PAPER

The mechanism of water pollutant photodegradation by mixed and core–shell WO₃/TiO₂ nanocomposites†

Abdisa Habtamu [ID] and Masaki Ujihara [ID] *

Environmental pollution is one of the biggest concerns in the world today, and solar energy-driven photocatalysis is a promising method for decomposing pollutants in aqueous systems. In this study, the photocatalytic efficiency and catalytic mechanism of WO₃-loaded TiO₂ nanocomposites of various structures were analyzed. The nanocomposites were synthesized *via* sol–gel reactions using mixtures of precursors at various ratios (5%, 8%, and 10 wt% WO₃ in the nanocomposites) and *via* core–shell approaches (TiO₂@WO₃ and WO₃@TiO₂ in a 9 : 1 ratio of TiO₂ : WO₃). After calcination at 450 °C, the nanocomposites were characterized and used as photocatalysts. The kinetics of photocatalysis with these nanocomposites for the degradation of methylene blue (MB⁺) and methyl orange (MO⁻) under UV light (365 nm) were analyzed as pseudo-first-order reactions. The decomposition rate of MB⁺ was much higher than that of MO⁻, and the adsorption behavior of the dyes in the dark suggested that the negatively charged surface of WO₃ played an important role in adsorbing the cationic dye. Scavengers were used to quench the active species (superoxide, hole, and hydroxyl radicals), and the results indicated that hydroxyl radicals were the most active species; however, the active species were generated more evenly on the mixed surfaces of WO₃ and TiO₂ than on the core–shell structures. This finding shows that the photoreaction mechanisms could be controlled through adjustments to the nanocomposite structure. These results can guide the design and preparation of photocatalysts with improved and controlled activities for environmental remediation.

1. Introduction

Increasing wastewater discharges from various sources pose enormous environmental challenges worldwide.[1] Due to rapid industrial growth, the environment has become highly contaminated with various organic and inorganic pollutants.[2,3] Dyes are common hazardous organic contaminants in wastewater.[4] They also impart color to the water and can produce harmful byproducts through chemical reactions.[5] The long-term consumption of water containing dyes could harm the liver, central nervous, and digestive systems of humans.[6] For this reason, many researchers are engaged in developing techniques to eliminate organic dyes from water systems.

Recently, various techniques, including using a green biochar/iron oxide composite,[7] coated membranes,[8] surfactant-modified biomass,[9] coagulation,[10] modified magnetic nano-sorbents,[11,12] hydrochar adsorption,[13,14] and photocatalytic degradation,[15,16] have been applied to remove both cationic and anionic dyes from water. Among these methods, semiconductor-based photocatalysis is thought to be the most promising method because it can convert a broad range of organic contaminants into less toxic compounds, including CO_2, and H_2O, without the use of expensive oxidants. With the aim of developing effective photocatalysts, various semiconductors have been examined individually or in combination with other materials. The modification of photocatalyst surfaces with other materials can improve the efficiency of photocatalysis.[17] Combining semiconductors with metals can enhance charge separation.[18–21] Elemental doping and combining different semiconductors[22,23] can change the band gap of the resulting materials and induce charge separation. Among the photocatalysts, TiO₂ has been widely investigated as a typical semiconductor photocatalyst[24,25] due to its high photocatalytic activity, low price, physicochemical stability, non-toxicity, and environmental friendliness.[26] Despite these advantages, the wide bandgap of TiO₂ (3.20–3.35 eV) limits the use of light to the UV range, shows rapid charge recombination and has limited efficiency.[27] To address these limitations, doping and combining TiO₂ photocatalysts with narrow

Graduate Institute of Applied Science and Technology, National Taiwan University of Science and Technology, 43 Keelung Road, 10607, Taipei, Taiwan. E-mail: masaki. ujihara@mail.ntust.edu.tw

bandgap semiconductors are viable options. Semiconductors such as MoO_3,[28] Ag_2CO_3,[29] ZnO,[30] and WO_3 (ref. 27) have been coupled with TiO_2 to improve its photocatalytic efficiency under UV light. Among them, WO_3 has attracted considerable amounts of attention due to its ability to absorb visible light (typically wavelengths <500 nm (ref. 31 and 32) and extended to >500 nm by the effects of oxygen vacancies[32]) WO_3 is also stable in oxidative and acidic environments and has low cost and low toxicity.[33] The crystal ionic radius of W^{6+} is close to that of T^{4+}; therefore, W^{6+} can be easily introduced into the lattice of titania to replace Ti^{4+} and form W–O–Ti links, or it can be positioned at interstitial locations,[34,35] which effectively induces lattice defects and increases the surface area of WO_3-coupled TiO_2. Moreover, WO_3-coupled TiO_2 shows enhanced O_2 chemisorption on its surfaces,[36] and this adsorbed oxygen improves charge separation. Thus, WO_3-coupled TiO_2 has emerged as a promising adsorbent and catalyst. However, based on the preparation methods and the nature of pollutants to be decomposed, different behaviors have been reported.[34,36–40] Some studies have stated that WO_3 doping boosted TiO_2 photocatalytic activity, whereas others reported that it had the reverse effect. Various factors, such as the nature of the dopants and their concentrations, the nature of pollutants, the intensity of light and irradiation time, dissolved oxygen concentration, reaction temperature, pH, surface area, the quantity of catalyst, and the surface morphology of the catalysts,[41] are now considered to have an impact on photocatalytic decomposition. For effective photocatalysts, WO_3/TiO_2 core–shell nanorods were developed.[42,43] Mixed WO_3/TiO_2 composites were utilized.[27,36,40,44–48] However, the comparative study among the core–shell and co-mixed structures, and the effects of structures on reaction mechanisms were not strongly reported. Therefore, we focused on the structural dependence for the dye decomposition.

During the photodecomposition process, adsorption of target compounds is a key first step to be considered.[49–51] In this study, cationic and anionic dyes (MB^+ and MO^-) were used to analyze the adsorption process of target compounds on the surface of WO_3-loaded TiO_2. Then, 3 different types of WO_3–TiO_2 nanocomposites (a mixture of TiO_2 and WO_3 formed by the sol–gel reaction and core–shell structures of $TiO_2@WO_3$ and $WO_3@TiO_2$ prepared by a hydrothermal method) were examined as photocatalysts, in addition to the single-component photocatalysts (TiO_2 and WO_3). The photodegradation of model target compounds was analyzed in terms of both the adsorption kinetics and reaction mechanism. The results can help guide the further design of photocatalysts consisting of semiconductor nanocomposites.

2. Experimental section

2.1 Materials

Titanium(IV) isopropoxide (TTIP, ACROS ORGANICS, CHINA), isopropanol (≥99.8% (GC), Honeywell|Riedel-de Haën™, France), sodium tungstate oxide dihydrate ($Na_2WO_4 \cdot 2H_2O$, 99.0–101.0%, Thermo Fisher Scientific.), ethanol (≥99.9%, Honeywell|Fluka™, Germany), nitric acid (65% w/w), hydrochloric acid (37%, reagent grade), ethylene glycol (99.5%,

ACROS ORGANICS), methylene blue (ACROS ORGANICS, INDIA), and methyl orange (ACROS ORGANICS, INDIA) were used without further purification. *Para*-benzoquinone (*p*-BQ) and ethylenediaminetetraacetic acid disodium salt (Na_2-EDTA) were purchased from Sigma-Aldrich and Fisher Chemical, respectively. Ultrapure water (resistivity of 18.2 mΩ cm, Yamato, Japan) was used throughout the experiments.

