# FeMoS<sub>2</sub> microparticles as an excellent catalyst for the activation of peroxymonosulfate toward organic contaminant degradation†

Cai-Wu Luo,<sup>\*ab</sup> Lei Cai,<sup>b</sup> Chao Xie,<sup>b</sup> Jing Wu<sup>c</sup> and Tian-Jiao Jiang<sup>b</sup>

The FeMoS<sub>2</sub> catalyst for activating peroxymonosulfate (PMS) is a promising pathway for removing organic pollutants in wastewater, however, the dominant FeS<sub>2</sub> phases and sulfur (S) vacancies in it are little involved. Herein, for the first time, novel bimetallic FeMoS<sub>2</sub> microparticles were synthesized by a simple method and then applied for PMS activation for degrading organic pollutants. The catalysts were characterized by several techniques, including X-ray diffraction and X-ray photoelectron spectroscopies. The results revealed that new FeMoS<sub>2</sub> microparticles containing S vacancies in the main FeS<sub>2</sub> phases were obtained. FeS<sub>2</sub> and S vacancies were found to play important roles for activating PMS by radical and nonradical pathways. More Fe<sup>2+</sup> and Mo<sup>4+</sup> were formed in the presence of S vacancies, which offered a new strategy for exploring novel heterogeneous catalysts in the activation of PMS for environmental remediation.

## 1. Introduction

Organic pollutants such as dyes are widely applied in various fields, *e.g.*, antibiotics,<sup>1</sup> food additives,<sup>2</sup> and microplastics,<sup>3</sup> *etc.* However, they are harmful to human health. Consequently, it is extremely necessary to remove them using various advanced oxidation processes.<sup>1–10</sup> Among these, the Fenton-like technology involving PMS activated by Fe-based catalysts is a good alternative. Over the past years, various Fe-based catalysts have been extensively developed,<sup>5–10</sup> including single<sup>6,7</sup> and bimetallic Fe-based catalysts.<sup>5,8–10</sup> Bimetallic Fe-based catalysts more easily facilitate PMS decomposition by accelerating the transformation of iron(II) and iron(III) (Fe<sup>2+</sup> and Fe<sup>3+</sup>, respectively) due to the function of another metal with variable valence states relative to single Fe-based states (formula (1)). Clearly, the former has more advantages than the latter in PMS activation.

To date, research has predominantly focused on Fe–Mn,<sup>8</sup> Fe–Cu,<sup>5,9</sup> Fe–Co,<sup>10</sup> Fe–Ni,<sup>11</sup> Fe–Ag,<sup>12</sup> and Fe–Mo.<sup>13–18</sup> Among these, they are either highly toxicity, such as cobalt and nickel, or expensive, such as silver. It is possible that molybdenum (Mo)

better boosts the transformation cycle of Fe<sup>2+</sup> and Fe<sup>3+</sup> relative to copper (Cu) and manganese (Mn). This is because the Mo (4d<sup>5</sup>5s<sup>1</sup>) atom accommodates more electrons in empty orbits than Cu (3d<sup>10</sup>4s<sup>1</sup>) and Mn (3d<sup>5</sup>4s<sup>2</sup>) atoms. In addition, Mo has other merits like lower toxicity. Clearly, it is an ideal alternative for Mo as a cocatalyst to promote PMS activation in Fe-based catalysts. Enhancement of the Fe/PMS system has been reported in the assistance of Mo species, such as Mo<sup>0</sup> (ref. 13) and MoS<sub>2</sub>.<sup>14–18</sup> Compared to Mo<sup>0</sup>, the exposed Mo<sup>4+</sup> species in MoS<sub>2</sub> are more suitable for activating PMS in the presence of unsaturated S species,<sup>14–19</sup> thereby inducing greater removal of organic pollutants. Recently, some FeMoS<sub>2</sub> heterogeneous catalysts in PMS-based reactions have been extensively explored, including Fe<sub>3</sub>O<sub>4</sub>@MoS<sub>2</sub>,<sup>20</sup> FeOOH@MoS<sub>2</sub>,<sup>21</sup> and Fe–MoS<sub>2</sub>,<sup>22</sup> which has to overcome the shortcomings of mixtures of FeMoS<sub>2</sub>-based homogeneous and heterogeneous catalysts.<sup>14–17</sup> However, these processes involve complex procedures. More importantly, most Fe species are deposited on MoS<sub>2</sub> surfaces, which results in long distances between Fe and Mo atoms, thereby affecting the Fe<sup>2+</sup>/Fe<sup>3+</sup> cycle. To alter this situation, FeMoS<sub>2</sub> has been directly prepared by high-temperature treatment of mixtures of Fe, Mo, S, and I powders.<sup>23</sup> The results show that Fe atoms are confined near Mo atoms and thus interatomic distances turn shorter, which is better for the adsorption and decomposition of PMS. However, the Fe content is extremely low inside the catalyst in this case, restricting larger applications. Nevertheless, this situation has provided a good inspiration for the synthesis of a novel FeMoS<sub>2</sub> with shorter distances between Fe and Mo atoms using *in situ* synthesis. Interestingly, researchers have found that small crystal phases of FeS<sub>2</sub> appear in FeMoS<sub>2</sub> *via* the above method.<sup>24,25</sup> It has been confirmed that

FeS<sub>2</sub> can effectively activate PMS to remove organic pollutants in wastewater,<sup>26,27</sup> even having a higher ability relative to MoS<sub>2</sub> alone in Fenton-like reaction.<sup>28</sup> It has been expected to be able to synthesize FeS<sub>2</sub> as dominant phases in FeMoS<sub>2</sub>-based materials to enhance catalytic activity. Also, this catalyst would be rich in S atoms. In this case, S vacancies are easily generated in these materials by suitable treatment.<sup>19,29</sup> Wu *et al.*<sup>29</sup> have demonstrated that the S vacancies play key role in activating PMS in the Fe(III)/CoS<sub>2</sub> system. Thus, it is promising to further strengthen the catalytic performance in FeMoS<sub>2</sub>. There is no doubt that the development of a new FeMoS<sub>2</sub> containing S vacancies with main FeS<sub>2</sub> phases is highly desired. To the best of our knowledge, the synthesis of this catalyst and its application for activating PMS to degrade organic pollutants has not been reported so far.

In this study, a new FeMoS<sub>2</sub> catalyst, containing S vacancies and FeS<sub>2</sub> as the dominant phases, was synthesized by a one-step method, which could efficiently activate PMS to degrade organic contaminants. Important influencing factors were studied in detail. A different reaction mechanism was found in this FeMoS<sub>2</sub> for PMS activation. The relationship between the catalyst structure and catalytic performance was established.

## 2. Experiments

### 2.1. Chemical reagents and materials

The chemical reagents and materials were supplied by commercial purchase. For instances, peroxymonosulfate (2KHSO<sub>5</sub>·KHSO<sub>4</sub>·K<sub>2</sub>SO<sub>4</sub>), 5,5-dimethyl-1-pyrro-lineN-oxide (DMPO, 98%), and 2,2,6,6-tetra-methylpiperidine (TEMP, 99%) were purchased from Sigma-Aldrich, Inc. (St Louis, MO, USA). Molybdenum(IV) sulfide (MoS<sub>2</sub>, ≥98.0%), furfuryl alcohol (C<sub>5</sub>H<sub>6</sub>O<sub>2</sub>, ≥98.0%), ammonium molybdate tetrahydrate ((NH<sub>4</sub>)<sub>6</sub>Mo<sub>7</sub>O<sub>24</sub>·H<sub>2</sub>O, ≥99.0%), and rhodamine B (RhB) were purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). Tiron (C<sub>6</sub>H<sub>7</sub>NaO<sub>8</sub>S<sub>2</sub>, >98.0%), sodium sulfide (Na<sub>2</sub>S·9H<sub>2</sub>O, >98.0%), and methyl orange (MO) were obtained from Damao Chemical Reagent Factory (Tianjin, China). Molybdenum trioxide (MoO<sub>3</sub>, ≥99.5%) and methylene blue (MB) were purchased from Kemiu Chemical Reagent Co., Ltd. (Tianjin, China). All the above-mentioned chemical reagents and materials were of analytical grade and employed without further purification.

### 2.2. Synthesis of FeMoS<sub>2</sub> catalysts

(i) *In situ* synthesis: 0.18 g or 0.94 g or 1.98 g of Fe(NO<sub>3</sub>)<sub>3</sub>·9H<sub>2</sub>O, 2.28 g of CH<sub>4</sub>N<sub>2</sub>S, and 0.196 g of (NH<sub>4</sub>)<sub>6</sub>Mo<sub>7</sub>O<sub>24</sub>·4H<sub>2</sub>O were mixed in 35 mL of distilled water and then evenly stirred. Afterward, the solutions were then autoclaved at 180 °C for 4 h. Then, they were dried at 60 °C and denoted as FeMoS<sub>2</sub>-IS-60. Finally, dried samples were calcined at different temperatures (200, 300, 400, or 500 °C) for 4 h with a heating rate of 5 °C min<sup>-1</sup> under air atmosphere, thus obtaining the targeted products, respectively denoted as FeMoS<sub>2</sub>-IS-200, FeMoS<sub>2</sub>-IS-300, FeMoS<sub>2</sub>-IS-400, and FeMoS<sub>2</sub>-IS-500. Herein, the theoretic concentrations of Fe in the above catalysts were 1.0, 5.0 and

10 wt%, respectively. Unless otherwise indicated, FeMoS<sub>2</sub>-IS-400 was abbreviated as FeMoS<sub>2</sub>-IS and the concentration of Fe was fixed at 5.0 wt%. The MoS<sub>2</sub>-IS, Fe–Mo, and Fe–S catalysts were synthesized by the same above procedures for FeMoS<sub>2</sub>-IS except for one of components. MoS<sub>2</sub>-300 was obtained by heating commercial MoS<sub>2</sub> powders at 300 °C for 4 h. The synthetic steps for FeMoS<sub>2</sub>-IS microparticles are displayed in Fig. S1.†

(ii) Post treatment: 0.19 g of Fe(NO<sub>3</sub>)<sub>3</sub>·9H<sub>2</sub>O and 0.50 g of MoS<sub>2</sub> were weighed and added separately to 50 mL of distilled water. After being evenly stirred, they were autoclaved at 180 °C for 4 h, then cooled to room temperature, and dried at 60 °C. Finally, the dried sample was treated at 400 °C for 4 h with a heating rate of 5 °C min<sup>-1</sup> under air atmosphere. The targeted product was denoted as FeMoS<sub>2</sub>-IE (theoretic Fe concentration, 5.0 wt%).

### 2.3. Characterization of catalysts

The crystal phases of catalyst were analyzed by using (XRD) spectroscopy with a D8-Advance X-ray Diffractometer (Bruker Corp., Billerica, MA, USA). The specific surface area and pore features of catalyst were measured by liquid nitrogen physisorption using an Autosorb-iQ/ASAP 2460 apparatus (Quantachrome Instruments Corp., Boynton Beach, FL, USA). The morphologies of catalysts were examined by scanning electron microscopy (SEM) on an SU-8100 instrument (Hitachi Instruments, Inc., Tokyo, Japan). Fourier transform-infrared spectroscopy (FT-IR) was measured on a Spectrum 100 (PerkinElmer, Inc., Waltham, MA, USA). Raman Spectroscopy was recorded using an LabRAM HR800 (Horiba Ltd., Tokyo, Japan). The surface elemental information of catalysts was characterized by X-ray photoelectron spectroscopy (XPS) on an Escalab 250xi instrument (Thermo Fisher Scientific Inc., Pittsburgh, PA, USA). The thermogravimetry (TG) was carried out on the TA SDT650/STA 449 F3 instrument. The vacancies of catalyst and reactive oxygen (O) species were measured by electron paramagnetic resonance (EPR) on a Bruker A300 (Bruker Corp). The zeta potential value was measured on Zetasizer Nano ZS90 (Malvern Instruments Ltd., Malvern, UK).

