Engineering graphitic carbon nitride for next-generation photodetectors: a mini review

 Yuan Li^{ab} and Haiwei Du^{id}*^c

Semiconductor photodetectors, as photoelectric devices using optical–electrical signal conversion for detection, are widely used in various fields such as optical communication, medical imaging, environmental monitoring, military tracking, remote sensing, etc. Compared to the conventional photodetector materials including silicon, III–V semiconductors and metal sulfides, graphitic carbon nitride (g-C₃N₄) as a metal-free polymeric semiconductor, has many advantages such as low-price, easy preparation, efficient visible light response, and relatively good thermal stability. In the meantime, the polymer characteristics also endow the g-C₃N₄ with good mechanical properties. Apart from being used for photo(electro)catalysts during the past decades, the potential use of g-C₃N₄ in photodetectors has attracted great research interests very recently. In this review, we first briefly introduce the structure and properties of g-C₃N₄ and the key performance parameters of photodetectors. Then, combining the very recent progress, the review focuses on the active materials, fabrication methods and performance enhancement strategies for g-C₃N₄ based photodetectors. The existing challenges are discussed and the future development of g-C₃N₄ based photodetectors is also forecasted.

1. Introduction

Photodetectors, transforming light signals to electrical signals for detection and sensing, are very important optoelectronic devices that have been widely used in various areas such as light communication, medical imaging, environmental monitoring, military tracking, and remote sensing. Semiconductor materials, as the critical components in photodetectors, can generate electrons and holes when absorbing photons with energy higher than their bandgap. The separation of photo-generated electrons and holes can directly give rise to the variation of electrical conductivity, thereby resulting in conversion from optical signals to electrical signals. Currently, the commonly used light-sensitive material for commercial photodetectors is silicon. The growth of high-purity silicon, however, usually involves expensive instruments, complicated and energy-intensive processing technologies. Due to a small bandgap of 1.12 eV, addition of waveguide grating structures is necessary when using silicon for ultraviolet (UV) photodetectors, not only reducing the sensing area but also increasing the cost.¹ In addition, the inherent rigidity and brittleness of crystalline silicon materials make it difficult to bend, rendering them unable to meet the requirements of next-generation flexible, foldable electronics even

wearable devices. Compared to silicon, III–V compound semiconductors (such as gallium arsenide, GaAs) have a larger bandgap, which can be used for photodetectors with higher carrier mobility and lower power consumption. However, GaAs-based photodetectors also face challenges such as complex fabrication processes and limitations in large-scale applications due to the presence of toxic elements. In recent years, with the continuous progress in materials science, researchers have conducted in-depth studies on various materials including carbon nanotubes,^{2,3} graphene,^{4,5} two-dimensional (2D) transition metal compounds,^{4,6–8} perovskite materials,^{9–11} inorganic wide-bandgap semiconductors,¹² and quantum dots.^{13,14} Significant progress has been made in improving the detection performance and optimizing device structures. Among them, it is of great significance to develop low-cost and easily fabricated photodetector devices based on organic optoelectronic materials.^{15,16}

Graphitic carbon nitride (g-C₃N₄) is a metal-free polymeric semiconductor material. In 2009, a benchmark study disclosing the water splitting performance of g-C₃N₄ by Wang *et al.* offered exciting opportunities for the study on g-C₃N₄ materials.¹⁷ In the past decades, g-C₃N₄ has been widely used in diverse fields such as artificial photosynthesis,¹⁸ photoelectrochemical devices,¹⁹ biomedicine,²⁰ sensors²¹ and optoelectronic devices.²² In general, g-C₃N₄, with good light response, thermal stability and mechanical property, can be prepared *via* a simple and cost-effective thermal polymerization/condensation of nitrogen-rich organic molecules. However, the physiochemical properties of g-C₃N₄ are mainly dependent on the polymerization

degree due to the polymer characteristics. The conventional thermal polymerization derived g-C₃N₄ contains abundant defects within the inner structure, strongly affecting the intrinsic conductivity. In addition, the as-synthesized g-C₃N₄ is bulk material, which needs to be transferred onto conductive substrates *via* different post-treatments, hindering the large-scale application of g-C₃N₄ in electronic devices to a certain extent. Thanks to the development of material synthesis and device processing technology, researchers have fabricated ultrafast and highly-sensitive g-C₃N₄ based optoelectronic devices with broad prospect of application in detection and sensing areas.²²

