance the charge separation. Commonly, excited electrons from the higher potential CB of PC-I is transferred to the lower potential CB of PC-II, and then to the graphene material sheets that enhance charge separations and hinder the electron–hole recombination. Then, the formed photoexcited electrons and holes react with oxygen and water to finally produce the highly reactive hydroxyl radicals responsible for organic pollutants degradation.

As a result, the overall improved photocatalytic efficiency of graphene-based photocatalysts can be attributed to better electron–hole pair separation, easier charge transportation ability, improved adsorption ability, reduced band gap energy, and improved visible light harvesting.

4. Photocatalytic applications

4.1 Degradation of organic pollutants

The discharge of a significant amount of contaminated water into the environment, which contains dyes, pesticides, pharmaceuticals, and phenols among other organic pollutants, is one of the results of progress and industrial diversification around the world. Photocatalysis is the most effective and easy method for the remediation and elimination of organic pollutants because of its comprehensive contaminant deconstruction ability. Here, we discussed some GO-supported semiconductor composites for the elimination of organic pollutants. For example, GO/ZnO hybrid layers was synthesized and exhibited higher photocatalytic performance over pure GO or ZnO under visible and UV-light irradiation. The improvement in the photocatalytic performance of the hybrid was attributed

to the role of GO in the separation and transport of the excited electron and positive hole.⁷⁵ Further, incorporation of 5% rGO into TiO_2 for the degradation MB dye gave superior photodegradation performance with about 86% removal of MB dye in 90 min compared to 28% removal for pristine TiO_2 in the same time, following PFO kinetics.⁷⁶ Moreover, the UV-vis spectra of MB dye after the photodegradation in the presence of MnFe_2O_4 and $\text{MnFe}_2\text{O}_4/\text{rGO}$ are displayed in Fig. 8a and b, respectively.⁷⁷ Pristine MnFe_2O_4 , took 290 minutes to eliminate 84% of the dye; while $\text{MnFe}_2\text{O}_4/\text{rGO}$ required 60 min to eliminate 97% of the dye, showing the enhanced catalytic efficiency upon the incorporation of rGO into MnFe_2O_4 with the resultant delay in the electron–hole recombination rate of the catalyst.⁷⁷ The photocatalytic decomposition of Rhodamine B (RhB) dye by TiO_2 NPs, TiO_2 nanowires (TNWs), GO/TNW and its reduced composites RTNW and R(GO/TNW) samples were examined, Fig. 9.⁷⁸ The degradation performance enhanced monotonically from TiO_2 NPs to TNWs and its GO/TNW composites; moreover, it was enhanced from RTNWs to R(GO/TNW)s as well, demonstrating an overall improvement in pore size and specific surface areas in nanowires and their composite after coupling with GO.⁷⁸ Moreover, several works were carried on for the synthesis of significantly efficient graphene-based heterostructure ternary composites. For example, $\text{GO}/\text{Fe}_2\text{O}_3/\text{WO}_3$ composite was synthesized and utilized for the photodegradation of crystal violet and MB dyes under visible light irradiation. The photocatalytic activity for eliminating dyes was found to be significantly enhanced with the heterocomposite as compared to pristine WO_3 and Fe_2O_3 particles or composite of $\text{Fe}_2\text{O}_3/\text{WO}_3$, WO_3/GO and $\text{Fe}_2\text{O}_3/\text{GO}$.⁷⁹ The improvement in the