### 2.4. Removal of contaminants in different reaction processes

Degradation reactions were conducted under atmospheric pressure and room temperature. First, a 10 mg L<sup>-1</sup> RhB solution was prepared using distilled water. Then, the catalyst together with PMS was immediately added into the solution to maintain the suitable concentration of each component. After addition, the removal reaction proceeded and, at intervals, samples collected, with methanol added to the samples to capture reactive oxygen species (ROS). The absorbance of RhB was measured by spectrophotometer and pH recorded using a pH meter before and after reaction. According to experimental requirements, the important reaction parameters and the related chemical reagents were timely adjusted under optimal conditions. The decomposition of PMS was quantified by the potassium iodide method.<sup>30</sup> The concentration of Fe<sup>2+</sup> was quantified using the 1,10-phenanthroline method, with Fe<sup>3+</sup>

first reduced by hydroxylamine hydrochloride and then total  $\text{Fe}^{2+}$  quantified by the above method.<sup>13–15</sup>

### 3. Results and discussion

#### 3.1. Characterization of catalysts

XRD patterns of  $\text{MoS}_2$ -IS and  $\text{FeMoS}_2$ -IS showed that, for  $\text{MoS}_2$ -IS, diffraction characteristic peaks located at  $2\theta = 14.38^\circ$ ,  $32.68^\circ$ ,  $39.54^\circ$ ,  $49.79^\circ$  and  $58.33^\circ$ , which were attributed to the crystal phases of  $\text{MoS}_2$  (PDF-# 37-1492, Fig. 1a). This originated from the reaction between ammonium molybdate and thiourea during hydrothermal treatment.<sup>21</sup> Some diffraction characteristic peaks located at  $2\theta = 12.76^\circ$ ,  $23.33^\circ$ ,  $27.33^\circ$  and  $58.80^\circ$  were ascribed to the crystal phases of  $\text{MoO}_3$  (PDF-# 05-0508). The introduction of O was derived from the oxidation of  $\text{MoS}_2$  in high-temperature treatment. In addition, introducing O also occurred during hydrothermal treatment.<sup>31</sup> These results were further confirmed from the Raman spectra (see Fig. 1c). In general, the widths of diffraction characteristic peaks were large in  $\text{MoS}_2$ -IS, implying that its crystallization was not high, in other words, it is very difficult to identify the crystal phases of  $\text{MoS}_2$  and  $\text{MoO}_3$ . It was agreement with the literature.<sup>20,21</sup> After

modification, the diffraction characteristic peaks of  $\text{FeMoS}_2$ -IS were greatly altered relative to those of  $\text{MoS}_2$ -IS, namely, some diffraction characteristic peaks disappeared and others newly appeared. On the one hand, this did not present diffraction characteristic peaks of  $\text{MoS}_2$ . This was most probably due to it being either highly dispersed on the support or having low crystallization. Simultaneously,  $\text{MoO}_3$  intensity signals were decreased. On the other hand, some clear diffraction characteristic peaks were newly observed. For example, sharp diffraction peaks located at  $2\theta = 36.96^\circ$ ,  $40.64^\circ$ ,  $47.30^\circ$ ,  $56.12^\circ$ ,  $58.82^\circ$ ,  $61.48^\circ$  and  $64.12^\circ$  were observed, which were attributed to the crystal phase of  $\text{FeS}_2$  (PDF-# 42-1340).<sup>24</sup> In other words, the main crystal phases of the catalyst were  $\text{FeS}_2$ . As mentioned above, the crystal phases of  $\text{FeS}_2$  were little identified in  $\text{FeMoS}_2$ . In fact,  $\text{FeS}_2$  has been employed to degrade organic pollutants in advanced oxidation processes,<sup>26,27,32,33</sup> but it was not  $\text{FeS}_2$  as dominant phases in the various  $\text{FeMoS}_2$  catalysts for activating PMS.<sup>20–22</sup> Consequently,  $\text{FeS}_2$  appearance was in favor of the activation of PMS in this reaction.

One wonders whether the synthesis and application of  $\text{FeS}_2$  occurs without the addition of Mo? The answer is No. As

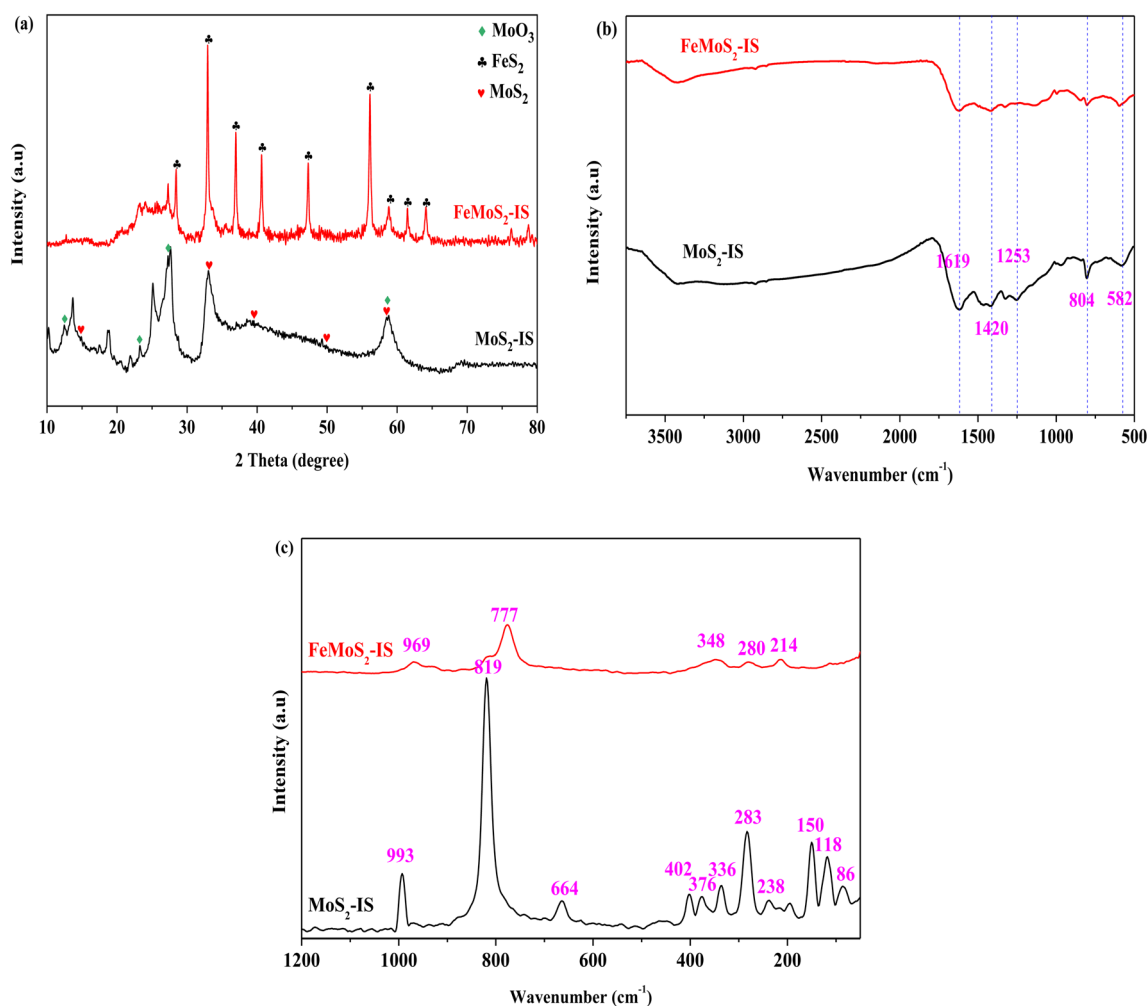

Fig. 1 (a) XRD patterns of  $\text{MoS}_2$ -IS and  $\text{FeMoS}_2$ -IS; (b) FT-IR spectra of  $\text{MoS}_2$ -IS and  $\text{FeMoS}_2$ -IS; (c) Raman spectra of  $\text{MoS}_2$ -IS and  $\text{FeMoS}_2$ -IS.

Table 1 Pore structure of different catalyst<sup>a</sup>

Catalysts	$S_{\text{BET}}$ ( $\text{m}^2 \text{g}^{-1}$ )	$V_{\text{Total}}$ ( $\text{cm}^3 \text{g}^{-1}$ )	$D_{\text{A}}$ (nm)
MoS <sub>2</sub> -IS	12.69	0.0346	10.91
FeMoS <sub>2</sub> -IS	7.85	0.0375	19.12

<sup>a</sup>  $S_{\text{BET}}$ ,  $V_{\text{Total}}$  and  $D_{\text{A}}$  were denoted as specific surface area, total pore volume and mean pore sizes, respectively.

evidenced by XRD characterization, the typical diffraction characteristic peaks of samples was mainly attributed to the structure of FeS<sub>2</sub> (Fig. S2a†). Therefore, the Mo existence was no a prerequisite for FeS<sub>2</sub> generation but it mainly affected the catalytic performance (see below Fig. 3). In addition, other active sites might have been highly dispersed on the support, such that they were not detected. For instance, with MoS<sub>2</sub>-300 as an indirect evidence, the reaction between S of MoS<sub>2</sub> and O in air occurred. Thus, S vacancies were formed due to the different atomic radius between S and O, as evidenced from EPR characterization (Fig. S2b†). The result indicated that the relative intensity of MoS<sub>2</sub>-300 was altered relative to those of MoS<sub>2</sub>, hinting that the S vacancies may generate in the FeMoS<sub>2</sub>.<sup>19</sup>

To further explore the differences, SEM was employed and MoS<sub>2</sub>-IS observed to exhibit a plate-like structure with the partially agglomerated appearance (Fig. S3a and b†). After modification, the morphology of FeMoS<sub>2</sub>-IS was greatly different and the catalyst shape became large aggregation particles. The pore structure of MoS<sub>2</sub>-IS and FeMoS<sub>2</sub>-IS showed that, for MoS<sub>2</sub>-IS, the  $S_{\text{BET}}$ ,  $V_{\text{Total}}$ , and  $D_{\text{A}}$  of this catalyst were 12.69  $\text{m}^2 \text{g}^{-1}$ , 0.0346  $\text{cm}^3 \text{g}^{-1}$ , and 10.91 nm, respectively (Table 1). After modification to form FeMoS<sub>2</sub>-IS, the  $S_{\text{BET}}$  was clearly reduced, which might be attributed to changed morphology, as evidenced from SEM results. In contrast, the  $V_{\text{Total}}$  and  $D_{\text{A}}$  of FeMoS<sub>2</sub>-IS were increased, which was beneficial for enhancing mass transfer. Combined with the removal of RhB and  $S_{\text{BET}}$ , the  $S_{\text{BET}}$  was confirmed not to be an important factor for improving RhB removal.