Scheme 1 shows the timeline of g-C₃N₄ for photodetector application since the first report in 2016. During the past seven years, researchers have developed different strategies to continuously optimize the performances of g-C₃N₄ based photodetectors. All these research progresses exemplify that g-C₃N₄ is a very promising materials for photodetectors, and the capability may arise from their intrinsic optical property and mechanical performance towards the practical devices. This review focuses on the latest research progress on g-C₃N₄ based photodetectors. First, the structure and basic characteristics of g-C₃N₄, as well as the main electrical performance parameters of photodetectors, are briefly introduced. Then, from the point of view of material and device design, the exploration of g-C₃N₄-based photodetectors and their performance regulation strategies are summarized in detail. Third, we analyze the existing issues of g-C₃N₄-based photodetectors and also discuss the research directions in the future.

2. Structure and properties of graphitic carbon nitride

The discovery of carbon nitride can be traced back to the nineteenth century. In 1834, Liebig firstly synthesized carbon nitride materials and named it as 'melon'.²⁴ In 1922, Franklin proposed a concept of carbon nitride (C₃N₄) which was considered as the final product of melon after calcination.²⁵ Pauling and Sturdivant first deduced that the coplanar tri-s-triazine units exist in the C₃N₄ structure in 1937.²⁶ Using the first principle method, Teter and Hemley found the polymorphism of carbon nitride, which have five crystal structures including α -C₃N₄, β -C₃N₄, cubic C₃N₄, pseudo-cubic C₃N₄ and graphitic C₃N₄ (g-C₃N₄).²⁷ Among these allotropes, g-C₃N₄ is

a metal-free n-type semiconductor and has a graphite-like layered structure (space group: *P6m2*; $a = b = 4.7420 \text{ \AA}$, $c = 6.7205 \text{ \AA}$; $\alpha = \beta = 90^\circ$, $\gamma = 120^\circ$),²⁷ with interlayers connected by van der Waals forces, and it is most stable at ambient temperature and pressure. As shown in Fig. 1, g-C₃N₄ mainly has two chemical structures consisting of triazine (Fig. 1a) and tri-s-triazine (Fig. 1b) units respectively. Through density functional theory, Kroke *et al.* found that g-C₃N₄ with tri-s-triazine as structural units is more stable.²⁸ Combining the X-ray diffraction and neutron diffraction, Irvine *et al.* proposed that the three-dimensional structure of g-C₃N₄ is formed by parallel chains of tri-s-triazine units following the A-B stacking order.²⁹ In addition, both carbon and nitrogen atoms in g-C₃N₄ structure undergo sp² hybridization, with overlapping sp² hybrid orbitals forming σ bonds, while the overlapping 2p_z orbitals form π bonds, ultimately creating a highly delocalized π -conjugated system (Fig. 1c).²³ It should be noted that g-C₃N₄ has different chemical bonding when compared to nitrogen-doped carbon material. In general, the C-N bond length of g-C₃N₄ is $\sim 1.33 \text{ \AA}$ while two cases are different: (i) the C-N bond length ranges from 1.38 to 1.40 \AA for the middle part of tri-s-triazine unit; (ii) the C-N bond length ranges from 1.45 to 1.48 \AA for the tri-coordinated N atoms connecting three tri-s-triazine units.³⁰ For nitrogen-doped graphene, the C-N bond length of N-substituted graphene is 1.41 \AA except for pyridinic N and pyrrolic N, of which the bond lengths are 1.33–1.34 \AA and 1.33/1.39 \AA respectively.³¹