2.2 Sol–gel synthesis of TiO_2 nanoparticles

The TiO_2 nanoparticles were prepared *via* a sol–gel approach.[52] First, 6.0 mL of TTIP was mixed with 11.6 mL of isopropanol. The mixture was vigorously stirred for 1 h, and 14.6 mL of water was added with vigorous stirring. After aging for 24 h, the white precipitate that formed was filtered and thoroughly washed with water. Then, the residue was dried at 80 °C for 12 h and calcined at 450 °C for 2 h. The obtained white mass was ground into a powder with a mortar and pestle.

2.3 Hydrothermal synthesis of TiO_2 nanoparticles

For comparison, TiO_2 nanoparticles were synthesized by a hydrothermal method.[53] First, 5.9 mL of TTIP was dissolved in 9.0 mL of ethylene glycol and stirred for 2 h. Then, the solution was transferred into a Teflon-lined autoclave, and 30.3 mL of water was added. The white slurry formed was heated at 220 °C for 6 h, and the resulting white precipitate was washed three times with water and twice with ethanol using centrifugation. Then, the white paste was dried at 80 °C for 12 h and calcined at 450 °C for 2 h. The obtained white mass was ground to a powder with a mortar and pestle. This powder was labeled hyd-TiO_2.

2.4 Synthesis of WO_3 nanoparticles by the sol–gel method

The sol–gel procedure for WO_3 synthesis was adapted from a previous report.[23] A powder of $Na_2WO_4 \cdot 2H_2O$ (1.0 g) was dissolved in 15 mL of water with stirring. To the solution, 7 mL of 1.0 M HCl was slowly added under vigorous stirring. Then, the obtained light yellowish solution was heated to 80 °C for 1 h. After the suspension was cooled to ambient temperature, the light yellowish precipitate was separated using centrifugation and washed three times with water to remove residual NaCl and HCl. Then, the yellow paste was dried at 80 °C for 12 h and ground into a powder with a mortar and pestle.

2.5 Hydrothermal synthesis of WO_3 nanoparticles

WO_3 nanoparticles were also prepared by a hydrothermal method. A powder of $Na_2WO_4 \cdot 2H_2O$ (2.0 g) was dissolved in 30.0 mL of water. Then, 10 mL of 5 N HNO_3 was added to the solution with vigorous stirring at ambient temperature. The mixture was moved to an autoclave and heated to 220 °C for 6 h. After the mixture was cooled to room temperature, the precipitates were collected by centrifugation, washed 3 times with water followed by ethanol, and dried at 80 °C for 12 h. A yellowish mass was obtained after calcination at 450 °C for 2 h and was ground to a powder with a mortar and pestle. This powder was labeled hyd-WO_3.

2.6   Sol–gel synthesis of WO₃/TiO₂ nanocomposites

Coprecipitation of WO_3 and TiO_2 was carried out for the preparation of the WO_3/TiO_2 nanocomposites. First, 6.0 mL of TTIP was mixed with 11.6 mL of isopropanol, and the mixture was vigorously stirred for 1 h. To control the ratio of WO_3 in the nanocomposites, a powder of $Na_2WO_4 \cdot 2H_2O$ (0.243 g for 5 wt%, 0.401 g for 8 wt%, and 0.512 g for 10 wt%) was dissolved in 14.6 mL of water and added to the TTIP solution with vigorous stirring. After the mixture was aged for 24 h, the precipitate was filtered and washed 3 times with water followed by ethyl alcohol. Finally, nanocomposites were obtained after drying at 80 °C for 12 h and calcination at 450 °C for 4 h, followed by crushing in a mortar. The single-component metal oxides (TiO_2 and WO_3) were denoted sol-TiO_2 and sol-WO_3, respectively.

2.7   Synthesis of core–shell TiO₂@WO₃

The core–shell nanocomposite $TiO_2@WO_3$ was produced with a hydrothermal method.[54] The hydrothermally synthesized TiO_2 (hereafter, called hyd-TiO_2, 632.5 mg) was dispersed in a solution of $Na_2WO_4 \cdot 2H_2O$ (100 mg of $Na_2WO_4 \cdot 2H_2O$ dissolved in 30 mL of water) with stirring for 60 min; the final mass ratio of $TiO_2 : WO_3 = 9 : 1$. The resulting white suspension was treated with dropwise additions of 5 N HNO_3 with vigorous stirring. Then, the suspension was transferred to a 50 mL Teflon-lined autoclave and heated at 220 °C for 6 h. The precipitate was washed using water and ethanol by centrifugation and dried at 80 °C for 12 h. Then, the $TiO_2@WO_3$ composite was obtained after calcination in air at 450 °C for 2 h, followed by crushing in a mortar.

2.8   Synthesis of core–shell WO₃@TiO₂

The reverse core–shell structure of $TiO_2@WO_3$ was also synthesized. First, 2.4 mL of TTIP and 10 mL of ethylene glycol were mixed and stirred for 2 h at ambient temperature. Next, a suspension of WO_3 was prepared by sonicating 70.3 mg of hyd-WO_3 in 28.9 mL of water for 60 min. These solutions and suspensions were mixed in a 50 mL Teflon-lined autoclave to make the final mass ratio of $TiO_2 : WO_3$ 9 : 1. Then, the obtained yellowish to white gel was heated at 220 °C for 6 h. After cooling, the product was washed using water and ethanol by centrifugation and dried for 12 h at 80 °C. Finally, a yellowish to white mass was calcined at 450 °C for 2 h, followed by crushing in a mortar.

2.9   Characterization

The morphology of the nanocomposites was observed with a field-emission scanning electron microscope (FESEM, JSM-7900F, JEOL LTD, Japan) at an acceleration voltage of 15 kV. Before SEM inspection, all samples were sputtered with Pt using a JEC-3000FC Auto Fine Coater (JEOL LTD, Japan). Elemental analysis was carried out using an energy dispersive X-ray (EDX) spectrometer equipped with an FESEM. The crystal structures were characterized using XRD (X-ray diffractometer, 2nd Gen D2 PHASER, Bruker) with Cu Kα radiation at an acceleration voltage of 30 kV and a current of 10 mA within the 2θ range from

10° to 80°. The presence and oxidation state of each element in the nanocomposites were determined using X-ray photoelectron spectroscopy (XPS, ULVAC PHI 5000 Versa Probe) using Al Kα monochromator (1486.6 eV) X-rays. A UV-VIS spectrophotometer (V-670, JASCO, Japan) was used to measure the absorption spectra of the organic dye solutions. UV-VIS diffuse reflectance spectroscopy (DRS) was conducted at a 45° irradiation angle with a UV-VIS spectrometer (SEC2000, ALS, Japan) with a light source from Ocean Optics DH-2000-BAL.

2.10   Adsorption analyses

The adsorption properties of the nanocomposites were analyzed by a batch process. A powder of the nanocomposite (4 mg) was dispersed in dye solutions (65 mL) of varying concentrations (1.0, 2.0, 4.0, 6.0, and 8.0 mg L^{-1}). Then, the suspension was stirred at ambient temperature under dark conditions for 30 min to achieve adsorption equilibrium. After adsorption, the suspension was separated into a supernatant and precipitate (the nanocomposite absorbed some of the dye) by centrifugation (for 60 s at 6000 rpm at neutral pH and room temperature), and the free dye concentration was determined from the UV-VIS absorption spectra of the supernatant: absorbance at the λ_{max} of the dye (662 nm for MB^+ and 464 nm for MO^-) was compared to that of the original dye solution (see Fig. S1 in the ESI†). The quantity of dye adsorbed on each nanocomposite (q_e) in mg g^{-1} was estimated according to eqn (1).

$$q_e = \frac{(C_0 - C_e) \times V}{m} \tag{1}$$

where C_0 and C_e are the dye concentrations (ppm) before and after adsorption from the solution, V is the volume (L) of the dye solution (=0.065), and m is the mass (g) of the nanocomposite. The theoretical curves were fitted to data plots by the software (ORIGIN 2018) with R^2 values.