The FT-IR and Raman spectra of MoS<sub>2</sub>-IS and FeMoS<sub>2</sub>-IS showed that for the MoS<sub>2</sub>-IS, five characteristic peaks appeared, located at 1619, 1420, 1253, 804, and 582  $\text{cm}^{-1}$ , in the region of 2000–500  $\text{cm}^{-1}$ , which belonged to the characteristic peaks of Mo–S (Fig. 1b and c).<sup>34,35</sup> After treatment, similar characteristic peaks appeared at the above positions, implying that Mo–S structure in the catalyst remained unchanged. Nevertheless, it was difficult to identify structural differences between them. Therefore, they were characterized by Raman analysis. MoS<sub>2</sub>-IS exhibited some characteristic peaks located at 445–448, 402, and 376  $\text{cm}^{-1}$ , which were attributed to the structure of 2H-MoS<sub>2</sub>.<sup>35</sup> In addition, some characteristic peaks located at 336, 283, and 150  $\text{cm}^{-1}$  were observed, belonging to the structure of 1T-MoS<sub>2</sub>.<sup>35</sup> The results demonstrated the co-existence of 2H–1T MoS<sub>2</sub> structure in MoS<sub>2</sub>-IS. The characteristic peaks located at 993, 819, and 664  $\text{cm}^{-1}$  were observed, which were ascribed to the structure of MoO<sub>3</sub>.<sup>35</sup> Thus, MoS<sub>2</sub>-IS was concluded to be composed of MoS<sub>2</sub> and MoO<sub>3</sub>. After modification, the above

characteristic peaks basically disappeared and some new characteristic peaks located at 969, 777, 348, 280, and 214  $\text{cm}^{-1}$  appeared. This suggested that a new structure in FeMoS<sub>2</sub>-IS was formed, which was different from MoS<sub>2</sub> and MoO<sub>3</sub>.

The surface elemental information of MoS<sub>2</sub>-IS and FeMoS<sub>2</sub>-IS was confirmed by XPS survey spectra, with the synthesized MoS<sub>2</sub>-IS and FeMoS<sub>2</sub>-IS primarily composed of Mo, S, and O (Fig. 2a). In addition, Fe also appeared in FeMoS<sub>2</sub>-IS. In terms of Mo-3d of MoS<sub>2</sub>-IS, one weak binding energy peak was located at 226.90 eV, which was attributed to S atoms at the external side of Mo–S (Fig. 2b).<sup>34–36</sup> There were also two binding energy (BE) peaks located at 229.75 and 233.05 eV, which respectively corresponded to characteristic peaks of Mo 3d<sub>5/2</sub> and Mo 3d<sub>3/2</sub>, which indicated that Mo<sup>4+</sup> was present in MoS<sub>2</sub>-IS.<sup>36</sup> The characteristic BE peak located at 229.75 eV was subdivided into two characteristic peaks located at 229.90 and 229.69 eV, corresponding to the structure of 2H-MoS<sub>2</sub> 3d<sub>5/2</sub> and 1T-MoS<sub>2</sub> 3d<sub>5/2</sub>.<sup>35</sup> Similarly, the characteristic BE peak located at 232.40 eV was subdivided into two characteristic peaks with the BEs at 233.20 and 232.57 eV, corresponding to the structure of 2H-MoS<sub>2</sub> 3d<sub>3/2</sub> and 1T-MoS<sub>2</sub> 3d<sub>3/2</sub>,<sup>35</sup> respectively. The above results showed that a mixed structure of 2H- and 1T-MoS<sub>2</sub> existed in MoS<sub>2</sub>-IS. In addition, one clear characteristic BE peak located at 236.30 eV corresponded to a characteristic peak of Mo-based oxides.<sup>34–36</sup>

After treatment, the characteristic peak of Mo 3d was altered. The ratio of Mo<sup>4+</sup> to Mo<sup>6+</sup> and S atoms from the external of Mo–S were both increased, but the ratio of 2H- and 1T-MoS<sub>2</sub> and concentration of Mo<sup>6+</sup> were both reduced in FeMoS<sub>2</sub>-IS, compared to MoS<sub>2</sub>-IS (Table S1†). This meant that this modification contributed more Mo<sup>4+</sup> and external S in Mo–S and/or FeS<sub>2</sub>. As mentioned above, the decomposition of PMS could be accelerated by enhancing the Fe<sup>2+</sup> and Fe<sup>3+</sup> cycle in the presence of Mo<sup>4+</sup>.<sup>13–18</sup> Simultaneously, more external S atoms in the catalyst were in better contact H<sup>+</sup> in solution such that more active sites, such as Fe<sup>2+</sup> and Mo<sup>4+</sup>, were exposed. Some authors have pointed out that Mo<sup>4+</sup>, not Mo<sup>6+</sup>, species were important active sites for decomposing PMS.<sup>34–36</sup> Accordingly, more Mo<sup>4+</sup> and less Mo<sup>6+</sup> species were in favor of strengthening PMS activation. For S 2p in MoS<sub>2</sub>-IS, there were two distinct characteristic BE peaks located at 163.70 and 162.65 eV,<sup>19,35</sup> which was respectively ascribed to the S 2p<sub>1/2</sub> and S 2p<sub>3/2</sub> (Fig. 2c). In addition, one characteristic peak located at 169.24 eV was attributed to –SO<sub>n</sub>– due to oxidation during catalyst synthesis.<sup>35</sup> After modification, the characteristic peak of S 2p was little changed. Interestingly, the O 1s spectrum could be deconvoluted into two components located at 531.54 and 530.91 eV, corresponding to hydroxyl groups in adsorbed water and O defects in the MoS<sub>2</sub>-IS (Fig. 2d). After modification, besides the above peaks, there appeared a new peak located at 531.30 eV, which was ascribed to surface adsorbed O species.<sup>35</sup> In the case of Fe 2p in FeMoS<sub>2</sub>-IS (Fig. 2e), a peak located at 707.25 eV was attributed to the existence of FeS<sub>2</sub>.<sup>32</sup> Also, the extra three characteristic peaks, located at 709.99 and 731.07 eV, corresponded to Fe<sup>2+</sup>.<sup>37</sup> Besides, the peak located at 720.18 eV was attributed to the satellite peak. This indicated that Fe<sup>2+</sup> was generated in the FeMoS<sub>2</sub>-IS due to the reduction of Fe<sup>3+</sup> by thiourea. There were two characteristic peaks located at 715.02 and 723.90 eV, which

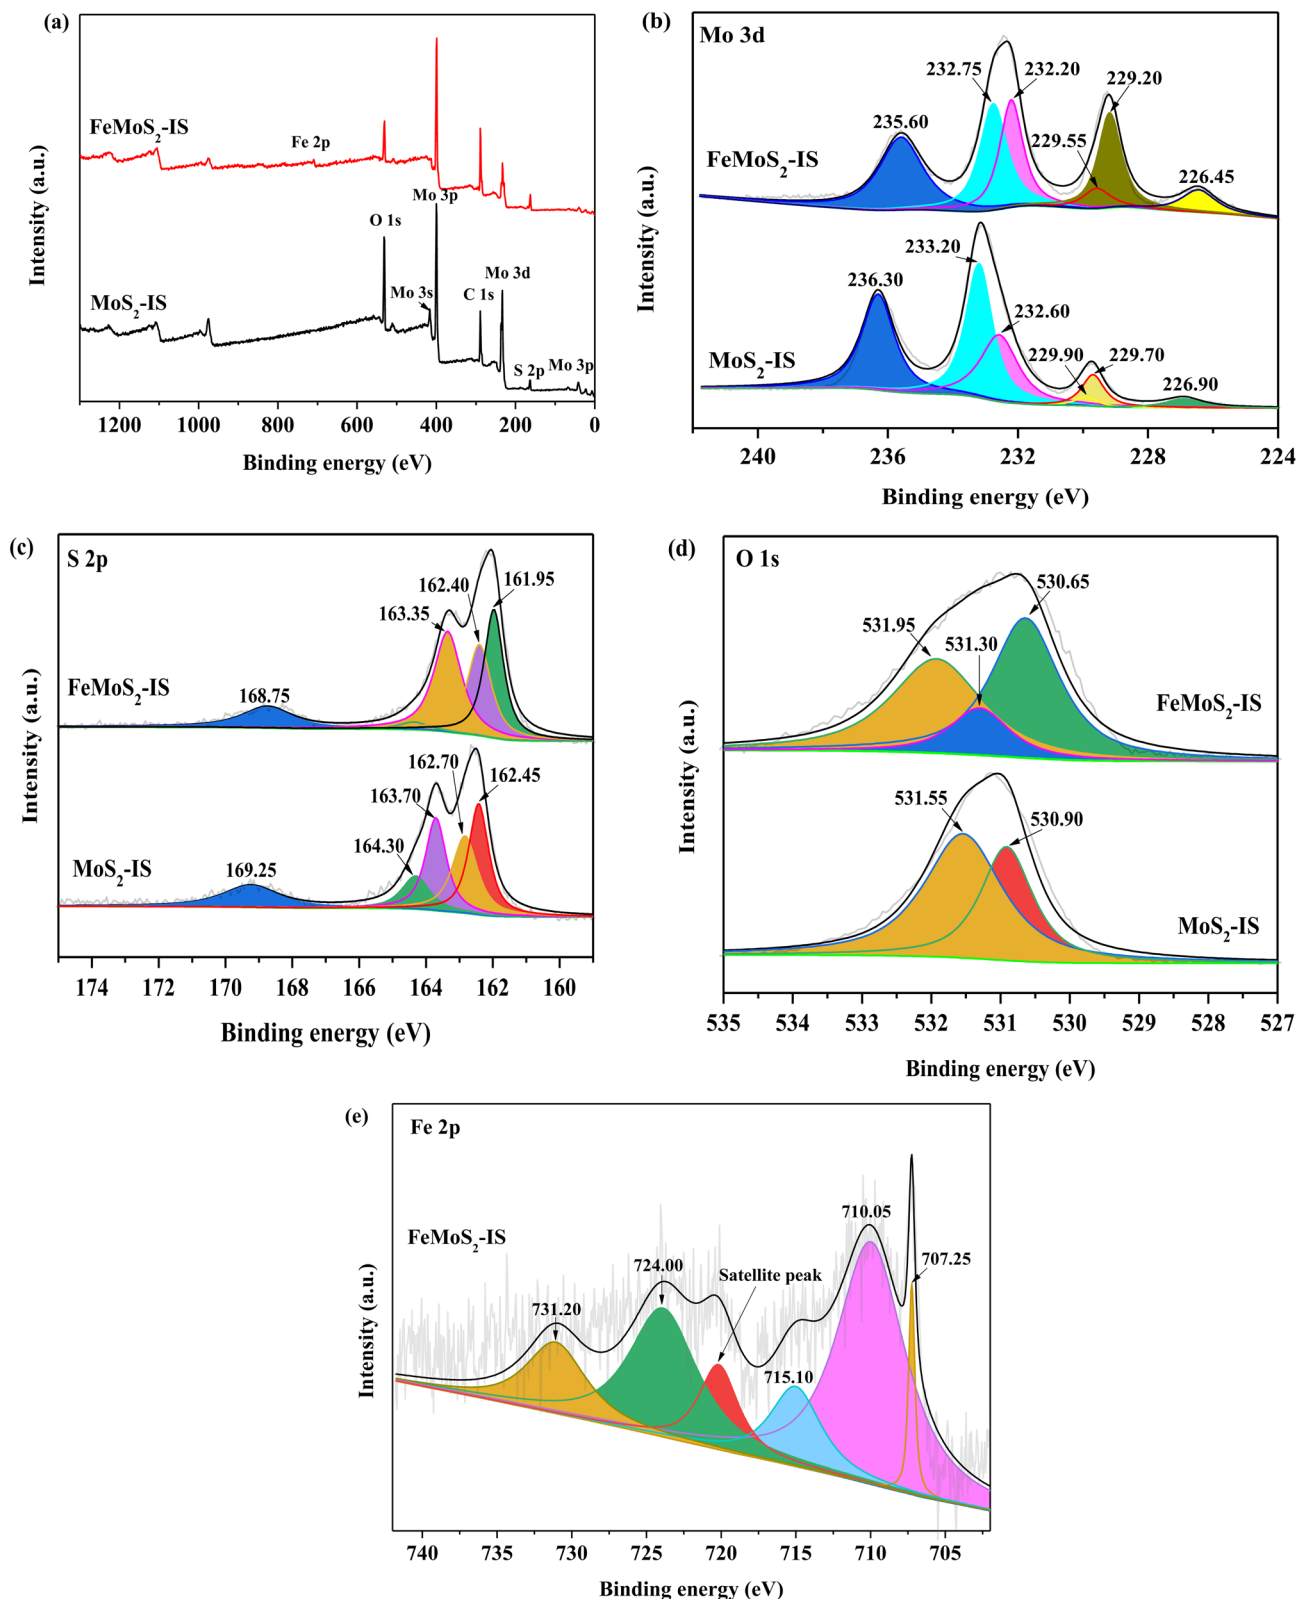

Fig. 2 XPS spectra of (a) survey spectra, (b) Mo 3d, (c) S 2p and (d) O 1s in the MoS<sub>2</sub>-IS and FeMoS<sub>2</sub>-IS, and (e) Fe 2p in the FeMoS<sub>2</sub>-IS.

corresponded to Fe<sup>3+</sup>. According to the peak areas of Fe<sup>2+</sup> and Fe<sup>3+</sup>, the Fe<sup>2+</sup> concentration and Fe<sup>2+</sup>/Fe<sup>3+</sup> ratio were 0.67 and 1.99, respectively, suggesting that most Fe<sup>3+</sup> in ferric nitrate was

reduced to Fe<sup>2+</sup> during synthesis. The higher Mo<sup>4+</sup>/Mo<sup>6+</sup> and a large number of Fe<sup>2+</sup> species were concluded to have been generated after Fe modification.