In general, g-C₃N₄ can be prepared by the thermal condensation of nitrogen-containing molecules including urea, melamine, dicyandiamide, *etc.* However, different preparation conditions can yield triazine or tri-s-triazine based g-C₃N₄ products. This can be attributed to two aspects: (i) because triazine unit has a higher energy, it is thermodynamically difficult to synthesize g-C₃N₄ with pure s-triazine units.³² In comparison to g-C₃N₄ with s-triazine units only, poly(triazine imide) (PTI) which is prepared with the assistance of molten salts, is likely to be generated.³³ (ii) Transforming triazine or tri-s-triazine units to highly condensed structure usually takes place above 520 $^\circ\text{C}$.¹⁹ When the temperature is increased, the polymerization degree is very hard to control due to the release of ammonia. As the structure of g-C₃N₄ is highly disordered, a slight change in the experimental condition is likely to lead to different structural character.

Compared to silicon and metal compound semiconductor materials, g-C₃N₄ has the following advantages. First, directly heating nitrogen-containing organic molecules to achieve the polymerization is the most commonly used synthetic method to prepare g-C₃N₄ in a low-cost manner since the raw materials are earth-abundant and easily accessible. Second, with a bandgap of 2.7 eV, the light sensitivity of g-C₃N₄ is outstanding in particular in the UV range.³⁴ Third, g-C₃N₄ has very excellent chemical stability and relatively good thermal stability. Fourth, as a polymer material with outstanding bending properties, g-C₃N₄ is also highly compatible with different polymer substrates for developing flexible, stretchable, and wearable devices. Table 1 compares the physical properties between g-C₃N₄ and several representative electronic materials for optoelectronic devices.

Scheme 1 The timeline of g-C₃N₄ for photodetector applications.

Fig. 1 Schematic illustration of chemical structure of $g\text{-C}_3\text{N}_4$: (a) triazine structure and (b) tri-s-triazine structure. Compared to other materials, $g\text{-C}_3\text{N}_4$ has a larger bandgap while the thermal conductivity and Young's modulus are comparable to that of silicon. However, the electron mobility of $g\text{-C}_3\text{N}_4$ is extremely low and the performance should be further optimized in order to meet the requirements of photodetector applications.

3. Main parameters of photodetectors

Although the semiconductor materials, device structures, and detection mechanisms vary for different types of photodetectors, their electrical performance can be quantitatively evaluated using key parameters such as switch ratio, responsivity, response time, signal-to-noise ratio, noise equivalent power, specific detectivity, external quantum efficiency, and gain.^{9,55–60} The following provides a brief introduction to the definitions and significance of each performance parameter.

3.1 On/off ratio

The ratio of the photocurrent (I_{light}) under constant optical intensity, wavelength, and bias conditions to the dark current (I_{dark}) without light irradiation. The magnitude of the on/off ratio serves as an important indicator of the photoresponse characteristics. For some semiconductors with a narrow

bandwidth used as photodetectors, higher dark currents (when the device cannot be switched off completely) directly affect the switch ratio.

3.2 Responsivity (R)

The ratio of the output photocurrent (or photovoltage) to the incident optical power at a given wavelength, expressed as $R(\lambda) = I(\lambda)_{\text{ph}}/P(\lambda)_{\text{in}}$ or $R(\lambda) = V(\lambda)_{\text{ph}}/P(\lambda)_{\text{in}}$, where $I(\lambda)_{\text{ph}}$ is the photocurrent, $V(\lambda)_{\text{ph}}$ is the photovoltage, and $P(\lambda)_{\text{in}}$ is the incident optical power. Responsivity represents the magnitude of the photocurrent (or photovoltage) generated per unit optical power and intuitively reflects the photodetectors' effectiveness in converting light to electric signals.