2.11   Photocatalytic activity analyses

To evaluate photocatalytic activity, a powder of the nanocomposite (4 mg) was dispersed in 65 mL of a dye solution (2.0 ppm) under continuous stirring at room temperature. After 30 min in the dark, the dispersion was irradiated at 365 nm using an LED light source (LLS-365, Ocean Optics, Tokyo, Japan). Then, 2.0 mL of the dispersion was sampled at 10 min intervals and centrifuged for solid–liquid separation. The dye concentration of the supernatant was then measured at the λ_{max} of the dye. To confirm the reactive species, scavenger solutions (1 ppm of p-BQ, Na_2-EDTA, and IPA) were used to scavenge superoxide radicals, holes, and hydroxyl radicals, respectively. The quantity (Q_d) of dye degraded was estimated in mg g^{-1} by subtracting the free dye concentration at time t (C_t, mg L^{-1}) from the dye concentration before light irradiation. Then, the decomposed quantity of the dye was calculated using eqn (2).

$$Q_d = \frac{(C_e - C_t) \times V}{m} \tag{2}$$

where V is the volume (L) of dye solution at the sampling time, and m is the mass (g) of catalysts.

The dye decomposition efficiency (%D) was also assessed using eqn (3).

$$\%D = \frac{(C_e - C_t)}{C_e} \times 100\% \quad (3)$$

The decomposition kinetics were analyzed as pseudo first-order reactions using the Langmuir–Hinshelwood model[55] and were plotted as $\ln(C_0/C_t)$ vs. the photoirradiation time (t, min), as in eqn (4).

$$\ln\frac{C_0}{C_t} = K_a t \quad (4)$$

where K_a is the degradation rate constant (min^{-1}). The theoretical curves were fitted to data plots by the software (ORIGIN 2018) with R^2 values.

3. Results and discussion

3.1 Structure of nanocomposites

The XRD patterns for the obtained nanocomposites are shown in Fig. 1. The sol-TiO$_2$ showed peaks at $2\theta = 25.4°$, $38.0°$, $48.1°$, $54.1°$, $55.2°$, $62.8°$, and $75.3°$, which correspond to the (101), (004), (200), (105), (211), (204), and (215) planes of the hexagonal crystal lattice of the TiO$_2$ anatase phase (JCPDS PDF 89-4921), while the sole diffraction peak at $31.0°$ (marked by an asterisk in Fig. 1A(a)) corresponds to the (121) plane of the orthorhombic crystal lattice of brookite phase of TiO$_2$ (JCPDS PDF 29-1360).

The sol-WO$_3$ showed peaks at $2\theta = 14.2°$, $23.1°$, $24.5°$, $28.4°$, $33.8°$, $36.8°$, $50.0°$, $52.3°$, $55.6°$, $58.2°$, and $63.5°$, which were, respectively assigned to the (100), (002), (110), (200), (112), (202), (220), (213), (222), (312), and (402) planes of the hexagonal crystal lattice of WO$_3$ (JCPDS PDF 85-2459). In the 5 wt% WO$_3$/TiO$_2$ nanocomposite, the presence of WO$_3$ was not well confirmed, which was probably due to the low concentration of WO$_3$.

The 8 wt% and 10 wt% WO$_3$/TiO$_2$ nanocomposites showed diffraction peaks for WO$_3$; however, some peaks (marked by ◆) significantly shifted from those of sol-WO$_3$ and were identified as a monoclinic phase of the tungsten oxide W$_{18}$O$_{49}$ (JCPDS PDF 05-0392). In contrast, the XRD peaks for TiO$_2$ in these nanocomposites appeared at the same positions as those in sol-TiO$_2$. These results suggested that the W ions were minor components in the nanocomposites (only 8 wt% and 10 wt%) and formed new crystal structures under the influence of Ti compounds.

The hyd-TiO$_2$ exhibited diffraction peaks at $2\theta = 25.4°$, $38.0°$, $48.1°$, $54.1°$, $55.2°$, $62.8°$, and $75.2°$, which correspond to the (101), (112), (200), (105), (211), (204), and (215) planes, respectively (Fig. 1B(a)). All the observed diffraction peaks belonged to anatase TiO$_2$ (JCPDS PDF 89-4921), and the peak for the (121) plane of the brookite phase was not observed. The hyd-WO$_3$ showed diffraction patterns at $2\theta = 23.4°$, $23.9°$, $24.6°$, $26.8°$, $28.9°$, $33.5°$, $34.4°$, $35.7°$, $42.1°$, $47.5°$, $48.5°$, $50.1°$, $53.6°$, $56.1°$, $62.4°$, and $76.6°$ corresponding to the (001), (020), (200), ($\bar{1}$20), ($\bar{1}$11), ($\bar{2}$01), (220), (121), (221), (002), (040), (140), (022), ($\bar{4}$20), ($\bar{3}$40), and (422) planes, respectively, which indicated a monoclinic WO$_3$ crystal (JCPDS PDF 05-0363). Thus, in contrast with the sol–gel method, the hydrothermal synthesis process could be adjusted to result in the monoclinic crystalline phase. Both the hydrothermally produced core–shell TiO$_2$@WO$_3$ and WO$_3$@TiO$_2$ showed diffraction peaks for anatase TiO$_2$, and peaks for WO$_3$ were not observed. The weakness of the XRD peak intensity of WO$_3$ suggested that the WO$_3$ shell was very thin and that the WO$_3$ core was covered with a thick TiO$_2$ shell.

The crystallite size (D) was computed from Debye–Scherrer's equation (eqn (5)).[52]

$$D = \frac{K\lambda}{\beta \cos\theta} \quad (5)$$

where K is the Scherrer constant (0.9), λ is the wavelength of the X-ray for CuKα (1.54184 Å), β is the FWHM of the peak in

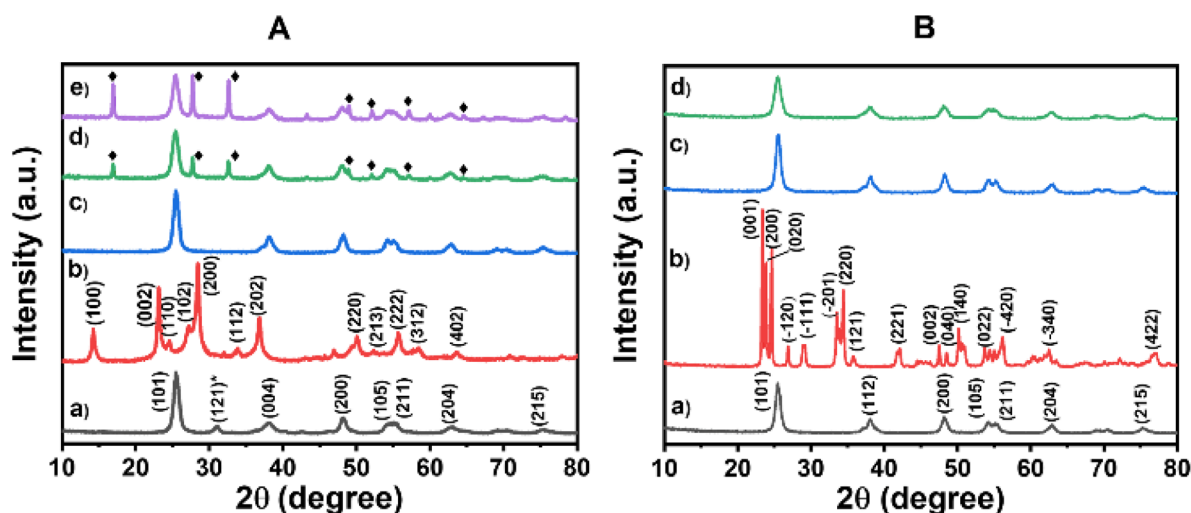

Fig. 1 XRD results of (A) the sol−gel prepared (a) sol-TiO$_2$, (b) sol-WO$_3$, (c−e) 5 wt%, 8 wt%, and 10 wt% WO$_3$/TiO$_2$; (B) hydrothermally prepared (a) hyd-TiO$_2$, (b) hyd-WO$_3$, (c) TiO$_2$@WO$_3$ and (d) WO$_3$@TiO$_2$.