### 3.2. Removal of organic pollutants in different catalytic reaction processes

Different catalysts for activating PMS in RhB removal in the darkness were compared. The RhB degradation efficiency was only 21% when PMS was used alone (Fig. 3). Although  $\text{MoS}_2$ -IS was added into the above system, RhB removal hardly increased. According to the pseudo-first order reaction equation, the reaction rate constant (denoted as  $k$ ) was calculated.<sup>20</sup> These values were 0.00456 and  $0.00669 \text{ min}^{-1}$  for PMS and PMS +  $\text{MoS}_2$ -IS, meaning that their reaction rates were extremely slow. This was because the  $\text{MoS}_2$ -IS contained a lot of  $\text{Mo}^{6+}$  species, such as  $\text{MoO}_3$ , as evidenced from XPS characterization, but it did not act as active sites.<sup>19</sup> Also, its low  $S_{\text{BET}}$  restricted increased catalyst activity and, accordingly, RhB removal was poor. The degradation efficiency of RhB was  $\sim 27\%$  at  $0.00867 \text{ min}^{-1}$  for its  $k$  using Fe-Mo as a heterogeneous catalyst. This indicated that the bimetallic Fe-Mo catalyst containing no S could activate PMS to remove RhB, which was in agreement with the literature.<sup>38</sup> However, this promotion was limited and

also illustrated that the S was very important factor for improving RhB removal. If a catalyst without Mo was employed, a positive effect should be achieved. Surprisingly, the results showed that the RhB degradation efficiency over Fe-S was only  $\sim 52\%$ , with  $k$  at  $0.02237 \text{ min}^{-1}$ . This was only due to the generation of  $\text{FeS}_2$ . Clearly, the role of Mo was important in the removal of RhB. In contrast, when  $\text{FeMoS}_2$ -IS was used as a heterogeneous catalyst under identical reaction conditions,  $\sim 86\%$  of RhB was removed, with  $k$  at  $0.66471 \text{ min}^{-1}$ , obtained only in 3.0 min in the presence of PMS. From the above results,  $\text{FeMoS}_2$ -IS possessed many active sites such as  $\text{FeS}_2$  and S vacancies and their synergism activated PMS to form ROS. Zhou *et al.*<sup>26</sup> have directly used pyrite for activating PMS for the effective degradation and mineralization of diethyl phthalate. Huang *et al.*<sup>39</sup> have considered that S vacancies accelerate electron transfer and reduce  $\text{Mo}^{6+}$  to  $\text{Mo}^{4+}$  in natural molybdenite/PMS systems. As a result, RhB removal was significantly increased relative to the control experiment.

As mentioned earlier, Fe-doped  $\text{MoS}_2$  was mainly synthesized *via* a post treatment.<sup>20–22</sup> Herein,  $\text{FeMoS}_2$ -IE was obtained

**Fig. 3** (a) RhB degradation of adsorption and different PMS system; (b) pseudo first order kinetics of different catalytic system and reaction rate constant (illustration); (c) removal of RhB activating PMS by  $\text{FeMoS}_2$  with different methods; (d) pseudo first order kinetics of different  $\text{FeMoS}_2$  activating PMS system and reaction rate constant (illustration). Reaction conditions:  $[\text{RhB}] = 10 \text{ mg L}^{-1}$ , initial pH = 3.0,  $[\text{Catal.}] = 1.0 \text{ g L}^{-1}$ ,  $[\text{PMS}] = 1.0 \text{ mM}$  and in the darkness.

by impregnation and high-temperature successive treatments and then it was applied for activating PMS. The results indicated that the RhB degradation efficiency, with  $k$  at  $0.03914 \text{ min}^{-1}$ , reached  $\sim 72\%$  at 30 min. The diffraction characteristic peaks of FeMoS<sub>2</sub>-IE were mainly ascribed to the mixed structure of MoS<sub>2</sub> and MoO<sub>3</sub> (Fig. S4†). Meanwhile, Fe species were not detected because they were either highly dispersed on the support or in low crystallinity. On the basis of FeMoS<sub>2</sub>-IS and FeMoS<sub>2</sub>-IE, a great difference was found on RhB removal, which was due to different structures between them. As mentioned above, the main phases in the former were MoS<sub>2</sub> and MoO<sub>3</sub> whereas the dominant phases in the latter were FeS<sub>2</sub>. As shown in eqn (2)–(5),<sup>32,33</sup> the FeS<sub>2</sub> to generate dissolved as well as surface Fe<sup>2+</sup> was an important reason for promoting RhB degradation. In a few words, this provided a new method for FeS<sub>2</sub> synthesis. In addition, this had many merits, *e.g.*, simple operation, low cost, and green. Accordingly, it possessed great potential for industrial application.

To further explore the roles of FeS<sub>2</sub> and S vacancies, the treatment temperature and Fe doping were investigated, particularly how temperature affected the formation of FeS<sub>2</sub> and S vacancies (Fig. 4a). When the treatment temperature was 400 °C, RhB removal was the highest, while with further elevation of temperature, RhB removal was clearly reduced. When the catalyst was not heat treatment, besides there being no FeS<sub>2</sub> and Mo–S, there was lower Mo<sup>4+</sup>/Mo<sup>6+</sup> and Fe<sup>2+</sup>/Fe<sup>3+</sup> ratios, and higher concentrations of Mo<sup>6+</sup> and 2H-/1T-MoS<sub>2</sub> obtained in FeMoS<sub>2</sub>-IS-60 relative to FeMoS<sub>2</sub>-IS-400 (or FeMoS<sub>2</sub>-IS), as evidenced by XRD and XPS results (Fig. S5 and S6a–S6e and Table

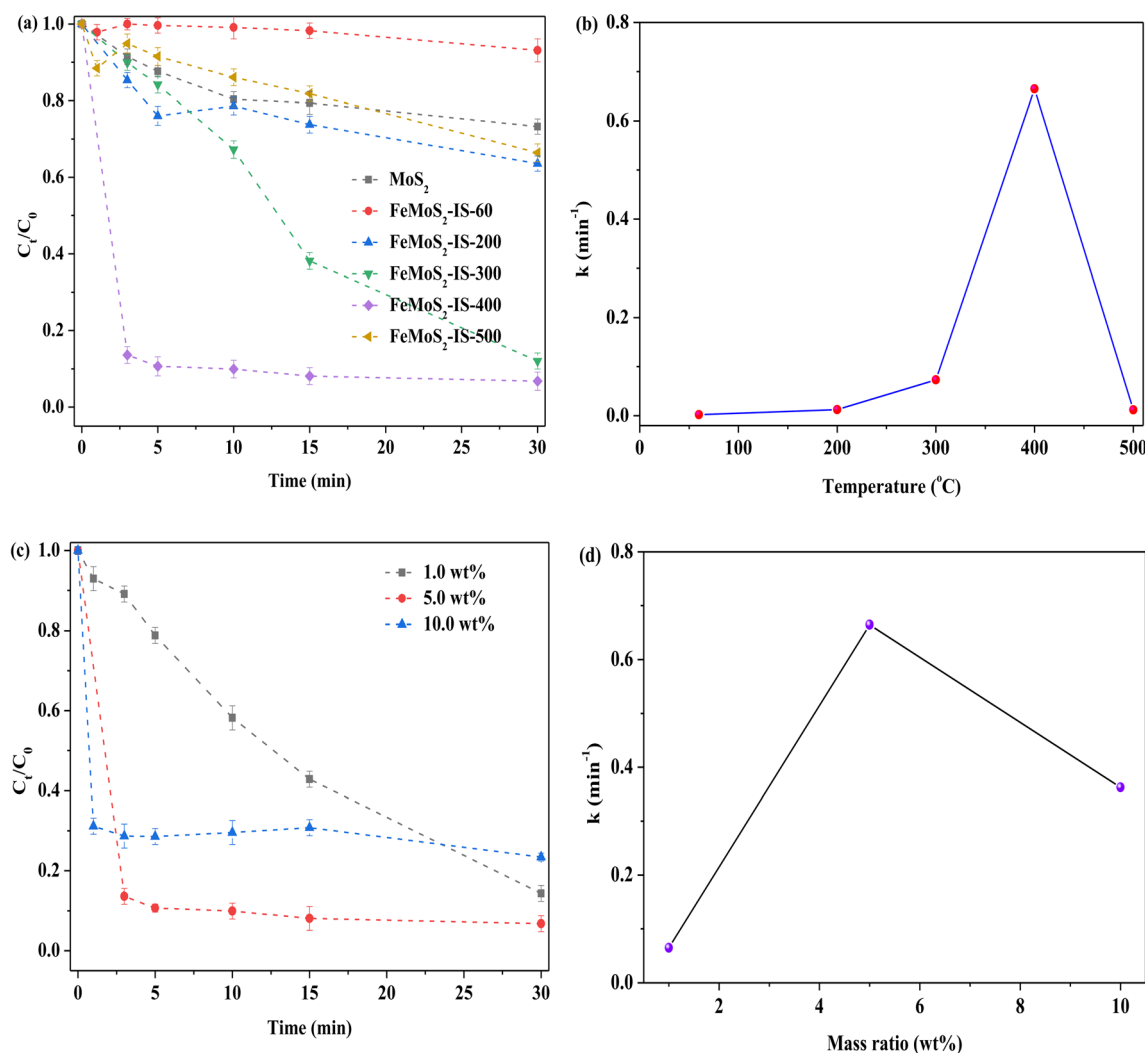

Fig. 4 (a) Effect of the calcined temperatures of catalyst on the removal of RhB; (b) relationship between calcined temperatures and reaction rate constant; (c) effect of the Fe concentration on the removal of RhB; (d) relationship between Fe concentration and reaction rate constant. Reaction conditions: [RhB] = 10 mg L<sup>-1</sup>, initial pH = 3.0, [Catal.] = 1.0 g L<sup>-1</sup>, [PMS] = 1.0 mM and in the darkness.

S1†). Accordingly, RhB removal was low. As the temperature was increased, S in the catalyst reacted with atmospheric O to form gaseous SO<sub>2</sub> and thus S vacancies generated and more Fe<sup>2+</sup> and Mo<sup>4+</sup> species exposed. In addition to the activation of PMS by Fe<sup>2+</sup> and Mo<sup>4+</sup>, S vacancies were able to activate PMS to form ROS.<sup>19,29</sup> This was due to the ability of defective sites to reduce the adsorption energy of PMS and prolong the bond length of peroxides (–O–O–) in PMS. As the indirect evidence, the comparison of MoS<sub>2</sub> and MoS<sub>2</sub>-300 for activating PMS on RhB removal was conducted. RhB removal over MoS<sub>2</sub>-300 was remarkably higher than that of MoS<sub>2</sub> (Fig. S7†). This result suggested that S vacancies could indeed facilitate RhB removal. Also, more FeS<sub>2</sub> was generated with increased calcination temperature and, as a result, RhB removal increased. When the temperature was too high, FeMoS<sub>2</sub>-IS structure was seriously destroyed, as evidenced from TG-DSC characterization (Fig. S8†). As a consequence, RhB degradation was remarkably reduced.