3.3 Response time

The response time refers to the time it takes for a photodetector to switch between dark current and photocurrent, reflecting its response ability to the changes of light signals. Typically, the response time can be defined as the time it takes for the photocurrent to rise from 10% to 90% (or fall from 90% to 10%) of its maximum steady-state value. When the photocurrent variation follows an exponential relationship, the response time can be defined as the time required for the photocurrent to increase to 63% ($1 - 1/e \approx 63\%$) of its steady-state peak value. The response time of different types of photodetectors primarily

Table 1 Comparison of $g\text{-C}_3\text{N}_4$ and several representative materials for optoelectronic devices

Materials	Bandgap (eV)	Electron mobility ($\text{cm}^2 \text{V}^{-1} \text{s}^{-1}$)	Thermal conductivity ($\text{W cm}^{-1} \text{K}^{-1}$)	Young's modulus (GPa)	Ref.
Si	1.12	~1400	~1.42	130–169	35–38
GaAs	1.42	9000	0.435	85.6–115.9	39–42
Graphene	0	2×10^5	5×10^3	2400 ± 400	43–46
MoS ₂	1.29	50–200	~52	270 ± 100	47–50
$g\text{-C}_3\text{N}_4$	2.7 (tri-s-triazine-based) 3.2 (triazine-based)	0.089	3.5–7.6	171	17 and 51–54

depends on the materials and detection mechanisms. For example, the response time of optoelectronic devices is related to carrier mobility, channel length, and bias voltage. The response time of photovoltaic devices depends on the thickness of the active layer and carrier mobility.⁵⁶

3.4 Specific detectivity (D^*)

D^* is the reciprocal of NEP. It was found that the NEP is related to the detectivity, detector area, and bandwidth.⁶¹ The D^* is defined as the following equation:⁶²

$$D^*(\lambda) = \frac{\sqrt{A_d f}}{(R/I_n)} \quad (1)$$

where A_d is the effective area of the device, f is the bandwidth, and I_n is the noise current. When dark current is predominantly caused by shot noise, the detectivity is given by:

$$D^*(\lambda) = \frac{I_{\text{light}}/P_{\text{in}}}{(2qI_{\text{dark}})^{1/2}} \quad (2)$$

where q is the elementary charge. D^* (expressed in Jones), as the most important performance parameter of a photodetector, is used to evaluate the performance of photodetectors with different configurations and sizes. D^* is directly proportional to responsivity and indirectly influenced by parameters such as wavelength, modulation frequency, and electric field.⁵⁵

3.5 External quantum efficiency (EQE)

EQE refers to the ratio of the number of electrons collected by a photodetector (*i.e.*, conversion of light to photocurrent) to the number of incident photons. In general, EQE is given by:

$$\text{EQE}(\lambda) = \frac{I_{\text{ph}}/e}{P_{\text{ph}}/(h\nu)} = R(\lambda) \frac{hc}{q\lambda} \cong R(\lambda) \frac{1.24}{q\lambda} \quad (3)$$

where e is the elementary charge, R is the responsivity, h is the Planck constant, ν and λ are the frequency and wavelength of the incident light, and c is the speed of light.

4. Design of graphitic carbon nitride photodetectors and the performance regulation strategies

Generally, g-C₃N₄ derived by thermal condensation method is powder material with a bulk structure, smaller surface area, lower crystallinity degree and abundant lattice defects. This type of g-C₃N₄ is not desired and not very suitable for photodetectors, due to the lower intrinsic conductivity and rapid recombination of photogenerated charge carriers. To effectively enhance the performance of g-C₃N₄, researchers recently have adopted various methodologies including atomic doping, heterostructure, composite design and controllable growth of high-quality film which will be introduced as follows.

4.1 Atomic doping and defect control

Atomic doping and defect engineering can directly influence the local electronic structure of g-C₃N₄, thereby altering the energy