radians, and θ is the diffraction angle in radians. The estimated average crystallite sizes of sol-TiO_2 (from peaks at $2\theta = 25.4°$, $31.0°$, $38.0°$, $48.1°$, $54.1°$, $55.1°$, and $62.8°$), sol-WO_3 (using all observed peaks), 5 wt% (from peaks at $2\theta = 25.5°$, $38.1°$, $48.2°$, $54.3°$, and $62.9°$), 8 wt% (from peaks at $2\theta = 16.9°$, $25.4°$, $27.7°$, $32.6°$, $38.0°$, and $48.0°$), and 10 wt% WO_3/TiO_2 (from peaks at $2\theta = 16.9°$, $25.5°$, $27.7°$, $32.6°$, $38.0°$, and $48.1°$) nanoparticles were 7.9 nm, 13.6 nm, 8.7 nm (for TiO_2), 14.7 nm (for TiO_2), and 20.1 nm (for TiO_2), respectively. For the hydrothermally synthesized materials, the observed average sizes of hyd-TiO_2 (from peaks at $2\theta = 25.4°$, $38.0°$, $48.1°$, $54.1°$, $55.2°$, and $62.8°$), hyd-WO_3 (using all diffraction peaks), $TiO_2@WO_3$ (from peaks at $2\theta = 25.5°$, $38.0°$, $48.3°$, $54.2°$, $55.3°$, and $62.9°$), and $WO_3@TiO_2$ (from peaks at $2\theta = 25.5°$, $38.0°$, $48.2°$, $54.2°$, $55.3°$, and $62.8°$) were 9.4 nm, 24.1 nm, 9.6 nm (for TiO_2), and 7.4 nm (for TiO_2), respectively. These results demonstrated that the preparation methods and the mixing ratios altered the crystallite sizes. The hydrothermal process could lead to larger crystals in TiO_2 and WO_3 than the sol–gel process, and a higher content of tungsten could result in larger crystals of TiO_2.

3.2 Optical properties of nanocomposites

The optical properties of the nanomaterials were studied with UV-VIS DRS (Fig. 2). Both sol-TiO_2 and hyd-TiO_2 exhibited high reflectance in the range greater than 350 nm, and with the addition of WO_3, the material reflectance decreased in this range (Fig. 2a and b). The reflectance of $TiO_2@WO_3$ was slightly lower than that of $WO_3@TiO_2$. Since WO_3 can absorb light of wavelengths shorter than 500 nm,[31,32,56] the lower reflectance could be partially explained by the photoexcitation of WO_3 in the short wavelength region. At longer wavelengths (>500 nm), the WO_3 and WO_3–TiO_2 nanocomposites showed lower reflectance than TiO_2. This could be explained by the existence of WO_x ($2 < x < 3$), which could absorb light, and by the structures of the film specimens.[32]

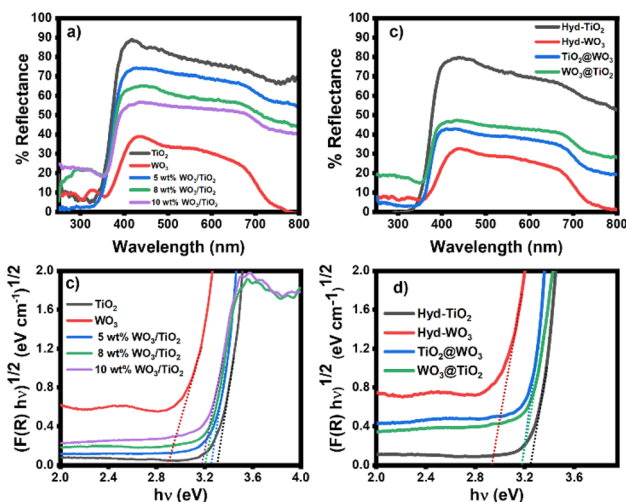

Fig. 2 (a and b) UV-VIS DRS spectra of the sol–gel and hydrothermally prepared samples and (c and d) bandgap energy analyses of nanocomposites.

The bandgap energy (E_g) of the metal oxides was determined using the Kubelka–Munk function and Tauc plots (Fig. 2c and d).[57] The E_g values were evaluated from the intercepts of the energy axis. The E_g values of TiO_2 and WO_3 were 3.2–3.3 eV and 2.8–2.9 eV, respectively, and compared with the materials prepared by the sol–gel method, hyd-TiO_2 and hyd-WO_3 showed slightly decreased E_g values, which was attributed to their larger crystal sizes.[58] The nanocomposites had E_g values between those of TiO_2 and WO_3: the sol–gel method resulted in E_g values of 3.25, 3.20, and 3.18 eV, corresponding to 5 wt%, 8 wt%, and 10 wt% WO_3/TiO_2, respectively (Fig. 2c). For core–shell $TiO_2@WO_3$ and $WO_3@TiO_2$, the E_g values were nearly identical at 3.18 eV (Fig. 2d). The intermediate E_g values (in between those of TiO_2 and WO_3) suggested interactions between TiO_2 and WO_3 in both the mixed and core–shell structures. Mutual effects in the nanocomposites can decrease the electron–hole recombination rate at the interface for TiO_2 and WO_3.

3.3 Morphological analyses of nanocomposites

The morphologies of the nanocomposites were observed using SEM (Fig. 3). The materials prepared by the sol–gel method consisted of aggregated spherical nanoparticles, and no systematic difference was observed. The hyd-TiO_2 consisted of aggregates of small nanoparticles, while the hyd-WO_3 showed large crystalline structures, as indicated by the XRD analysis. However, the surface morphology of the core–shell nanocomposites did not show a significant difference. This suggests that the WO_3 shell in the $TiO_2@WO_3$ nanocomposite could not develop large crystals because it grew from small TiO_2 particles.

The EDX results identified the presence of titanium (Ti) and oxygen (O) in TiO_2, tungsten (W) and O in the WO_3 oxide, as well as the presence of Ti, W, and O in the nanocomposites obtained from both the sol–gel and hydrothermal methods. The weight ratios of W to Ti in the sol–gel and core–shell nanocomposites are shown in Table 1. The experimentally obtained W ratios in the nanocomposites prepared by the sol–gel method were significantly higher than the corresponding theoretical values, which suggests that a significant amount of Ti compounds were not recovered during the preparation process relative to the W compounds. In contrast, the hydrothermally prepared nanocomposites showed W ratios that agreed well with the theoretical values. This suggests that the hydrothermal process immobilized the Ti compounds in the nanocomposites during crystal growth. The higher W ratio in $TiO_2@WO_3$ relative to $WO_3@TiO_2$ could be explained by the fact that the TiO_2 core was covered by the WO_3 shell.

3.4 Chemical states of nanocomposites

XPS analysis was conducted to determine the chemical states of the sol–gel synthesized and hydrothermally synthesized nanocomposites (Fig. 4). The peak parameters are shown in the ESI (Tables S1–S3 in the ESI†). The survey XPS spectrum showed the existence of oxygen (O 1s), titanium (Ti 2p), tungsten (W 4p and 4f), and carbon (C 1s) on the material surfaces.[44] The carbon contribution originated from the substrate and was used to calibrate the binding energy.
Fig. 3 SEM images (upper) and EDX (lower) results for sol−gel (a−e) and hydrothermally (f−i) synthesized materials.