As mentioned above, Fe modification was in favor of strengthening RhB removal. On the basis of this reason, the

influence of Fe concentration was examined in FeMoS<sub>2</sub>-IS. When the catalyst Fe concentration was increased from 1.0 to 5.0 wt%, RhB degradation efficiency became rapid, at ~86% in 3.0 min, as compared to that of the former at 30 min (Fig. 4c and d). Further increasing Fe concentration, RhB removal was remarkably reduced. XRD results showed that the main phase was not FeS<sub>2</sub> in the 1.0 and 10.0 wt% Fe-modified catalysts (Fig. S9†). Therefore, RhB removal was decreased. In brief, the above results well illustrated that FeS<sub>2</sub> and S vacancies were two essential factors for enhancing RhB degradation.

### 3.3. Effects of operation parameters on RhB removal

Examination of the effects of initial pH on RhB removal revealed that removal was more favorable under acidic conditions, compared to neutral and alkaline conditions (Fig. 5a). When the initial pH was 3.0, RhB removal was the highest, while at pH 7.0, the obtained result was still satisfactory. Removal was decreased at pH 9.0, at ~50%. Under an acidic environment, S atoms on the surface of FeMoS<sub>2</sub>-IS were trapped by H<sup>+</sup> in solution to generate H<sub>2</sub>S,<sup>22,23</sup> in which case, more active sites, such

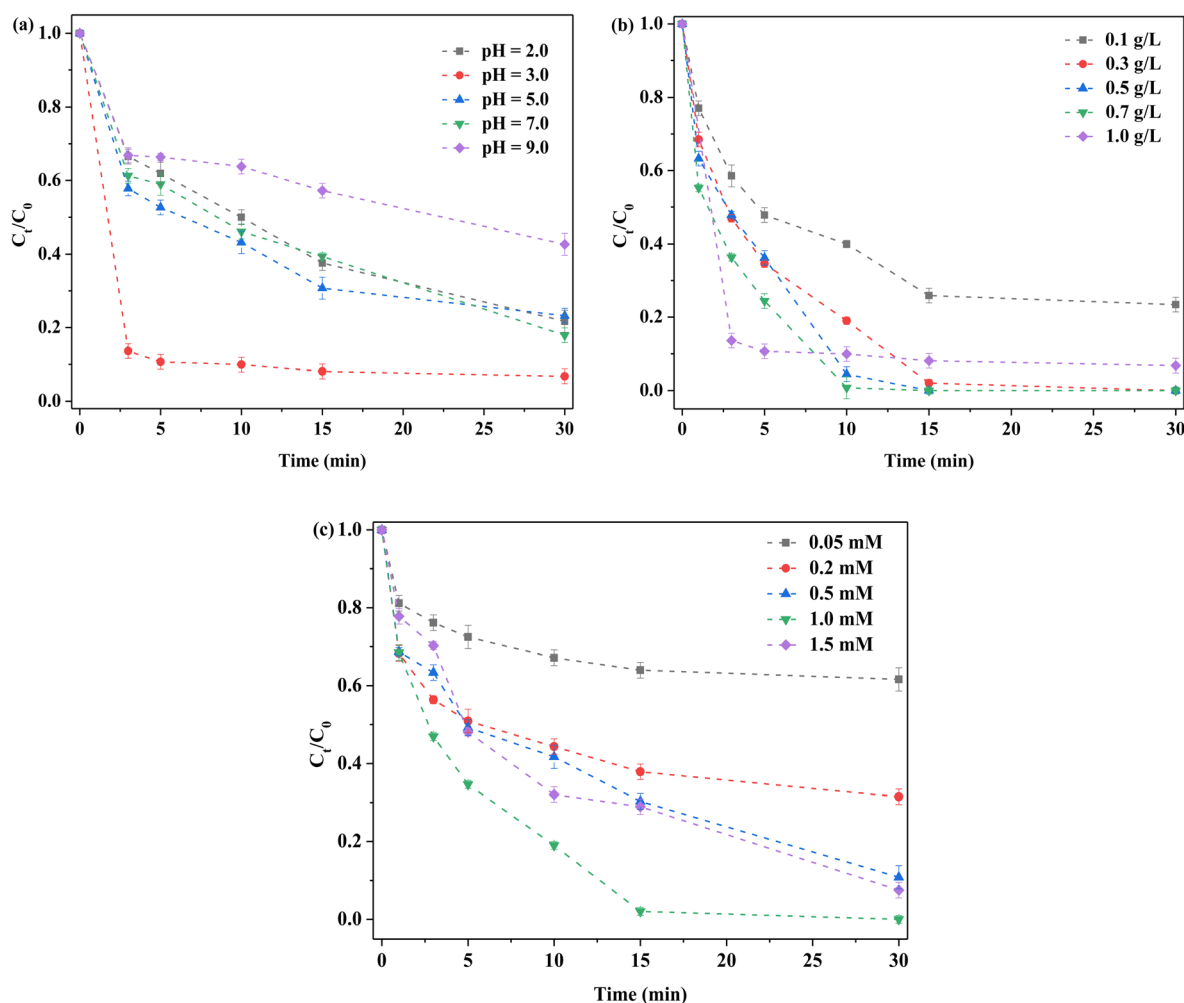

Fig. 5 Optimized reaction conditions on the removal of 10 mg L<sup>-1</sup> RhB in the FeMoS<sub>2</sub>-IS catalyzed PMS system in the darkness. (a) Initial pH. Reaction conditions: [FeMoS<sub>2</sub>-IS] = 1.0 g L<sup>-1</sup> and [PMS] = 1.0 mM; (b) catalyst dosage. Reaction conditions: initial pH = 3.0 and [PMS] = 1.0 mM; (c) PMS concentration. Reaction conditions: initial pH = 3.0 and [FeMoS<sub>2</sub>-IS] = 0.3 g L<sup>-1</sup>.

as  $\text{Fe}^{2+}$  and  $\text{Mo}^{4+}$ , were exposed and thus more ROS generated, such that the above co-actions promoted RhB removal. In an alkaline environment, this effect was suppressed due to inhibition of S atom capture and, accordingly, RhB degradation decreased. In addition, after PMS was added into the reaction system, the solution became acidity. Except for an initial pH of 2.0, all solutions retained about pH 3.0 after reaction (Fig. S10†). In this case, the above-mentioned effect was to a lesser extent inhibited. The zeta potential value of  $\text{FeMoS}_2\text{-IS}$  was  $-1.66$  mV at  $\sim 3.0$  pH while the RhB was a cationic dye. Thus, this was in favor of adsorbing RhB. Generally, RhB removal was high over a wide pH range.

Based on the above results, the effects of  $\text{FeMoS}_2\text{-IS}$  dosages were examined (Fig. 5b). When  $0.1 \text{ g L}^{-1}$  of catalyst was applied, RhB degradation efficiency was  $\sim 77\%$  in 30 min. With increased dosage, the degradation rate was accelerated. When the catalyst dosage was within  $0.3\text{--}0.7 \text{ g L}^{-1}$ , all degradation efficiency was  $\sim 100\%$  in 15 min. However, when the dosage exceeded  $0.7 \text{ g L}^{-1}$ , the removal started to decrease. The dosage of catalyst was insufficient, as there was not enough active sites to activate PMS. Therefore, the removal of RhB was low. With increasing catalyst dosage, more ROS were produced and, hence, the removal increased. When the catalyst dosage was too high, agglomeration occurred between catalyst particles, thereby affecting PMS activation. Meanwhile, the repulsion force between catalyst and PMS increased due to their similar charges.<sup>40</sup> Similarly, the removal was decreased.

Here, the PMS concentration was optimized. The degradation efficiency of RhB was  $\sim 38\%$  at 30 min when  $0.05 \text{ mM}$  PMS was employed (Fig. 5c). With increased PMS concentration, RhB removal increased. When the PMS concentration was  $1.0 \text{ mM}$ , the removal reached the highest and began to decrease with further increased PMS. Increased PMS concentration generated more ROS and thus produced higher RhB removal. When PMS was too high, the removal decreased, which was mainly due to the reaction between partially activated PMS without organic pollutants. In addition, there was newly formed ROS, such as  $\text{HO}_2^{\cdot}$ .<sup>41</sup> The activity of these species was less than that of the original system. Accordingly, RhB degradation was reduced. In short, optimal reaction conditions were established and therefore the best degradation obtained.

Common anions, including chloride, nitrate and bicarbonate ions ( $\text{Cl}^-$ ,  $\text{NO}_3^-$ , and  $\text{HCO}_3^-$ , respectively) were captured by the highly oxidizing free radical species and the corresponding reaction rate constants considerably varied.<sup>22,23,42–44</sup> In this reaction system, different cations and anions were respectively added. RhB degradation efficiency was observed to be close to 100% after 15 min of reaction without any extra anions (Fig. 6a). When different anions ( $\text{Cl}^-$ ,  $\text{NO}_3^-$ ,  $\text{HCO}_3^-$ , and  $\text{H}_2\text{PO}_4^-$ ) were employed, great changes appeared in RhB degradation.  $\text{Cl}^-$  promoted removal based on the original reaction system, whereas other anions (including  $\text{NO}_3^-$ ,  $\text{HCO}_3^-$ , and  $\text{H}_2\text{PO}_4^-$ ) suppressed degradation. After adding  $\text{Cl}^-$ , the degradation efficiency reached 100% in 10 min, which indicated that  $\text{Cl}^-$  played a positive role in RhB removal. To further explore this effect, different concentrations (50, 100, 300 and 500 mM) of NaCl were investigated (Fig. 6b). RhB removal

ability was observed to be clearly strengthened by introducing low or high NaCl concentrations, which further confirmed that  $\text{Cl}^-$  was indeed a beneficial additive. This was because  $\text{Cl}^-$  could react with strong free radical species to form other free radical species.<sup>41</sup> Accordingly, the promotion might have been attributable to newly formed active species such as  $\text{Cl}^{\cdot}$  and  $\text{Cl}_2^{\cdot}$ . In addition, other active chlorine species were formed.<sup>42,43</sup> For  $\text{NO}_3^-$ , RhB removal decreased, which might have been attributable to the competition for reactants. For the  $\text{HCO}_3^-$ , the degradation was severely inhibited after  $\text{HCO}_3^-$  addition, because solution pH was altered and sharply increased toward 8–9. Under alkaline condition, the binding of  $\text{H}^+$  with S atoms on the catalyst surface did not occur,<sup>22,23</sup> thereby reducing the exposure of active sites, such as  $\text{Mo}^{4+}$  and  $\text{Fe}^{2+}$  species. In addition,  $\text{HCO}_3^-$  reacted with PMS or its related ROS.<sup>20</sup> Thus, removal was clearly decreased after  $\text{HCO}_3^-$  was added. Similar to  $\text{HCO}_3^-$ , the solution pH was remarkably increased after  $\text{H}_2\text{PO}_4^-$  was added to the reaction system, such that it was clear that an inhibition effect occurred due to alkaline condition. In addition, interactions between  $\text{H}_2\text{PO}_4^-$  and Mo on the catalyst could generate a heteropoly acid salt.<sup>45</sup> Hence,  $\text{H}_2\text{PO}_4^-$  had a clear negative influence on RhB removal.