level positions and achieving enhanced light response and improved charge carrier separation efficiency. Goswami *et al.* utilized hydrogen atom filling in the nitrogen vacancies of g-C₃N₄ (H-g-C₃N₄) to modulate its optoelectronic properties.⁶⁴ After hydrogen atom filling, the H-g-C₃N₄ exhibits a significant redshift in optical absorption spectrum, extending from the visible light range to the near-infrared region, with a narrow band gap of only 2.06 eV and a significant decrease in fluorescence intensity. Owing to effective charge carrier separation and enhanced light absorption at interfacial defects, the photodetector based on H-g-C₃N₄/p-type silicon demonstrates excellent performance in a wide spectral range of 350 to 1100 nm: responsivity of 0.34 A W⁻¹, external quantum efficiency of 59%, and an on/off ratio greater than 1000. Ray *et al.* synthesized boron-doped g-C₃N₄ (B_xC_yN_z) nanosheets with enhanced UV absorption and extended visible-light absorption edge (Fig. 2b).⁶³ The local nitrogen atom deficiency in the structure can form trap centers that facilitate the separation of photo-generated electron-hole pairs. Subsequently, a single-electrode triboelectric nanogenerator (STENG) based on B_xC_yN_z nanosheets was fabricated and used for wearable UV photodetection. By assembling B_xC_yN_z and polypropylene (PP), UV light is irradiated through PP onto the B_xC_yN_z layer (Fig. 2c), and the variation in open-circuit voltage is achieved under both UV-illuminated and non-illuminated conditions through continuous switching between touch and non-touch modes (Fig. 2d and e). When the light power increases to 1.5 mW cm⁻², the output voltage decreases from 20.3 V to 12.9 V, with a response time of less than 5 s (Fig. 2f). The closed-circuit voltage connected to the load decreases to approximately 60% of the value without light illumination (Fig. 2g). Under UV light irradiation, B_xC_yN_z generates photo-generated electron-hole pairs that migrate to the top and bottom, creating opposite electric fields, which reduce the friction charge and result in a decrease in the potential and open-circuit voltage of the STENG.

4.2 Heterostructure

Constructing heterostructure is the most commonly used strategy for designing g-C₃N₄ based photodetectors.⁶⁵⁻⁷⁶ Shan *et al.* fabricated high-quality g-C₃N₄ films on Si substrate using a vapor-phase transport-assisted condensation method.⁶⁵ The g-C₃N₄/Si heterostructure exhibited a distinct response under the light irradiation from 300 to 1000 nm with a responsibility of 133 A W⁻¹ and detectivity of 3.3×10^{12} Jones (Fig. 3a and b). When exposed to light irradiation, the τ_{rise} and τ_{fall} were 28 and 70 μ s, respectively (Fig. 3c). A position-sensitive detector based on the g-C₃N₄/Si heterojunction showed a superior nonlinearity of 0.9% and the maximum sensitivity was 352 mV mm⁻¹ at 808 nm (Fig. 3d and e). According to the energy level diagram, a type-I heterojunction can be formed between g-C₃N₄ and Si since the Fermi level of g-C₃N₄ is higher than that of Si (Fig. 3g). Under the light irradiation, the photogenerated electrons migrate to g-C₃N₄ while the holes are accumulated on the Si side (Fig. 3h), which can be used for self-powered photodetectors after connecting to the positive and negative terminals of external circuit. When the laser spot was incident on the PSD,

the separation of photogenerated carriers by the built-in field left a gradient of charge carriers between the illuminated and non-illuminated parts. Once the excessive electrons in the

illuminated area moved to the electrode, a lateral photovoltaic voltage was created to achieve the PDS function (Fig. 3i). In addition, they replaced the silicon with GaN and also found a built-in electric field in $g-C_3N_4/GaN$ heterostructure,⁷⁵ of which the sensitivity was up to 355 $mV\ mm^{-1}$ and the nonlinear value of 0.5% at room temperature. When the temperature was elevated to 700 K, the sensitivity (315 $mV\ mm^{-1}$) and nonlinear value (1.4%) were still superior to the commercial Si devices.

Alshareef *et al.* utilized a low-temperature solution processing method to fabricate a type-II heterojunction consisting of P-doped $g-C_3N_4$ (PCN-S) nanosheets and $CH_3NH_3PbCl_xI_{3-x}$ (MLHP) perovskite.⁷⁰ Since the dark current decreased by two orders of magnitude, the on/off ratio of the device reached up to 10^5 (Fig. 4a), with a responsivity of 1.7 $A\ W^{-1}$ and a detectivity of 1.1×10^{12} Jones (Fig. 4b). When a heterojunction formed between PCN-S and MLHP, the interfacial band bending took place to form a barrier, hindering the electron transfer from MLHP to PCN-S (Fig. 4c). Under light illumination, the photo-generated carriers in MLHP can reduce the built-in electric field and lead to an upshift of Fermi level. As a result, the decreased barrier between conduction bands of PCN-S and MLHP promoted the electron transfer from MLHP to PCN-S and thereby enhanced the photocurrent (Fig. 4d). In addition, the PCN-S/MLHP photodetector exhibited excellent moisture resistance owing to the improved hydrophobicity. Zhang *et al.* constructed a type-II van der Waals heterojunction by combining Bi zero-dimensional (0D) quantum dots (QDs) and $g-C_3N_4$ nanosheets.⁷² The photodetection performances were studied *via*