Table 1 Weight ratios of elements in the nanocomposites as analyzed by the EDX and XPS methods

Nanocomposite	Synthesis method	EDS result	XPS result	Theoretical ratio
TiO_2 (Ti : O)	Sol–gel process	1.3		1.4
WO_3 (W : O)		4.2		3.8
5 wt% WO_3/ TiO_2 (W : Ti)		0.15	0.22	0.07
8 wt% WO_3/ TiO_2 (W : Ti)		0.21	0.28	0.12
10 wt% WO_3/ TiO_2 (W : Ti)		0.23	0.33	0.15
TiO_2 (Ti : O)	Hydrothermal process	1.1		1.4
WO_3 (W : O)		3.8		3.8
$TiO_2@WO_3$ (W : Ti)		0.18	0.26	0.15
$WO_3@TiO_2$ (W : Ti)		0.16	0.20	0.15

The deconvoluted XPS spectra of O 1s showed three distinct peaks in all specimens. The peak at the lowest binding energy (530.4 eV for 5 wt%, 529.7 eV for 8 wt%, 530.0 eV for 10 wt% WO_3/TiO_2, 530.0 eV for $TiO_2@WO_3$, and 530.0 eV for $WO_3@TiO_2$) was attributed to the lattice oxygen (O^{2-}) of O–Ti bonds in TiO_2 and O–W bonds in WO_3,[40] whereas the middle peaks (531.8 eV for 5 wt%, 530.9 eV for 8 wt%, 531.3 eV for 10 wt% WO_3/TiO_2, 531.0 eV for $TiO_2@WO_3$, and 531.3 eV for $WO_3@TiO_2$) could be attributed to substoichiometric WO_x ($2 < x < 3$)[40,59,60] or hydroxide groups adsorbed on the oxide surface as W–O–H and Ti–O–H,[40] which correspond to oxygen vacancies. To compensate for the charge imbalance in the oxygen-deficient

state, OH groups were bound to the metal cations. Thus, the density of oxygen vacancies is indicated by the intensity of these mid-binding energy peaks.[61] The third peaks, which were located at the highest binding energy (533.4 eV for 5 wt%, 532.8 eV for 8 wt%, 533.0 eV for 10 wt% WO_3/TiO_2, 532.7 eV for $TiO_2@WO_3$, and 532.5 eV for $WO_3@TiO_2$), could be attributed to contamination from oxygen-containing hydrocarbons,[40] H_2O,[59] or surface-adsorbed O_2.[62] The peak areas (%) of the mid-binding energy peaks ranged from 11% to 18%, which indicated that significant numbers of oxygen vacancies were formed in the nanocomposites, as suggested from the UV-VIS DRS spectra (Fig. 2). These oxygen vacancies could extend the lifetime of the charge carriers and increase the photocatalytic activity of these catalysts.

The presence of only one Ti 2p doublet for Ti $2p_{3/2}$ and Ti $2p_{1/2}$ indicated that all Ti atoms shared the same oxidation state (Ti^{4+}).[40] The binding energies of Ti $2p_{3/2}$ for the sol–gel synthesized nanocomposites of 5 wt%, 8 wt%, and 10 wt% WO_3/TiO_2 were 459.1 eV, 458.4 eV, and 458.9 eV, respectively, while they were 459.3 eV and 458.7 eV for the hydrothermally prepared $TiO_2@WO_3$ and $WO_3@TiO_2$, respectively. The binding energies of Ti $2p_{1/2}$ for 5 wt%, 8 wt%, and 10 wt% WO_3/TiO_2 were 464.8 eV, 464.0 eV, and 464.6 eV, respectively, whereas they were 464.9 eV and 464.4 eV for $TiO_2@WO_3$ and $WO_3@TiO_2$, respectively. The minor change in energy in the nanocomposites could be attributed to the interactions of W–O–Ti bonds; however, the changes were not significantly or systematic.

The peaks of W 4f appeared as two doublets. The first pair (peaks 1 and 3) might have arisen from W^{5+} in substoichiometric WO_x ($2 < x < 3$),[40] which corresponds to an oxygen
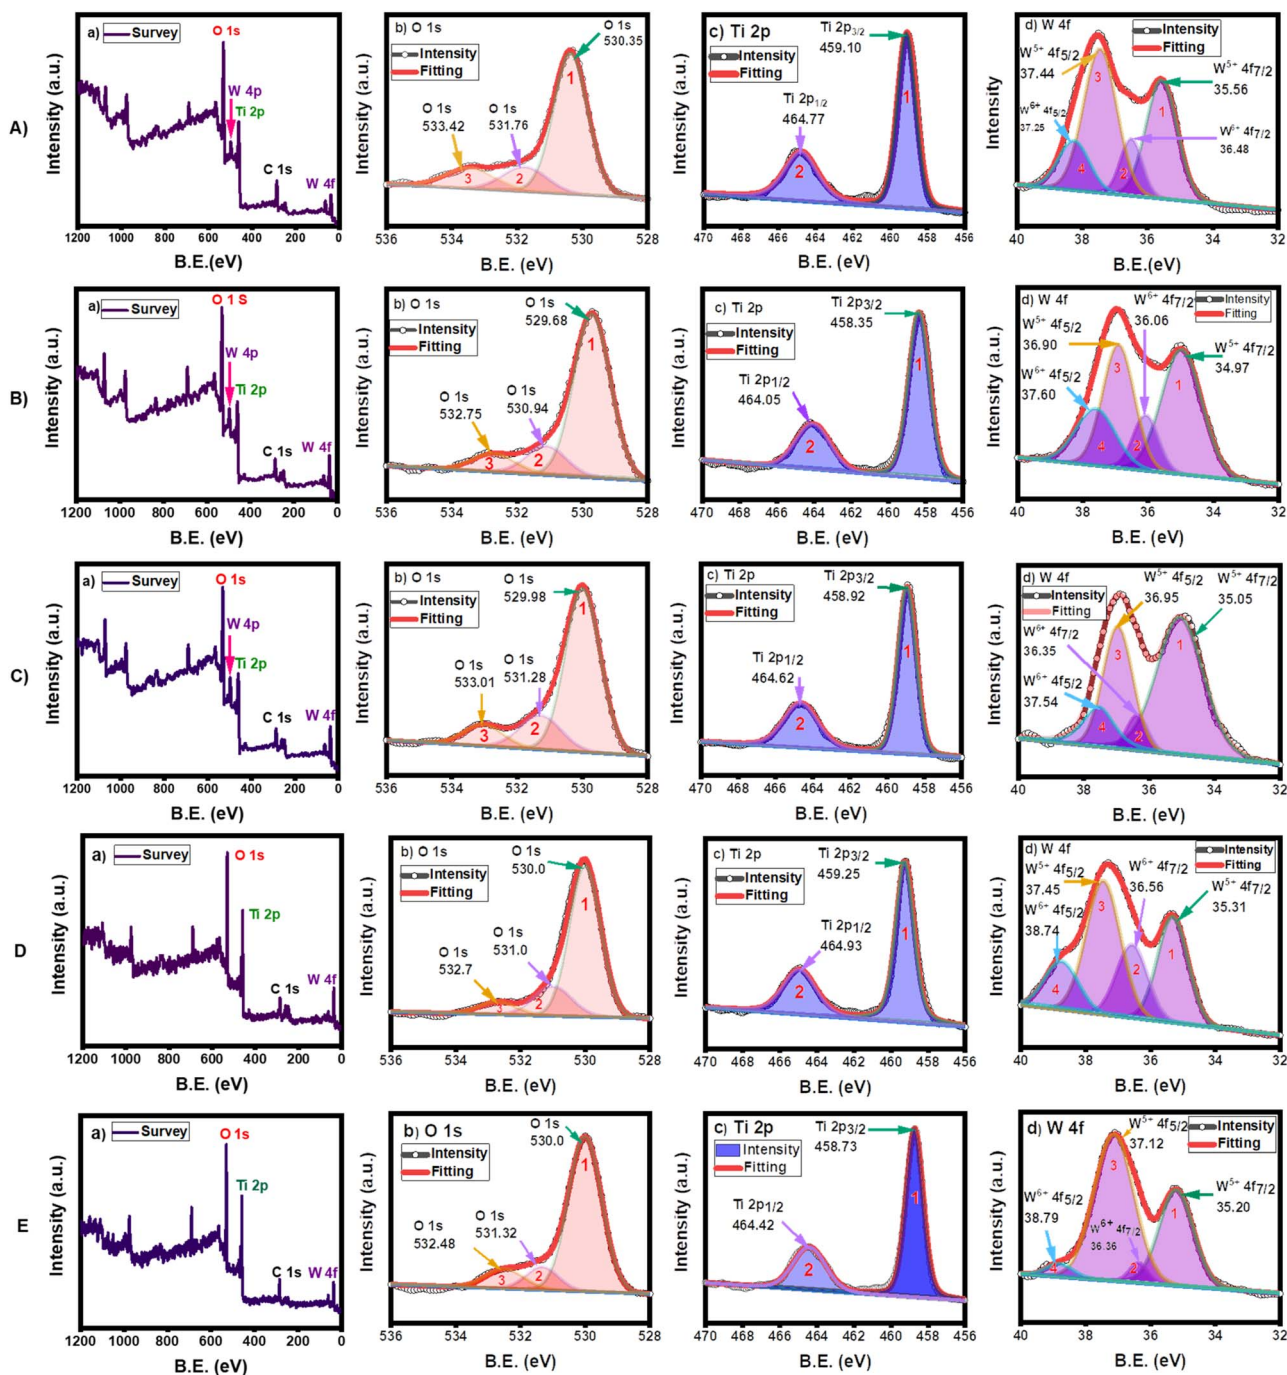