To explore the influence of cations on RhB removal, various cations, including  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Mg}^{2+}$ , and  $\text{Ca}^{2+}$  with  $\text{Cl}^-$  as the anion were examined in detail. The order of the activity in terms of RhB removal was  $\text{Na}^+ > \text{Mg}^{2+} > \text{K}^+ > \text{Ca}^{2+} > \text{control}$  (Fig. 6c). The results indicated that these cations had no inhibitory effect on RhB degradation. Promotion might have been due to the presence of  $\text{Cl}^-$ . To explore the contribution of  $\text{Na}^+$  and  $\text{Cl}^-$ ,  $\text{Na}^+$  was replaced by  $\text{Mg}^{2+}$  with the same concentration of  $\text{Cl}^-$  (Fig. 6d). When  $\text{MgCl}_2$  was used as the precursor, RhB removal was significantly lower than that of NaCl as precursor. Thus, the above-mentioned promotion was attributed to the coaction of cations and anions, with the contribution of  $\text{Cl}^-$  greater than that of  $\text{Na}^+$ . To explore the influence of water types, tap water and river water (Xiang-Jiang River, Hunan, China) as solvents were selected. The RhB degradation efficiencies were 100 and 70% in tap and river water at 30 min, respectively (Fig. 6e). In general, the catalyst exhibited satisfactory degradation in different water environments. Using river water as solvent, the low degradation might have been due to the presence of natural organic humic acids and various inorganic salts. In short, the  $\text{FeMoS}_2\text{-IS/PMS}$  system had a strong ability to resist external interference. In addition, different organic pollutants were investigated in this system. Most of organic pollutants (RhB, MB, MO, and AOII) were rapidly removed in 30 min, especially AOII (Fig. S11†). These results indicated that the catalytic system possessed excellent ability to remove organic pollutants in wastewater.

The stability of  $\text{FeMoS}_2\text{-IS}$  was examined and it was observed that the degradation efficiency of RhB reached 100% with its 1st cycle of reaction (Fig. S12†). After reaction, the catalyst was regenerated by filtering the reaction solution, washing the solid with distilled water and ethanol to separate liquid and solid, and dried. Finally, the dried sample was calcined at  $400^\circ\text{C}$  for 1.5 h. According to the same reaction conditions as the 1st reaction, the regenerated catalyst was added into a 2nd reaction

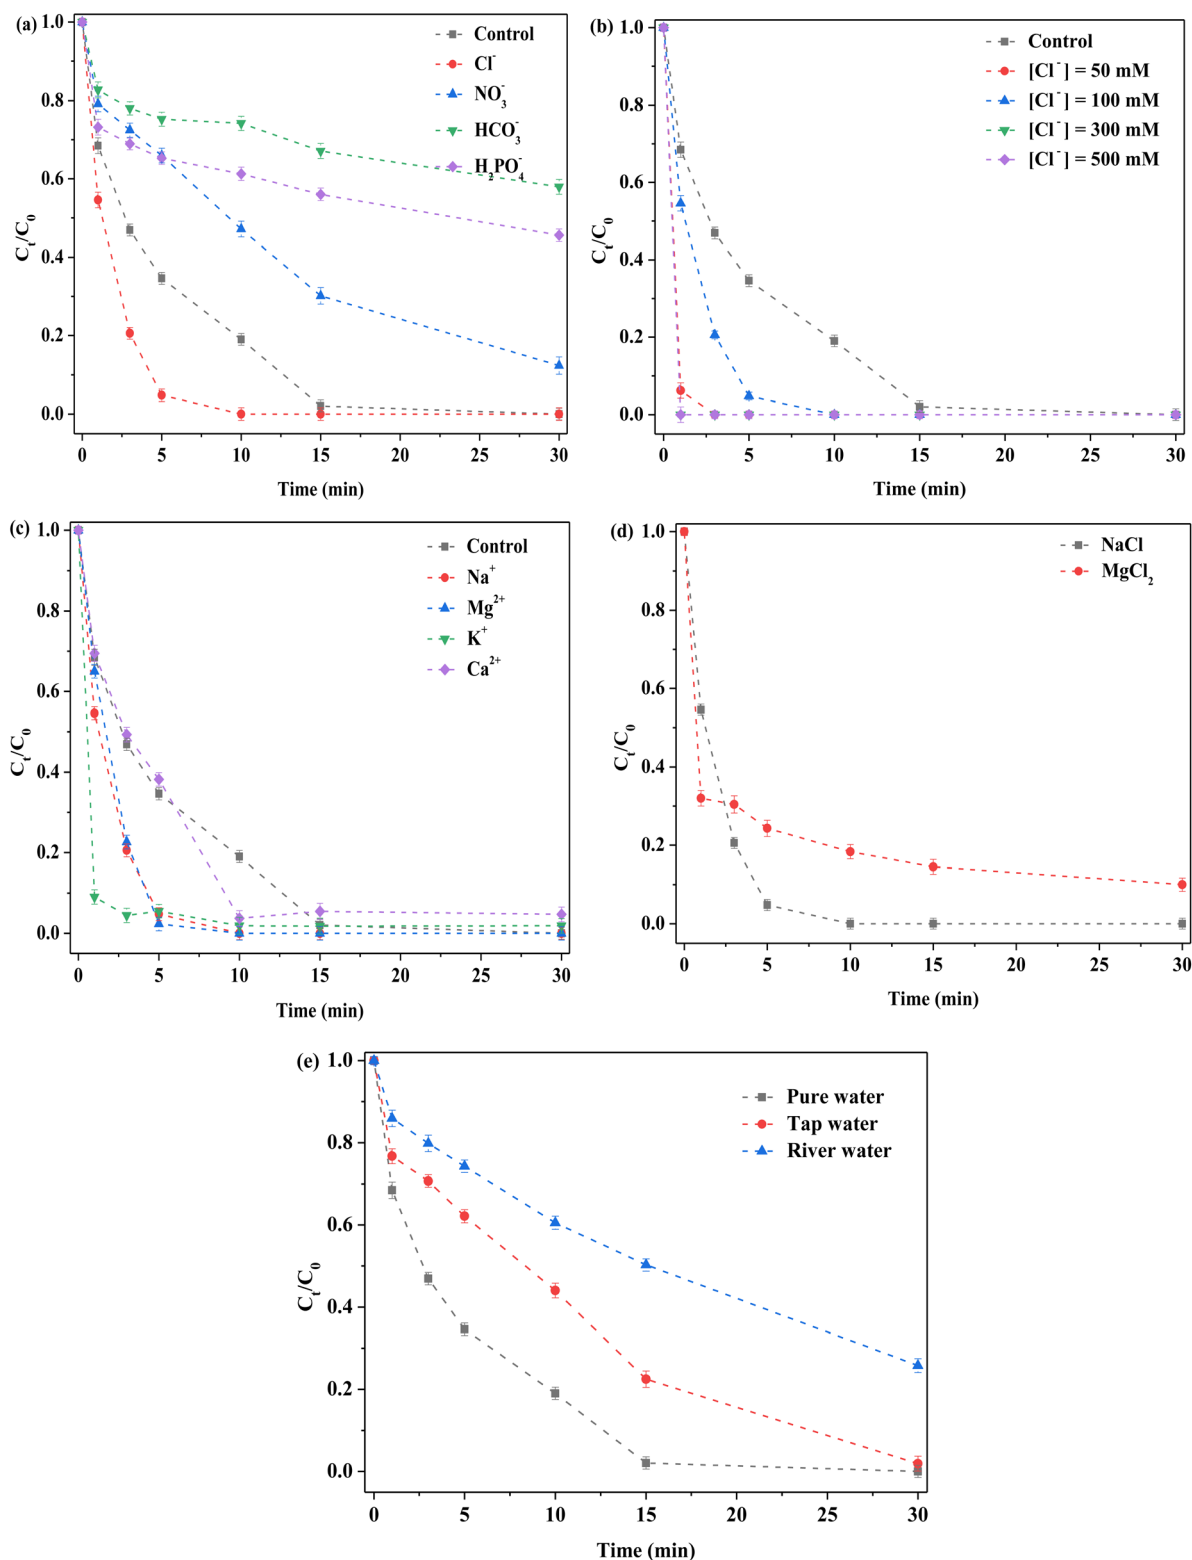

Fig. 6 Effect of various factors on the removal of RhB. (a) Anions; (b)  $\text{Cl}^-$  concentration; (c) cations; (d) different cations with the same concentration of  $\text{Cl}^-$ ; (e) types of water. Reaction conditions:  $[\text{RhB}] = 10 \text{ mg L}^{-1}$ , initial pH = 3.0,  $[\text{FeMoS}_2\text{-IS}] = 0.3 \text{ g L}^{-1}$ ,  $[\text{PMS}] = 1.0 \text{ mM}$ , [anions or cations] = 100 mM and in the darkness.

solution. The results indicated that the degradation efficiency of RhB arrived at 100% after 30 min of reaction. Repeating the above same steps, several reactions and regeneration were

conducted. After the 5th reaction, the degradation efficiency of RhB was slightly decreased, implying that the catalyst possessed basically retained original activity. Notably, the used catalyst

had to be treated at high temperature to recover the initial catalytic activity because it was covered and/or blocked the active sites of catalyst by the intermediates and/or products, which was the main reason for remarkably decreased RhB removal (Fig. S13†). By a simple calcination, the used catalyst was well regenerated.

The structure of fresh and used  $\text{FeMoS}_2\text{-IS}$  was characterized by XRD, which showed that used catalyst was greatly changed after the several reaction cycles, compared to that of fresh catalyst, with the diffraction characteristic peaks of  $\text{FeS}_2$  no longer apparent, which was mainly attributed to the structure of  $\text{MoO}_3$  (Fig. S14†). This situation mainly originated from the leaching of Fe and oxidation of  $\text{MoS}_2$  during reaction and regeneration, which were the main reasons for decreasing catalytic activity after the reaction and regeneration. To further confirm this difference, the changes in surface elements on the catalyst after reaction were characterized by XPS. One characteristic peak located at  $\sim 707.25$  eV did not appear in Fe 2p, implying that Fe-S had disappeared and, meanwhile, the ratio of  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$  was remarkably reduced, meaning that a lot of

$\text{Fe}^{2+}$  were oxidized to  $\text{Fe}^{3+}$  (Fig. S15 and Table S1†). This change was further confirmed in S 2p, where the  $\text{S}^{2-}$  was completely eliminated and the peak was attributed to one characteristic of  $\text{SO}_n^-$ . This indicated that Mo-S and Fe-S on the catalyst surface did not indeed exist. For Mo 3d, the ratio of  $\text{Mo}^{4+}$  and  $\text{Mo}^{6+}$  was reduced whereas the concentration of  $\text{Mo}^{6+}$  increased, hinting that great oxidation was occurred. This was confirmed by O 1s XPS characterization; that is, the concentration of lattice O in the catalyst had increased, which was further supported by the fact that the color of the catalyst had turned from black to white. The above results illustrated that the heterogeneous reaction was happened on the surface of catalyst.