Fig. 4 (a) I - V curves of (i) MLHP-only and (ii) PCN-S/MLHP hybrid photodetectors measured in the dark and under various wight light irradiation. photoelectrochemical testing. After forming a heterojunction between Bi QDs and g -C₃N₄, the redistribution of intrinsic charge carriers resulted in the formation of a depletion region at the interface. Under illumination, photo-generated electrons and holes diffused in opposite directions. As the conduction band (CB) position of g -C₃N₄ is lower than that of Bi QDs, photo-generated electrons transferred from the CB of Bi QDs to the CB of g -C₃N₄, while photo-generated holes moved from the valence band (VB) of g -C₃N₄ to the VB of Bi QDs, thereby creating a built-in electric field. The presence of the built-in electric field effectively promoted the separation of photo-generated carriers and improved the light response capability.

4.3 Composite design

Alshareef *et al.* first exfoliated bulk g -C₃N₄ and MoS₂ into nanosheets, and then mixed them to form an inorganic-organic thin-film composite (Fig. 5a), which was used for the fabrication of planar photodetectors.⁷⁷ With the decreasing content of g -C₃N₄, the absorption of the composite material towards UV light gradually weakened, while its visible light absorption capability increased (Fig. 5b). When the two components were present in equal proportions, the photodetectors exhibited the highest on/off ratio under 532 nm and 365 nm wavelength illuminations (Fig. 5c), with maximum responsivity and specific detectivity values of 4 A W⁻¹ and 4 × 10¹¹ Jones, respectively (wavelength: 365 nm, light power: 0.5 W cm⁻²). Femtosecond transient absorption spectra confirmed that the composite material possessed faster photogenerated charge carrier transfer dynamics, which was the main reason for the increase in photocurrent. Furthermore, the thin-film composite photodetectors also exhibited outstanding mechanical performance, as the on/off ratio did not show significant degradation even after bending at different degrees and multiple bending tests (Fig. 5d

Fig. 5 (a) Schematic illustration of the process for preparation of g -C₃N₄ and MoS₂ hybrid dispersions used for photodetector; (b) absorbance at wavelengths of 672 and 308 nm and (c) on-off ratio as a function of the g -C₃N₄ and MoS₂ ratio. (d) On-off ratio of the photodetectors containing g -C₃N₄ and MoS₂ hybrid with different bending radius. (e) On-off ratio of the photodetectors containing g -C₃N₄ and MoS₂ hybrid with different bending cycles at a banding radius of ≈ 4 mm. Reproduced from ref. 77 with permission. and e). Zhao *et al.* used g -C₃N₄ quantum dots to modify the interface of tin oxide/perovskite.⁷⁸ It was found that the g -C₃N₄ quantum dots were able to improve the crystallinity of the perovskite layer, reduce grain boundaries and defects, and suppress the recombination of photogenerated charge carriers. After the modification with g -C₃N₄ quantum dots, both the responsivity and on/off ratio of the photodetectors were greatly enhanced.