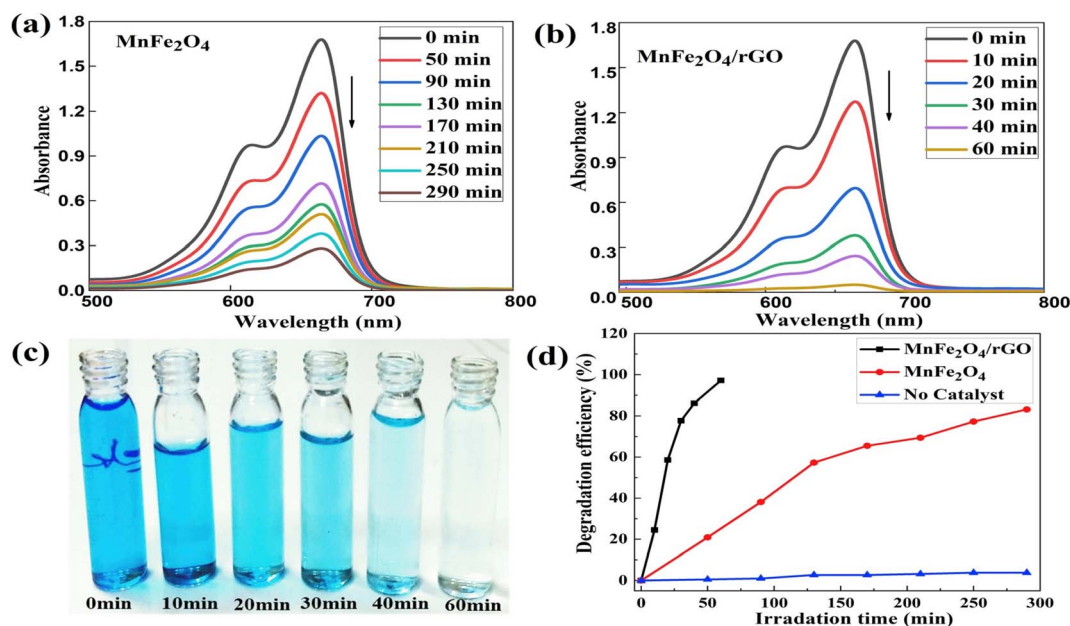

Fig. 8 Degradation of MB over (a) MnFe₂O₄ nanoparticles, and (b) MnFe₂O₄/rGO, (c) change in color of the MB solution in presence of MnFe₂O₄/rGO, (d) the photocatalytic degradation efficiency of MB dye in the absence (blue) and presence of photocatalysts: MnFe₂O₄ (red), MnFe₂O₄/rGO (black) at different UV irradiation times reprinted with permission from ref. 77. Copyright 2022 Elsevier.

photocatalytic activity of the ternary Fe₂O₃/GO/WO₃ photocatalyst is attributed to Z-Scheme in which the excited electrons in the CB of WO₃ (photosystem I) transferred over graphene oxide as mediator and recombined with the positive holes in the VB of Fe₂O₃ (photosystem II). Hence, the hole–electron pair recombination can be delayed in both systems.⁷⁹ Further, Fe₃O₄@CuO-rGO ternary photocatalyst was synthesized by

a hydrothermal method and was applied to MB dye photodegradation.⁸⁰ The as-synthesized Fe₃O₄@CuO-rGO photocatalyst has a broad-visible illumination adsorption domain and improved charge separation compared to pristine CuO or Fe₃O₄@CuO composite, as well as improved photocatalytic activity toward MB dye degradation under visible light illumination surpassing those of CuO, Fe₃O₄, CuO-rGO, Fe₃O₄-rGO,

Fe₃O₄@CuO, and Fe₃O₄/CuO-RGO catalysts.⁸⁰ Tables 1 and 2 illustrate some examples of semiconductor/graphene-based binary and ternary composites used in the photocatalytic degradation of organic pollutants including for example dyes, pharmaceuticals, pesticides, and phenols.

4.1.1 Effect of operating factors. Photocatalytic degradation of organic pollutants is affected by numerous operating conditions, such as the photocatalyst mass, temperature, pH, oxidizing species, initial concentration of pollutant, and irradiation light intensity, wavelength and time, as shown in Fig. 10.⁸¹

4.1.1.1 Effect of pH. The pH of the medium greatly affects the photocatalyst efficacy as it affects the photogenerated electron-hole pair separation process and the sorption behavior of the semiconductor photocatalyst. The point of zero charge (pzc) of a synthesized photocatalyst mainly depends on the pH of the medium and consequently affects the adsorption behavior towards anionic and cationic pollutants. Moreover, the pH of the medium controls the predominant oxidation species, whereby at higher and lower pH levels, hydroxyl radicals and holes were found to be the most essential oxidation species.⁸²

Therefore, determining the ideal pH level is an important step that might affect the photocatalytic process. For instance, the photodegradation efficiency of Orange G dye over GO-TiO₂ and its heteroatom doped variant rGO(NS)-TiO₂ photocatalysts was greatly affected by the medium pH.⁸³ At low pH values, the surface of the catalyst becomes positively charged that facilitates its attraction with the negatively charged dye molecules; however, at higher pH values the photocatalytic activity was reduced. In another study, MB dye photo degradation improved with raising the pH value due to the increased attraction between the cationic dye and ZnO/graphene/TiO₂ photocatalyst (pH_{pzc} = 6.4); however, at pH > 11.0, OH⁻ competes with the photocatalyst in attracting the cationic MB molecules resulting in lower decomposition efficiency, Fig. 11a.⁸⁴ Further, the photocatalytic degradation of Amido black dye over rGO-NiS was more efficient at neutral pH values.⁷³ On the other hand, the increased degradation of MO-RhB dyes mixture over CuS-ZnS-G in alkaline (pH 10.38) and acid media (pH 4.45) reflected the role H⁺ and OH⁻ ions in the dye degradation.⁸⁵ At acidic conditions, more H⁺ radicals are formed due to the interaction of H⁺ ions with electrons present in graphene layers resulting in

the dissociation of H₂O₂ and the formation of the highly reactive OH[•] radicals, responsible for the dyes degradation. However, in basic conditions, the concentration of OH⁻ ion increases and reacts with positively charged holes to form

highly active OH[•] radicals. The obtained results also suggested that the presence of H⁺ or OH⁻ ions significantly delayed the electron-hole recombination.⁸⁵

Fig. 10 Schematic shown of operational parameters affecting the photocatalytic degradation of organic pollutants.⁸¹

Copyright 2022 Elsevier.