### 3.4. Leaching of various ions during reaction and their effects

Decomposition of PMS had an important influence on ROS formation and the test was conducted.<sup>30</sup> When  $\text{MoS}_2\text{-IS}$  acted as catalyst, the decomposition efficiency of PMS was no more than 5% at 30 min (Fig. 7a). This was main reason for the low RhB

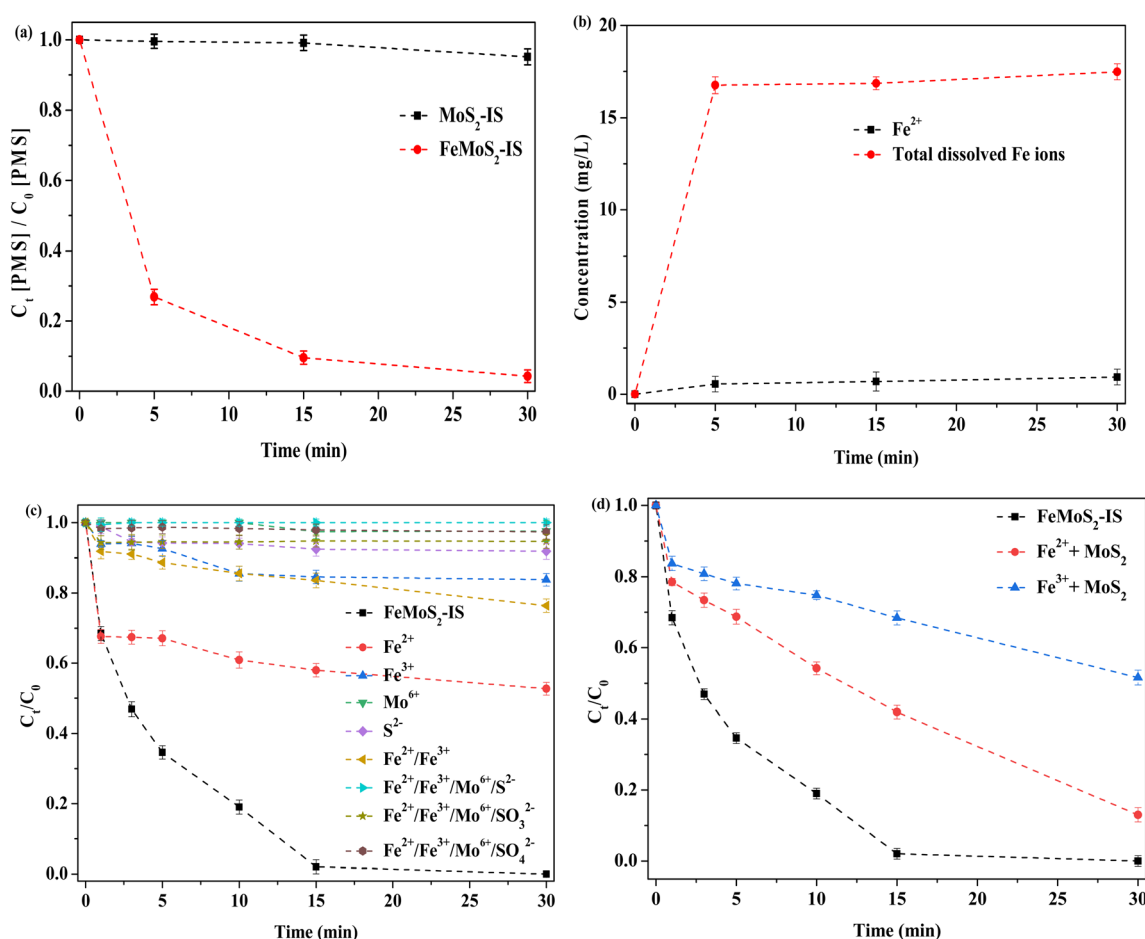

Fig. 7 (a) The decomposition of PMS; (b) the leaching of  $\text{Fe}^{2+}$  and total dissolved Fe ions; (c) removal of RhB in the PMS-based homogeneous reaction system; (d) removal of RhB in the PMS-based heterogeneous reaction system. Reaction conditions:  $[\text{RhB}] = 10 \text{ mg L}^{-1}$ , initial pH = 3.0,  $[\text{FeMoS}_2\text{-IS and MoS}_2] = 0.3 \text{ g L}^{-1}$ ,  $[\text{PMS}] = 1.0 \text{ mM}$ ,  $[\text{Fe}^{2+}] = 0.55 \text{ mg L}^{-1}$ ,  $[\text{Fe}^{3+}] = 15.46 \text{ mg L}^{-1}$ ,  $[\text{Mo}^{6+}] = 1.11 \text{ mM}$ ,  $[\text{S}^{2-}] = [\text{SO}_3^{2-}] = [\text{SO}_4^{2-}] = 0.14 \text{ mM}$  and in the darkness.

degradation. In contrast, when FeMoS<sub>2</sub>-IS was the catalyst, the decomposition efficiency of PMS reached as high as ~95% in the same time. Thus, FeMoS<sub>2</sub>-IS had a higher ability to activate PMS and thus removed more RhB in solution. Also, the source of ROS was mainly from PMS decomposition.

During reaction, some ions were leached. To examine this, Fe<sup>2+</sup> and total Fe ions were evaluated (Fig. 7b). After reaction to 30 min, the concentrations of Fe<sup>2+</sup> and total Fe ions were 0.55 and 16.01 mg L<sup>-1</sup>, respectively. Based on the above eqn (2)–(5), soluble Fe ions were generated. According to the calculation, the loss efficiency of total Fe ions was ~5.0 wt%, implying that the catalyst had a good stability. Similarly, Mo and S ions moved from the catalyst and entered the reaction solution. Thus, the effect of their activation on PMS in the homogeneous system was investigated (Fig. 7c). When Fe<sup>2+</sup> alone was used as homogeneous catalyst, the degradation efficiency of RhB was 47% after 30 min of reaction, which suggested that dissolved Fe<sup>2+</sup> made some contributions on RhB removal because Fe<sup>2+</sup> itself could directly activate PMS.<sup>14–16</sup> The degradation efficiency of RhB was both below 25% when Fe<sup>3+</sup> or Fe<sup>2+</sup>/Fe<sup>3+</sup> were employed, which indicated that these Fe ions' ability to activate PMS was poor. When soluble Mo ion ((NH<sub>4</sub>)<sub>6</sub>Mo<sub>7</sub>O<sub>24</sub>·H<sub>2</sub>O as precursor) was used, the degradation efficiency of RhB was only ~2% at 30 min, hinting that dissolved Mo ion had little activation effect on PMS. Similarly, S<sup>2-</sup> (Na<sub>2</sub>S as a precursor) alone could not accelerate the removal rate. Surprisingly, the removal did hardly occur when all dissolved ions (Na<sub>2</sub>SO<sub>3</sub> and Na<sub>2</sub>SO<sub>4</sub> as SO<sub>3</sub><sup>2-</sup> and SO<sub>4</sub><sup>2-</sup> precursors, respectively) were simultaneously added into the reaction system. This result indicated that it contributed the extremely low degradation for RhB even when various ions from the catalyst leached during reaction.

It has been reported that the homogeneous Fe<sup>2+</sup> or Fe<sup>3+</sup> ions can remarkably enhance RhB removal in the MoS<sub>2</sub>/PMS system.<sup>14–18</sup> To verify this deduction, a series of experiments were designed. The degradation efficiency of RhB was respectively 87 and 48% in Fe<sup>2+</sup>/MoS<sub>2</sub>/PMS and Fe<sup>3+</sup>/MoS<sub>2</sub>/PMS systems, which meant that Fe ions dissolved by interactions with MoS<sub>2</sub> in the FeMoS<sub>2</sub>-IS could accelerate RhB removal (Fig. 7d). In other words, the heterogeneous catalytic reaction played a vital role on RhB removal. To date, there has been a debate regarding the main active sites in the catalyst FeS<sub>2</sub> activating persulfate. Some researchers<sup>46,47</sup> have suggested that Fe<sup>2+</sup> played a major role. Others<sup>48</sup> have pointed out that S species were involved in this reaction in addition to Fe<sup>2+</sup>. Exploring whether Fe<sup>2+</sup> was on the catalyst surface or in solution, different researchers have come to different conclusions: (i) dissolved Fe<sup>2+</sup>,<sup>49</sup> (ii) Fe<sup>2+</sup> on the surface of heterogeneous catalyst,<sup>50</sup> and (iii) Fe<sup>2+</sup> in the both solution and heterogeneous catalysts.<sup>51</sup> Clearly, this reaction behavior was different from that of FeS<sub>2</sub> catalytic PMS systems in previous studies.

### 3.5. Identifying ROS in RhB removal

To examine the mechanism of PMS activation, different quenchers were used to detect possible ROS in the FeMoS<sub>2</sub>-IS/PMS system. In general, free radical species (including SO<sub>4</sub><sup>•-</sup>, <sup>•</sup>OH, and O<sub>2</sub><sup>•-</sup>) and non-free radical species, such as singlet

oxygen (<sup>1</sup>O<sub>2</sub>), usually appeared in the process of PMS activation. In this experiment, methanol (MeOH) was used to identify as SO<sub>4</sub><sup>•-</sup> and <sup>•</sup>OH,<sup>13–15</sup> tiron applied for capturing O<sub>2</sub><sup>•-</sup>,<sup>52,53</sup> and furfuryl alcohol (FFA) employed for capturing <sup>1</sup>O<sub>2</sub>,<sup>14</sup> as shown in Fig. 8a–c. FeMoS<sub>2</sub>-IS was an Fe-based catalyst in the Fenton-like reaction and SO<sub>4</sub><sup>•-</sup> and <sup>•</sup>OH usually produced during PMS activation. This was verified by the reaction with MeOH. After MeOH in different concentrations (500 and 1000 mM) was employed, RhB degradation efficiency decreased from 100 to 89% and 85% in 30 min, respectively, implying the presence of SO<sub>4</sub><sup>•-</sup> and <sup>•</sup>OH in the reaction solution but with limited effect. After the addition of phenol with different concentrations, the inhibitions were clearly observed (Fig. S16(a)†), implying that the above two species were appeared on the surface of catalyst. It was further confirmed by the EPR characterization. As shown in Fig. S16(b)†, the signals of SO<sub>4</sub><sup>•-</sup> and <sup>•</sup>OH were appeared and the signal of <sup>•</sup>OH turned stronger with increasing reaction time, implying that the <sup>•</sup>OH was generated from the reaction between SO<sub>4</sub><sup>•-</sup> and H<sub>2</sub>O.<sup>15</sup> This was mainly attributed to the activation of PMS by Fe<sup>2+</sup> and Mo<sup>4+</sup>.<sup>13–23</sup> The above results confirmed that the SO<sub>4</sub><sup>•-</sup> and <sup>•</sup>OH were not main ROS in this reaction. When tiron at different concentrations (10 and 100 mM) was used, RhB degradation efficiencies were both <5% in 30 min. This indicated that the reaction system contained a lot of O<sub>2</sub><sup>•-</sup> species and played an important role in degradation. When FFA at different concentrations (500 and 1000 mM) was applied, RhB degradation efficiencies were both no more than 5%, which showed that <sup>1</sup>O<sub>2</sub> existed in the reaction system. Notably, FFA could react with PMS, resulting in reduced RhB removal.<sup>18</sup> To confirm the existence of O<sub>2</sub><sup>•-</sup> and <sup>1</sup>O<sub>2</sub> in the reaction system, EPR characterization was applied using DMPO (methanol as solvent) and TEMP, respectively. Some noticeable signals of DMPO-O<sub>2</sub><sup>•-</sup> adduct were detected in the FeMoS<sub>2</sub>-IS/PMS system, confirming that the appearance of O<sub>2</sub><sup>•-</sup> had occurred (Fig. 8d). Similarly, remarkable signals of TEMP-<sup>1</sup>O<sub>2</sub> were observed, implying that many <sup>1</sup>O<sub>2</sub> were formed in this system (Fig. 8e). This reaction was concluded to indeed contain a mixture of radical and non-radical species, with O<sub>2</sub><sup>•-</sup> and <sup>1</sup>O<sub>2</sub> as main ROS.