Fig. 4 XPS survey and high-resolution spectra of the sol−gel method: (A) 5 wt% WO_3/TiO_2, (B) 8 wt% WO_3/TiO_2 and (C) 10 wt% WO_3/TiO_2, and core−shell method: (D) $TiO_2@WO_3$ and (E) $WO_3@TiO_2$ with (a) survey, (b) O 1s, (c) Ti 2p, and (d) W 4f.

vacancy. The second pair (peaks 2 and 4) was ascribed to W^{6+} in WO_3.[61] The ratio of W 4f to Ti 2p determined from the peak area in the nanocomposites (Tables 1 and S3 in the ESI†) was 0.22, 0.28, 0.33, 0.26, and 0.20 for 5 wt%, 8 wt%, 10 wt% WO_3/TiO_2, $TiO_2@WO_3$, and $WO_3@TiO_2$, respectively. These values were larger than those obtained by the EDX method, which suggested that the W component existed more on the surface than in the bulk phase of the nanocomposites. The detection of W in the core−shell $WO_3@TiO_2$ nanocomposite and Ti in the core−shell

$TiO_2@WO_3$ nanocomposite suggested that the core–shell structures were imperfect, although the compositions were controlled to an extent.

Fig. 5 shows the ratios of the %area of XPS peaks for each element in the nanocomposites. The changes in the %area of both W^{5+} and W^{6+} in the nanocomposites indicated the high ratios of W^{5+} on the surface of the nanocomposites. The existence of W^{5+} can extend the light absorption range, and W^{5+} can provide an electron to molecular oxygen to form superoxide
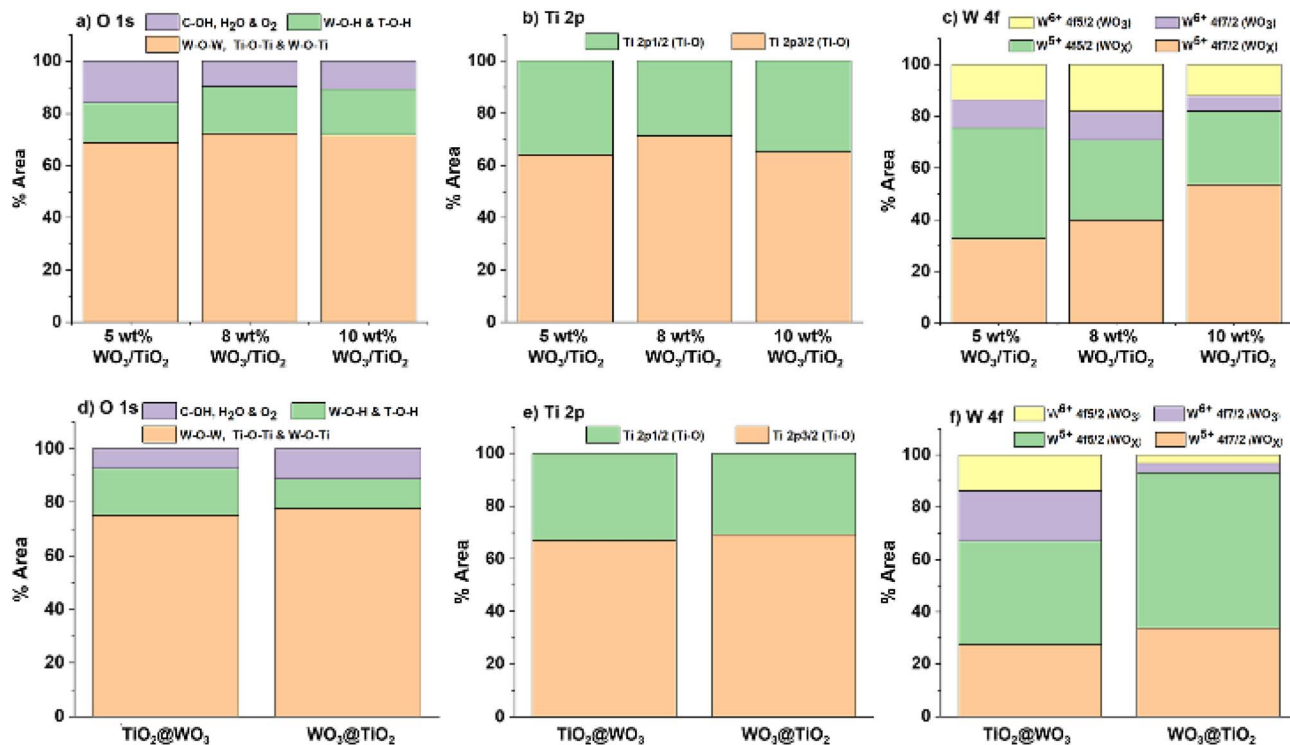

Fig. 5 Ratios of chemical states for nanocomposites prepared by the sol–gel method ((a) O 1s, (b) Ti 2p, and (c) W 4f) and the core–shell method ((d) O 1s, (e) Ti 2p, and (f) W 4f).

radicals ($O_2^{\bullet-}$) under light irradiation. Therefore, a higher ratio of W^{5+} on the surface could be an advantage for photocatalysis. On the other hand, the low positive charge on the surface induces low attractive interactions with negatively charged dyes, which is disadvantageous for photocatalysis.