4.1.1.2 Effect of initial pollutant concentration. The initial concentration of the organic pollutant significantly affects the photodegradation activity. Previous research found that increasing the initial concentration to a certain extent increased photo degradation; however, increasing the initial concentration further decreased photocatalytic activity due to the difficulty of light reaching the photocatalyst surfaces,⁸⁶ and surface adsorbed pollutant molecules prevent reactive radicals from interacting with the catalyst surfaces.⁸⁷ Thus, photo degradation decreased with higher initial pollutant concentration as part of the irradiation light is absorbed by the pollutant molecules and prevented from interacting with the catalyst surfaces,⁸⁸ Fig. 11b. Further, the decreased photocatalytic efficiency was also attributed to the limited generation of OH^\bullet radicals by the heavily covered photocatalyst surfaces.⁸⁹ Similarly, the reduced degradation efficiency at high initial concentrations of pollutants was attributed to the low penetration of light and limited availability of surface active sites of the photocatalyst.⁹⁰

4.1.1.3 Effect of photocatalyst dose. Photocatalyst weight is a significant parameter in photocatalytic processes, wherein the increase in the photocatalyst mass provides more active sites and increases the generation of hydroxyl and peroxide radicals.⁹¹ However, exceeding the optimum photocatalyst dosage can reduce photocatalytic activity due to catalyst particle agglomeration and the resulting decrease in active surface area, as well as irradiant light penetration.⁹² Thus, increasing the catalyst mass increased the photocatalytic efficiency up to an optimum dose, after which increasing the catalyst mass

increased the turbidity of the test solution, which increased light scattering and inhibited photocatalytic pollutant degradation, Fig. 11c.^{93,94} On the other hand, the rate of the malachite green dye degradation increased rapidly by increasing the catalyst dose and then remained almost constant in the range of 23.5–43.5 mg of the catalyst.⁹⁵

4.1.1.4 Effect of irradiation light intensity. The excitation of photocatalysts is usually improved by raising the incident light intensity. At low light intensities, the separation of photo-generated electron-hole pairs suffers from recombination, which reduces the formation of free radicals and the degradation efficiency of organic pollutants; this effect can be overcome by increasing the light intensity. Thus, increasing the intensity of incident light increased the efficiency of pollutant degradation because more photons were present for excitation, resulting in the formation of more photogenerated pairs in the semiconductor and an increase in reaction rate, Fig. 11d.⁹⁶ Similar results were obtained by other works.^{97,98}

4.1.1.5 Effect of oxidizing species. In photocatalytic reactions, oxygen species and reactive radicals are considered the main contributors to pollutant's degradation. Oxidants enhance the performance of the degradation process and decrease reaction time by the generation of reactive oxygen species.⁹⁹ For example, H_2O_2 can produce hydroxyl radicals and withdraw electrons away from the CB resulting in improvements in the separation of charge. However, excess H_2O_2 can act as a scavenger for OH^\bullet or produce peroxy groups which may adversely effect the degradation process.¹⁰⁰ Thus, the addition of H_2O_2 reduced the

degradation time of crystal violet dye from 280 to 60 minutes; however, large amounts of H_2O_2 resulted in less effective OH^\cdot radicals.¹⁰¹ Further, the H_2O_2 dose exhibited a prominent effect on the degradation characteristics of MB on FeVO_4 ; where higher concentrations of H_2O_2 resulted in poor degradation due to recombination effects.¹⁰² Similarly, in the presence of hydrogen peroxide and proper catalysts, azo dyes underwent rapid photocatalytic degradation.¹⁰³