### 3.6. Feasible synthetic and reaction mechanisms

When all the precursors were added into the water, the solution pH was 1.8. In this environment, the Fe and Mo ions existed in the form of Fe<sup>3+</sup> and Mo<sub>7</sub>O<sub>24</sub><sup>6-</sup>. After thiourea introduction, it combined with Fe<sup>3+</sup> and Mo<sub>7</sub>O<sub>24</sub><sup>6-</sup>. Under hydrothermal condition, some Fe<sup>3+</sup> and Mo<sup>6+</sup> were reduced to Fe<sup>2+</sup> and Mo<sup>4+</sup> by thiourea to form the polymer structure, namely, –Mo–S<sub>2</sub>–Fe–S<sub>2</sub>–Mo–.<sup>22</sup> This situation allowed a tight connection between FeS<sub>2</sub> and MoS<sub>2</sub> and they were thus better able to interact with each other. After high temperature treatment, this special structure was partially broken to form FeS<sub>2</sub> and MoS<sub>2</sub>. When the Fe concentration was too low, more MoS<sub>2</sub> was formed and, meanwhile, some MoO<sub>3</sub> and S vacancies also produced. When the Fe concentration was too high, more FeS<sub>2</sub> was generated, but it easily combined with O<sub>2</sub> in the air to form iron oxides like α-Fe<sub>2</sub>O<sub>3</sub>, due to the lack of Mo protection. The treatment temperature was another important factor for generating FeS<sub>2</sub>.

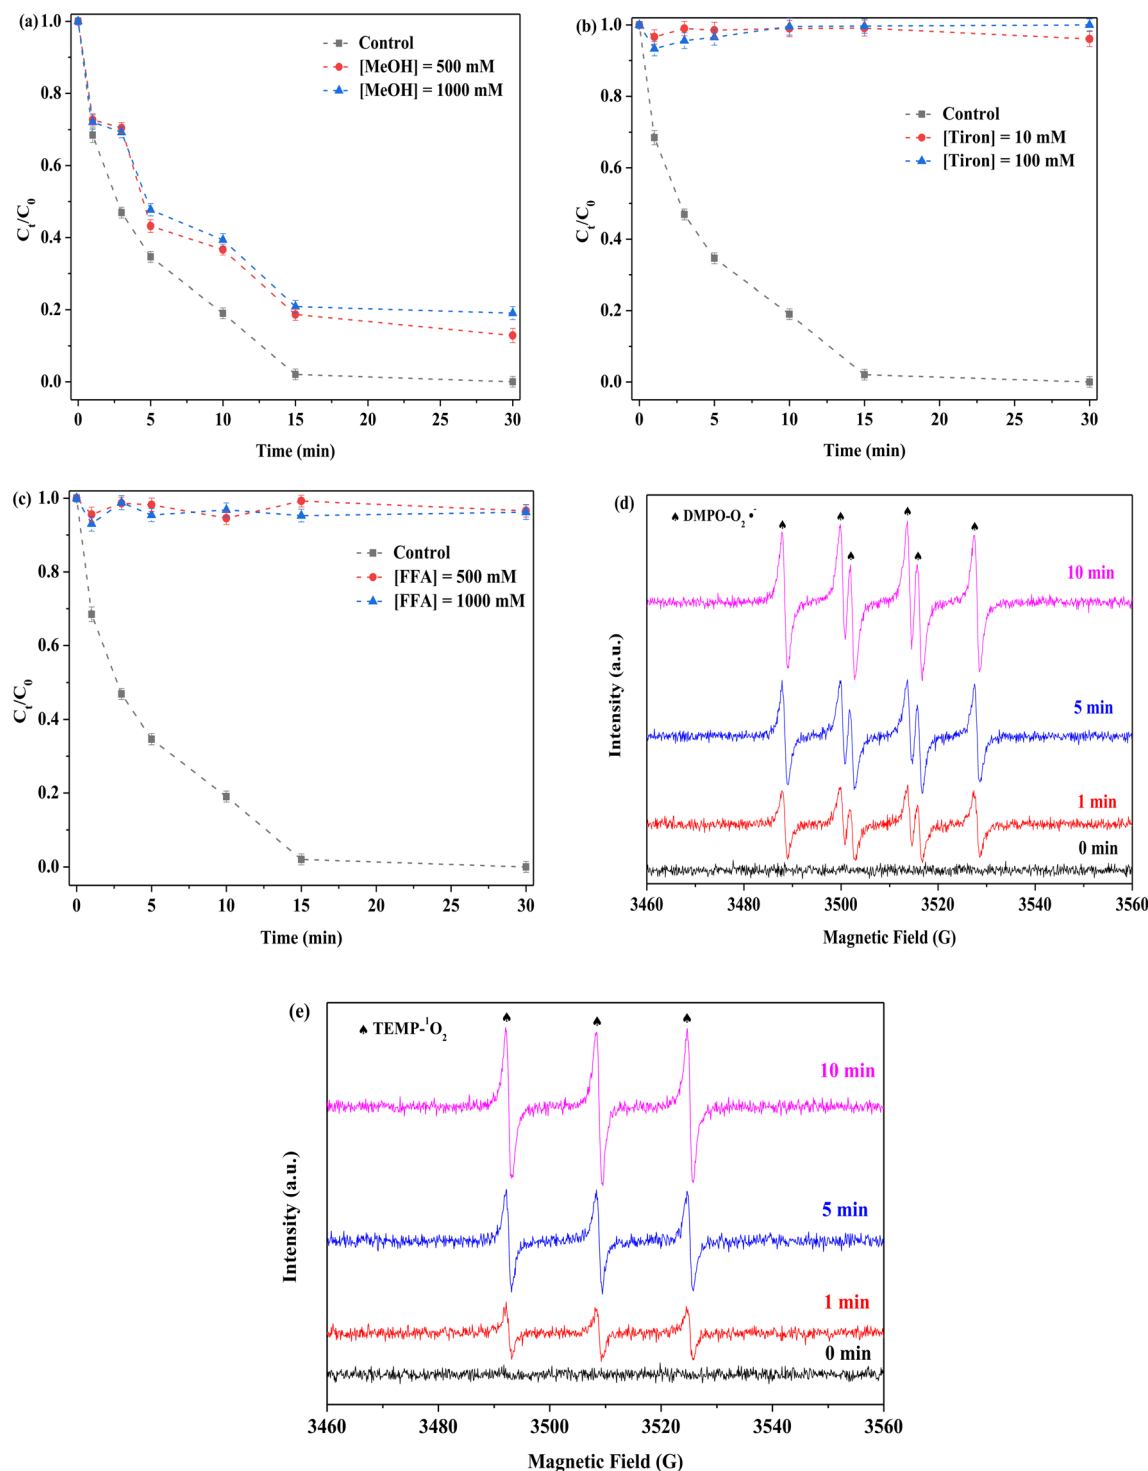

Fig. 8 Effect of (a) MeOH, (b) Tiron and (c) FFA on the removal of RhB in the FeMoS<sub>2</sub>-IS/PMS process and signals of EPR (d) and (e). Reaction conditions: [RhB] = 10 mg L<sup>-1</sup>, initial pH = 3.0, [FeMoS<sub>2</sub>-IS] = 0.3 g L<sup>-1</sup>, [PMS] = 1.0 mM and in the darkness.

When the temperature was too low, the above special structure was not decomposed to FeS<sub>2</sub>. When the temperature was too high, the catalyst was oxidized such that its structure was seriously destroyed. In addition, higher temperature could generate more S vacancies and the existence of S vacancies induced higher Fe<sup>2+</sup>/Fe<sup>3+</sup> and Mo<sup>4+</sup>/Mo<sup>6+</sup>.

Based on the above results, a feasible reaction mechanism was proposed (Fig. 9). This was a typical heterogeneous catalytic reaction, which was different from that of the literature.<sup>20–23,46–51</sup> The solution exhibited acidity during reaction and thus solution H<sup>+</sup> corroded FeS<sub>2</sub> and MoS<sub>2</sub> on the surface of FeMoS<sub>2</sub>-IS to expose more Fe<sup>2+</sup> and Mo<sup>4+</sup> to generate SO<sub>4</sub><sup>•-</sup> and <sup>•</sup>OH by the activation of PMS.<sup>13–23</sup> Simultaneously, the catalyst could

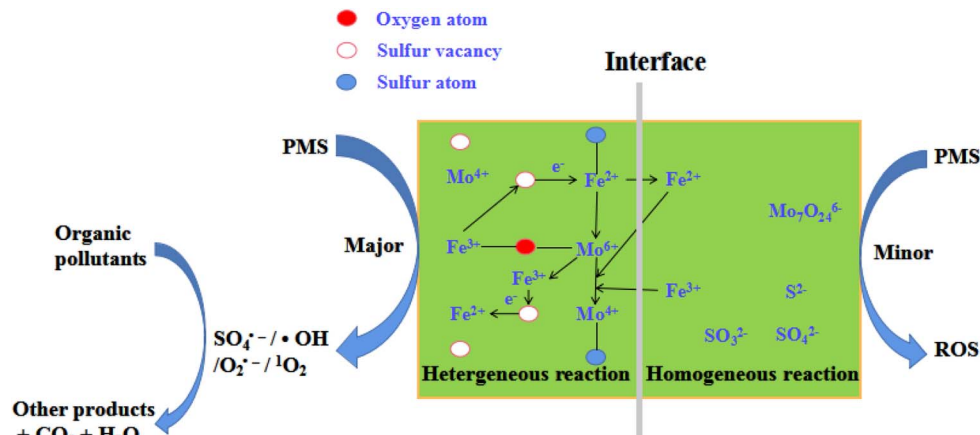

Fig. 9 Schematic illustration of the removal of organic pollutants in the FeMoS<sub>2</sub>-IS/PMS system.

adsorb these ions by electrostatic interactions. Thus, these were coordination with Mo species to form Fe<sup>2+</sup>/Fe<sup>3+</sup> and Mo<sup>4+</sup>/Mo<sup>6+</sup> cycles, thereby accelerating PMS decomposition toward O<sub>2</sub><sup>•-</sup> and <sup>1</sup>O<sub>2</sub>. In addition, FeMoS<sub>2</sub>-IS was rich in S vacancies and these sites had good affinity for PMS, which then reacted with each other to form intermediates.<sup>35</sup> At the liquid–solid interface, these intermediates finally evolved into O<sub>2</sub><sup>•-</sup> and <sup>1</sup>O<sub>2</sub>. Also, O<sub>2</sub><sup>•-</sup>, as an intermediate, reacted with each other to generate <sup>1</sup>O<sub>2</sub>.<sup>20</sup> In addition, the surface Mo<sup>6+</sup> on the catalyst could react with O<sub>2</sub><sup>•-</sup> to produce <sup>1</sup>O<sub>2</sub>.<sup>20</sup> Notably, the Mo<sup>6+</sup> peroxo complex species could generate <sup>1</sup>O<sub>2</sub>.<sup>14</sup> The above pathways were displayed in formulas (6)–(17).

On all accounts, Fe, Mo, and S played important roles in the structure and catalytic performance of catalyst. First, for Fe

ions, Fe<sup>2+</sup> acted as an important active site for the formation of FeS<sub>2</sub> and the activation PMS/dissolved O<sub>2</sub> to generate ROS. Second, the effect of Mo mainly involved in this reaction and promoted RhB removal. Finally, the role of S suppressed the oxidation of low-valent Fe and Mo to high-valent metal ions. In addition, it provided a source of S deficient sites and could directly adsorb and activate PMS.

## 4. Conclusions

In summary, new Fe–Mo microparticles containing S vacancies with FeS<sub>2</sub> as the dominant phases were successfully synthesized by the *in situ* synthesis. The catalyst effectively removed RhB by PMS activation in wastewater. High-temperature treatment and doping Fe were both beneficial for the formation of active sites, such as FeS<sub>2</sub> and S vacancies. This system could effectively eliminate RhB over a wide pH range. All cations had positive effects on the RhB degradation but anions exhibited a dual effect. After operating through several reaction and regeneration cycles, the removal of RhB was still good. It was confirmed that SO<sub>4</sub><sup>•-</sup>, •OH, O<sub>2</sub><sup>•-</sup> and <sup>1</sup>O<sub>2</sub> were important ROS in this reaction system, providing a good pathway for degrading organic pollutants in wastewater.