3.5 Adsorption process of dyes

The adsorption behaviors of cationic MB^+ and anionic MO^- onto the nanocomposites were investigated in the range of 1–8 mg L^{-1} initial dye concentrations (the data and the fitting curves are shown in Fig. S2 and S3 in the ESI†). The adsorption performances of the pure oxides and composite materials were evaluated by the Langmuir isotherm adsorption models.[63–65] The Langmuir adsorption isotherms of the dyes are depicted in eqn (6) below:

$$q_e = \frac{q_m K_L C_e}{1 + K_L C_e} \tag{6}$$

where q_e is the equilibrium adsorption capacity (mg g^{-1}) at a specific dye concentration, q_m is the adsorption maximum capacity of adsorbents (mg g^{-1}) when the concentration of dye is sufficiently high, K_L is the Langmuir adsorption constant (L mol^{-1}), and C_e is the equilibrium free dye concentration (mg L^{-1}). The experimental values of q_m and K_L were fitted with the nonlinear fitted Langmuir isotherm adsorption curves. The fitting equations are given in Table 2.

The adsorption of MB^+ from different initial concentrations was explored at pH 7.4 without pH control. The adsorption of different MO^- initial concentrations was probed at pH 6.7

without pH control. As observed in Fig. 6a, the amount of adsorbed MB^+ (q_e) rose as the initial concentration increased and became saturated at high concentrations (6–8 ppm). The amount of adsorbed MO^- (q_e) also increased as the initial concentration increased in the low concentration range (1–2 ppm) and became almost saturated at higher concentrations (2–8 ppm), except for a slight increase and decline for TiO$_2$ (Fig. 6b). For the adsorption of MB^+, the Langmuir model fitted well ($R^2 > 0.9$), indicating that the adsorption of MB^+ on the nanocomposites followed a monolayer adsorption process. However, the Langmuir model did not yield good fits for adsorption of MO^- (R^2 was in the range of 0.3490 to 0.8428), which could be explained by the low adsorption amounts of MO^- (two orders of magnitude smaller than those of MB^+, except for TiO$_2$), leading to large errors.

Then, dye adsorption on the nanocomposites was analyzed with eqn (7).[5]

$$\Delta G = -RT \ln K_L \tag{7}$$

where ΔG is the Gibbs free energy change, R is the gas constant (8.314 J mol^{-1} K^{-1}), and T is the absolute temperature (298 K). The large ΔG of MB^+ adsorption could be due to the electrostatic interactions between the metal oxides (negatively charged) and the cationic dye (Table 2). In general, K_L and ΔG increased as the tungsten component increased, which suggested that WO$_3$ promoted dye adsorption. According to the reported zeta potential measurements of TiO$_2$, the surface charge of TiO$_2$ is positive over the pH range of 2.50 to 7.35,[66] and therefore, the

Table 2 The Langmuir adsorption model parameters for the MB^+ and MO^- adsorption process and the Gibbs free energy change in the adsorption process

surface of TiO$_2$ in this study (pH 7.4) was slightly negatively charged. In contrast, the neutral point of WO$_3$ is pH 1.9,[67] and therefore, a higher proportion of tungsten resulted in a more negative charge on the surface. The difference in the K_L and the ΔG of the core–shell TiO$_2$@WO$_3$ and WO$_3$@TiO$_2$ nanocomposites demonstrated the enhanced adsorption of MB$^+$ on WO$_3$. However, the nanocomposites provided a higher adsorption capacity than WO$_3$, despite their lower interactions with MB$^+$: this could be explained by the large surface area of the nanocomposites. A comparison of preparation methods shows that sol-TiO$_2$ and sol-WO$_3$ resulted in stronger interactions (higher K_L and ΔG) but lower adsorption capacities than hyd-TiO$_2$ and hyd-WO$_3$, respectively. As the XRD analysis indicated, the sol–gel method provided smaller crystal grains; however, these crystals were aggregated, and the surface area available for adsorption was likely to be limited (Fig. 1 and 3). The stronger interaction of the sol-metal oxides with MB$^+$ could be due to the defects on the surface of the sol-metal oxides, which served as pockets. Among the nanocomposites, the hydrothermally prepared TiO$_2$@WO$_3$ provided a higher adsorption capacity, although the K_L and ΔG were similar to those for the 5 wt% WO$_3$/TiO$_2$ nanocomposite, which had a lower W-component on its surface (Table 1). Therefore, in terms of availability and efficiency, the W component was more effectively utilized for adsorbing MB$^+$ in the nanocomposites prepared by the sol–gel method than those prepared by the hydrothermal method. The advantage of TiO$_2$@WO$_3$ was its large surface area, which allowed for a high adsorption capacity, and this was achieved by the secondary deposition of WO$_3$.

In terms of the adsorption behavior of MO$^-$, it should be noted that the ΔG of MO$^-$ adsorption could not be precisely estimated because of the poor correlation coefficients (<0.9) obtained. However, TiO$_2$ showed a higher adsorption capacity than the others for MO$^-$ adsorption, and the nanocomposites

also exhibited stronger interactions due to the higher compositional ratio of titanium, as expected from the surface charge of the nanocomposites. The K_L and ΔG of TiO$_2$ for MO$^-$ were comparable to those for MB$^+$ adsorption. This finding suggests that the TiO$_2$ nanoparticles provided binding sites for both the cationic and anionic dyes. The lower adsorption capacity of hyd-TiO$_2$ for MO$^-$ compared with MB$^+$ suggests that the number of cationic binding sites was lower in hyd-TiO$_2$, which could be due to the difference in crystallinity and the crystal structures shown by the XRD measurements (Fig. 1). The tungsten enhanced the adsorption of MB$^+$ and weakened the adsorption of MO$^-$ on the nanocomposite surfaces.[68] However, the K_L and ΔG values indicated that some nanocomposites also provided effective binding sites for MO$^-$, especially the 5 wt% WO$_3$/TiO$_2$ and WO$_3$@TiO$_2$ nanocomposites.

3.6 Photocatalysis of dyes

The photocatalytic activity of the synthesized materials was evaluated by dye decomposition. The resulting absorption spectra are shown in Fig. S4 and S5 in the ESI.† The decomposition curves and their kinetic analyses for MB$^+$ and MO$^-$ are shown in Fig. 6.

The MB$^+$ was irradiated with UV light in an aqueous solution of pH 7.4. Measurements were also performed under dark conditions, and the decrease in concentration was in the range of 1–8% of the initial concentration, which could have been caused by the disaggregation of the nanocomposites induced by stirring. In the absence of nanocomposite materials, the degradation of MB$^+$ was 14.4% under UV irradiation, which was lower than that in the presence of nanocomposites. Compared with TiO$_2$ and WO$_3$, the nanocomposites exhibited better photocatalytic activity under UV light irradiation. The photocatalytic activity of 8 wt% WO$_3$/TiO$_2$ was highest among the sol–gel nanocomposites, with 94.9% decomposition after 2 h, while

5 wt% WO$_3$/TiO$_2$ achieved the lowest degradation (84.7%) during the same irradiation time. The core–shell TiO$_2$@WO$_3$ demonstrated superior photocatalytic activity, with 95.8% decomposition after 1 h of UV irradiation, while WO$_3$@TiO$_2$ demonstrated lower activity (decomposition of 82.5%) after 2 h than 5 wt% TiO$_2$@WO$_3$. The reaction rates were analyzed as pseudo first-order reactions using eqn (4) and the Langmuir–Hinshelwood model.[65] The rate constant (K_a^*) for each nanocomposite and dye is summarized in Table 3.