4.4 Controllable fabrication of high-quality films

As introduced above, the g -C₃N₄ bulk powder prepared by conventional methods is not high desired and still needs to be post-treated through secondary exfoliation before being coated onto substrate surfaces to fabricate thin film devices. Although small-sized and ultra-thin g -C₃N₄ nanosheets can be further processed into micro-nano devices, the existing processes for preparing g -C₃N₄ films still have significant limitations in manufacturing large-sized optoelectronic devices at the wafer level. Moreover, the overall device performances are strongly

dependent on the structural defects, surface roughness, and weak bonding between the thin film and substrate resulting from multiple material processing steps. Shan *et al.* proposed a vapor transport-assisted condensation (VTC) synthesis method, which achieved controllable preparation of wafer-sized $g\text{-C}_3\text{N}_4$ films.⁷⁹ In the traditional direct thermal polymerization method, a large number of holes exist in the products due to the sublimation and low migration rate of the melamine precursor during the pyrolysis process, making it difficult to obtain uniform high-quality films (Fig. 6A). Using the VTC method, melamine and the substrate were placed in the low-temperature (300 °C) and high-temperature (550 °C) region respectively. The appropriate amount of gaseous melamine formed in the low-temperature region can uniformly transport to the substrate surface to complete the polymerization process (Fig. 6B). In addition, the hydrogen bonding interaction between the terminal -NH groups of the $g\text{-C}_3\text{N}_4$ structure and water molecules leads to the formation of wrinkles on the film surface, which can be peeled off from the quartz substrate surface and then float on the water. Then, the peeled $g\text{-C}_3\text{N}_4$ was transferred onto a polyethylene terephthalate (PET) flexible substrate through a glass capillary (Fig. 6C–F). The responsivity of the flexible $g\text{-C}_3\text{N}_4$ UV photodetector array was 207 mA W^{-1} , with a switch ratio of 250 and a response time of 6 ms. Liang *et al.* obtained high-quality $g\text{-C}_3\text{N}_4$ films using a laser direct writing (LDW) technology. They coated a mixture of pre-calcinated precursor powder, carbon black, and ethylene glycol onto a conductive glass surface and then irradiated the glass back-side with a near-infrared laser at a wavelength of 1064 nm. The instantaneous high temperature and pressure generated by the laser enable the completion of the copolymerization reaction within only 4 s.⁸⁰ The photodetector (with 36 pixels) prepared by LDW technology not only exhibits excellent mechanical performance and stability but also has a dark current of only $4.43 \times 10^{-11} \text{ A}$, which is beneficial for achieving a high signal-to-noise ratio.

4.5 Others

Using chemical vapor deposition, Xiao *et al.* prepared an asymmetric carbon nitride nanotube membrane (ACNNM) in an anodized aluminum oxide template.⁸¹ Such ACNNM was used for ion-transport-based self-powered photodetector. Unlike the conventional photodetectors that directly use the separated charge carriers for detection and sensing (Fig. 7a), their ion-type photodetector involves electrolyte and the separated photo-induced charge carriers in the asymmetric nanotube structure can drive ion separation and transport within the nanotube channels, generating an ion current signal (Fig. 7b and c). When exposed to green and blue light, a current is detected without applying bias voltage, indicating that the ACNNM can be used for self-powered photodetectors. Additionally, the responsivity of this photodetector decreases by an order of magnitude with decreasing light power, and the response time was 0.05 s. Although the photodetection performance is slightly inferior to that of traditional photodetectors, the carbon nitride ion-type photodetector still exhibits excellent biocompatibility and structural flexibility, which are very

Fig. 7 Schematic illustration of (a) the typical electron-transport-based photodetector and (b) ion-transport-based photodetector. important in the field of bioelectronics. Palanisamy *et al.* transferred g-C₃N₄ thin film onto the surface of single-layer graphene field-effect transistor (FET) as the UV photodetector.⁸⁴ The light response is dependent on the g-C₃N₄ thin film, achieving an on/off ratio of 157 and responsivity was up to 3 × 10³ A W⁻¹. Shan *et al.* investigated the photodetection characteristics of g-C₃N₄ through *in situ* pressure-dependent electrical test.⁸² The photocurrent of g-C₃N₄ increased nearly twofold when a pressure of 3.6 GPa was applied (Fig. 7d and e). Such photocurrent increase can be attributed to the enhanced interlayer interactions resulting from a smaller bandgap of g-C₃N₄ after applying pressure since the electrons were more easily excited from the valence band to the conduction band. Ding *et al.* revealed that introducing nitrogen defects in g-C₃N₄ can reduce the bandgap to 2.4 eV.⁸³ When applying the external pressure, the bandgap is further reduced to 1.7 eV, which is the lowest value reported in the literature for g-C₃N₄. Upon the pressure applied, the photocurrent of g-C₃N₄ can increase by approximately 50% while bandgap recovers to 1.87 eV when the pressure is released. *In situ* synchrotron X-ray diffraction and Raman spectroscopy further confirm that the changes in the bandgap originate from pressure-induced and nitrogen vacancy-induced amorphization effects. In addition, the performance of graphitic carbon nitride based photodetectors have been summarized in Table 2.