4.2 Hydrogen production

By 2050, the energy gap from conventional energy sources including natural gas, coal, and oil will be 14 TW, which requires the search for sustainable sources to bridge this gap.¹⁰⁴ Nature stores large amounts of hydrogen in the form of water. Therefore, the environmentally friendly production of hydrogen using the efficient combination of solar energy and water has significant potential to satisfy the world's energy demands nowadays as well as in the future. Several semiconductors have been used to catalyze the generation of hydrogen from water. The quick recombination of photogenerated electrons and holes within photocatalysts limits the practical applicability of this technique. The incorporation of graphene onto the semiconductor can improve photocatalytic H_2 -production. For instance, rGO/MoS₂/g-C₃N₄ heterostructure photocatalyst was synthesized by hydrothermal route and showed a high H_2 -production rate of $317 \mu\text{mol h}^{-1} \text{g}^{-1}$, and a quantum yield of 3.4% at 420 nm.¹⁰⁵ The ternary photocatalyst exhibited greater photocatalytic activity compared to optimized Pt-loaded g-C₃N₄.¹⁰⁵ Further, incorporation of N-doped graphene onto CdS photocatalyst greatly improved the hydrogen generation rate, from solution containing Na₂S and Na₂SO under visible-light irradiation.¹⁰⁶ The reported optimal content of N-doped graphene was 2.0 wt%, which produced a H_2 -generation rate of $210 \mu\text{mol h}^{-1}$ compared to bare CdS that gave $40 \mu\text{mol h}^{-1}$. The potential of graphene is lower than the CB of CdS and greater than the reduction potential of H^+ , which facilitates the transport of electrons from the CB of CdS to graphene and the reduction of H^+ , and consequently improves the H_2 -production activity. Moreover, graphene/AgIO₄/ZnO/heterostructure was synthesized *via* a sonochemical route for the photoproduction of hydrogen.¹⁰⁷ The generation in OH^\cdot radical ($E_{\text{VB}} = +2.88 \text{ eV}$) that is recorded from PL analysis of terephthalic acid demonstrated charge migration that was dominant through the Z-scheme.¹⁰⁷

5. Desorption and regeneration

Photocatalyst regeneration and recycling are regarded as essential basic elements of any photocatalytic process from an economic and environmental perspective. The regeneration and reuse of photocatalysts lower the operation cost, which is extremely desirable for real wastewater treatment plants. Several GO-semiconductor composites exhibited great reusability with most tested organic pollutants. For example, Fe₃O₄-amino functionalized GO exhibited a 97% removal efficiency of Reactive Black 5 after six cycles of reuse.¹⁰⁸ The reduction of

nearly 3% in the elimination efficiency can be related to the saturation of active sites of photocatalysts.¹⁰⁸ Further, the rGO-based photocatalyst was successfully used four consecutive cycles using acetone as the regenerating agent.¹⁰⁹ Moreover, XRD, FTIR, and SEM results did not display any significant chemical or morphological changes in ZnO/CoFe₂O₄/N-doped G and ZnO/ZnFe₂O₄/N-doped G photocatalysts after ten repeated cycles.¹¹⁰ However, with MnFe₂O₄/rGO the photocatalytic degradation efficiency decreased slightly and reached 88% after the fourth run.⁷⁷

6. Conclusions and perspectives

In this study, we reviewed various strategies for the synthesis and characterization of semiconductors/graphene-based photocatalysts and their potential applications in photocatalytic H_2 -production as well as degradation of organic pollutants, *e.g.*, dyes, pharmaceuticals, phenols and pesticides. The incorporation of graphene or one of its derivatives into semiconductors significantly boost the photocatalytic performance by enhancing the adsorption ability, and light harvesting in the visible domain, and reducing the band-gap energy as well as by inhibiting the recombination of the photogenerated electron-hole pairs. Studies of various parameters affecting photocatalytic processes revealed that increasing the oxidant dose, catalyst mass, and irradiation time up to a certain optimum limit generally improved the rate of photocatalytic degradation, while increasing the initial pollutant concentration generally decreased it. The pH of the solution, on the other hand, can have a dual impact on the process. The mechanisms of the photocatalytic process have been thoroughly discussed. The reusability studies revealed the high efficiency of graphene-based photocatalysts. However, there are more research gaps and challenges that need to be addressed and studied in detail in the future:

(1) Designing the morphology of graphene/semiconductor composite to further enhancement of the photocatalytic performance. Materials designing should aim at improved light harvesting, increased catalyst surface area, and enhanced mass transport.

(2) Many studies dealt with improving the performance of photocatalysis over short periods of time and under optimal experimental conditions. The performance of the catalysts should be tested over long periods to study their stability and simulated wastewater should be utilized for photocatalytic experiments.

(3) The majority of photocatalytic experiments are carried out on a laboratory scale, but future work should concentrate on the efficiency of the prepared photocatalyst on a pilot scale to validate their effectiveness in industrial applications and identify the real operational challenges. The economic feasibility and return on investment of using these materials in various applications should also be investigated.

(4) Finally, the bio-safety of composites must be emphasized. When used in wastewater remediation, a portion of the synthesized composite may be released into the environment.

Following that, the full extent of these composites' toxicity to humans, animals, and the environment must be investigated.

Despite the challenges mentioned, graphene-based semiconductor photocatalysts have limitless applications and prospects in solving energy shortages and industrial waste treatment.