These activities were inconsistent with the orders of both the adsorption rate (K_L) and the adsorption capacity (q_m) of the nanocomposites (Table 2). To some extent, the magnitude of the reaction rates could be explained by several factors: (1) the tungsten in the nanocomposites provided higher reaction rates due to its strong interaction with MB$^+$, (2) the absorbance of TiO$_2$ was low at an excitation wavelength of 365 nm, (3) among the sol–gel nanocomposites, the adsorption capacities determined the order of the reaction rates, and (4) TiO$_2$@WO$_3$ showed highest rate constant, which could because it also had the highest adsorption capacity. However, these explanations were not sufficient for explaining the lower rate constant of WO$_3$, which had a high adsorption constant and moderate adsorption capacity. Upon dividing K_a^* by K_L and q_m, WO$_3$ exhibited the lowest rate constant per (adsorption rate x adsorption mass), while that of TiO$_2$@WO$_3$ was the highest, followed by that of hyd-TiO$_2$. Therefore, the photocatalytic activity was not determined only by the adsorption amount and the adsorption rate.

Fig. 7 (a–c) Photocatalytic decomposition of MB$^+$ over core–shell TiO$_2$@WO$_3$, WO$_3$@TiO$_2$, and coprecipitated 8 wt% WO$_3$/TiO$_2$ with various scavengers under UV light irradiation; (d–f) kinetic analysis of MB$^+$ decomposition.

Fig. 8 Dye decomposition mechanism using (A) TiO₂@WO₃, (B) WO₃@TiO₂, and (C) WO₃/TiO₂ nanocomposites.

For comparison, the anionic MO⁻ was also degraded at pH 6.7 under UV light irradiation. The reaction rate was much lower than that of MB⁺, which could be expected from the adsorption parameters discussed above (Table 2). Among the nanocomposites, WO₃@TiO₂ demonstrated the highest efficiency (degradation of ∼6% MO⁻), whereas TiO₂@WO₃ demonstrated the lowest efficiency (degradation of ∼2% MO⁻). The negative surface charge from the tungsten oxides had adverse effects on the photocatalysis of MO⁻. Upon dividing K_a^* by K_L and q_m, the nanocomposites demonstrated a clear tendency: a higher composition of tungsten resulted in a higher rate constant. This could be explained by the stronger light absorption at 365 nm by tungsten components. However, the higher rate constants per (adsorption rate × adsorption mass) of 10 wt% WO₃/TiO₂ and TiO₂@WO₃ suggested that the nanocomposite decomposed MO⁻ more effectively than TiO₂ and WO₃.

Compared with other studies for the MB⁺ degradation performance (Table S4 in the ESI†), the activity of 8 wt% WO₃/TiO₂ was 1.34 times higher than that of 25 wt% mixed WO₃/TiO₂.[46] The activity of the core–shell TiO₂@WO₃ of the current study was 3.59 times higher than that of 36 wt% core–shell WO₃/TiO₂.[43] These results indicate that the large amount of WO₃ is not essential for the effective photocatalyst.

3.7 Dye decomposition mechanism

To study the active species present during photocatalysis with the nanocomposites, dye photocatalysis was analyzed in the presence of active species scavengers. The active species generated by TiO₂ and WO₃ are considered to be superoxide anions (O₂⁻), holes (h⁺), and hydroxyl radicals (HO·), which can be scavenged by p-BQ, Na₂-EDTA, and IPA, respectively.[38,48,69,70] The degradation curves and the kinetic analyses are shown in Fig. 7 and Table 4.

The addition of scavengers decreased the decomposition rate in all cases. These results indicated that hydroxyl radicals were the most active species for all the photocatalysts examined. When IPA was used to quench hydroxyl radicals, the K_a values of the photocatalysts decreased to a similar level (0.70–0.99 × 10⁻² min⁻¹). The activity of TiO₂@WO₃ exhibited the greatest decrease with the use of IPA, and the effect of IPA on WO₃@TiO₂ was the smallest. This suggests that WO₃ on the nanocomposite surface mainly provides hydroxyl radicals as the active species; the OH⁻ groups attached to W⁵⁺/⁶⁺ could be directly oxidized by holes to generate hydroxyl radicals.

A comparison of the effects of p-BQ and Na₂-EDTA show that the K_a of TiO₂@WO₃ decreased more with the addition of Na₂-EDTA than p-BQ, while the 8 wt% WO₃/TiO₂ nanocomposite was similarly quenched by both scavengers. These results suggest that the activity of the core–shell TiO₂@WO₃ depended on the activity of holes more than photoexcited electrons, while the codeposited WO₃/TiO₂ used both to a similar extent. In the reversed structure, the core–shell WO₃@TiO₂ nanocomposite also demonstrated a stronger effect with Na₂-EDTA than p-BQ; however, its activity was much lower than that of TiO₂@WO₃,

and the decrease in the K_a value was not large. The effects of Na_2-EDTA and p-BQ (*i.e.*, the amounts of scavenged holes and electrons) were not greatly different for $WO_3@TiO_2$, and the K_a values became similar to those of 8 wt% WO_3/TiO_2. The weak effects of scavengers on $WO_3@TiO_2$ suggested that the active species (O_2^-, hole, and $HO^•$) were rapidly changed to other species or quenched in the nanocomposite by recombination.

In the core–shell nanocomposites, the photoinduced charges were considered to be adequately separated. Because the conduction band (CB) of TiO_2 has a more negative redox potential (-0.5 V) than the CB of WO_3 ($+0.2$ V), as reported by Escobar *et al.* (2020),[38] the photogenerated electrons in TiO_2 can easily be transferred to WO_3 to reduce W^{6+} to W^{5+}.[48] According to Escobar *et al.* (2020), the valence band (VB) of WO_3 has a more positive redox potential ($+3.1$ V) than the VB of TiO_2 ($+2.8$ V);[38] therefore, the photogenerated h^+ can move from WO_3 to TiO_2 (Fig. 8). This charge separation extended the lifetime of the active species and improved the activity of holes on $TiO_2@WO_3$, while WO_3 rapidly caused recombination and decreased photocatalytic activity, although it had the highest K_L value (Tables 2 and 3). In the codeposited WO_3/TiO_2, similar charge separation occurred, and both holes and photoelectrons were active on the surface. In the reversed core–shell $WO_3@TiO_2$, the photoexcited electrons (and superoxide anions) were likely to be the main species, but the electron transfer process from TiO_2 to WO_3 was competitive with the process of superoxide anion generation. This competition also occurred for hole transfer, and therefore, the activity of $WO_3@TiO_2$ was strongly suppressed. These mechanisms are illustrated in Fig. 8.

4. Conclusions

In this study, WO_3-loaded TiO_2 nanocomposites of various WO_3 compositions were prepared using sol–gel (coprecipitation) and hydrothermal (core–shell) approaches. The structures of the nanocomposites were analyzed using XRD, SEM, EDX, XPS, and DRS, and adsorption-driven photocatalysis was comprehensively examined. Using cationic methylene blue (MB^+) and anionic methyl orange (MO^-), the adsorption behaviors of the dyes were explained by the electrostatic interaction between the dyes and the negatively charged surfaces of metal oxides, especially with respect to the tungsten component. From the Langmuir adsorption model, the adsorption rate and the adsorption capacity were analyzed for each metal oxide. The core–shell $TiO_2@WO_3$ demonstrated greater maximum adsorption capacity ($q_m = 55.8$ mg g^{-1}) than the sol–gel-produced nanomaterials, indicating that more active sites were available for photocatalysis. Through a kinetic study, the photocatalytic decomposition reactions of both MB^+ and MO^- on the sol–gel and core–shell metal oxides were analyzed. The WO_3-loaded TiO_2 nanocomposites showed considerably higher activity for MB^+ than for MO^-. The reaction rate per (adsorption rate x adsorption capacity) was calculated for each photocatalyst, and a synergistic effect was found. Using scavengers for active species, a charge separation mechanism was considered to improve the photocatalytic activity of complex metal oxides relative to simple oxides. Thus, the high efficiency of the core-

shell $TiO_2@WO_3$ was explained. These results and the approaches used in this study could be useful for designing photocatalysts consisting of hybrid metal oxides.