5. Conclusion and future perspectives

The structural design, fabrication processes, and performance optimization of g-C₃N₄-based photodetectors have emerged as a new hotspot in the research field of semiconductor materials. They provide new research directions for the development of novel optoelectronic devices. This review summarizes the recent progress in g-C₃N₄-based photodetectors and in particular discusses the research strategies for device fabrication and

performance optimization. The enhancement in detection performances of g-C₃N₄-based photodetectors have been achieved by integrating with various semiconductor materials such as oxides, perovskites and quantum dots.

Since the core component of g-C₃N₄-based photodetectors is the thin-film material, the density, uniformity and defect content of the thin films therefore directly affect the device performance. Despite researchers' efforts to enhance the quality of g-C₃N₄ films through various novel fabrication methods, there are still challenges in achieving wafer-scale, high polymerization/crystallinity, and low-defect g-C₃N₄ films for photodetectors with higher responsivity and larger gain. In the future, the development of g-C₃N₄ photodetectors can focus on the following aspects:

(i) Given that the transport kinetics of photogenerated charge carriers are affected by the low intrinsic conductivity of g-C₃N₄, how to simply prepare high-quality thin films will play a critical role in achieving practical application of g-C₃N₄ based photodetectors. Due to the fact that the precursors used for g-C₃N₄ synthesis are organic small molecules, conventional physical fabrication methods such as molecular beam epitaxy, magnetron sputtering, and pulsed laser deposition are not highly suitable. Therefore, it is crucial to further improve the current chemical vapor deposition (CVD) techniques to accelerate molecular interactions, reduce precursor volatilization, and enhance the copolymerization degree. This will enable the production of high-quality films with high crystallinity and good adhesion to substrates, which are the key factors for g-C₃N₄ photodetectors.

(ii) The currently reported g-C₃N₄ optoelectronic devices are mainly used for UV light detection. In the future, much efforts can be devoted to enhance the light-responsive performance of g-C₃N₄ in the visible and even near-infrared (NIR) regions through compositional modification and structural regulation. On the one hand, introducing the NIR-responsive plasmon metals (such as Au and Ag) is able to enhance the light

harvesting owing to the surface plasmon resonance (SPR) effect. On the other hand, compared to planar and symmetric structure, forming highly disordered structure can effectively achieve the $n \rightarrow \pi^*$ electron transition, thereby further extending the light absorption range. These strategies open up possibilities for the applications of $g\text{-C}_3\text{N}_4$ photodetectors across the entire spectrum.

(iii) To more effectively enhance the detection performance of the current devices, it is worth exploring the heterostructures with emerging materials such as 2D transition metal sulfides/selenides, black phosphorus, MXenes, etc. In particular, the formation of van der Waals heterostructures can not only broaden the wavelength range of photodetection but also significantly improve the response speed and detection sensitivity of the devices.

(iv) Compared to semiconductors like Si and GaAs, $g\text{-C}_3\text{N}_4$ is a polymer material with relatively good mechanical properties. The synthesis of $g\text{-C}_3\text{N}_4$ typically requires high-temperature polymerization while flexible substrates normally cannot be used at such high temperature. Therefore, developing various techniques to transfer high-quality films onto flexible polymer substrates while ensuring an outstanding film-substrate adhesion is highly desired. This enables the realization of flexible photodetectors used in display devices, wearable devices, smart robots, and other fields.
