# Direct observation of bicarbonate and water reduction on gold: understanding the potential dependent proton source during hydrogen evolution†

Gang-Hua Deng,<sup>a</sup> Quansong Zhu,<sup>b</sup> Jaclyn Rebstock,<sup>b</sup> Tomaz Neves-Garcia<sup>b</sup> and L. Robert Baker<sup>\*b</sup>

The electrochemical conversion of CO<sub>2</sub> represents a promising way to simultaneously reduce CO<sub>2</sub> emissions and store chemical energy. However, the competition between CO<sub>2</sub> reduction (CO<sub>2</sub>R) and the H<sub>2</sub> evolution reaction (HER) hinders the efficient conversion of CO<sub>2</sub> in aqueous solution. In water, CO<sub>2</sub> is in dynamic equilibrium with H<sub>2</sub>CO<sub>3</sub>, HCO<sub>3</sub><sup>−</sup>, and CO<sub>3</sub><sup>2−</sup>. While CO<sub>2</sub> and its associated carbonate species represent carbon sources for CO<sub>2</sub>R, recent studies by Koper and co-workers indicate that H<sub>2</sub>CO<sub>3</sub> and HCO<sub>3</sub><sup>−</sup> also act as proton sources during HER (*J. Am. Chem. Soc.* 2020, **142**, 4154–4161, *ACS Catal.* 2021, **11**, 4936–4945, *J. Catal.* 2022, **405**, 346–354), which can favorably compete with water at certain potentials. However, accurately distinguishing between competing reaction mechanisms as a function of potential requires direct observation of the non-equilibrium product distribution present at the electrode/electrolyte interface. In this study, we employ vibrational sum frequency generation (VSFG) spectroscopy to directly probe the interfacial species produced during competing HER/CO<sub>2</sub>R on Au electrodes. The vibrational spectra at the Ar-purged Na<sub>2</sub>SO<sub>4</sub> solution/Au interface, where only HER occurs, show a strong peak around 3650 cm<sup>−1</sup>, which appears at the HER onset potential and is assigned to OH<sup>−</sup>. Notably, this species is absent for the CO<sub>2</sub>-purged Na<sub>2</sub>SO<sub>4</sub> solution/gold interface; instead, a peak around 3400 cm<sup>−1</sup> appears at catalytic potential, which is assigned to CO<sub>3</sub><sup>2−</sup> in the electrochemical double layer. These spectral reporters allow us to differentiate between HER mechanisms based on water reduction (OH<sup>−</sup> product) and HCO<sub>3</sub><sup>−</sup> reduction (CO<sub>3</sub><sup>2−</sup> product). Monitoring the relative intensities of these features as a function of potential in NaHCO<sub>3</sub> electrolyte reveals that the proton donor switches from HCO<sub>3</sub><sup>−</sup> at low overpotential to H<sub>2</sub>O at higher overpotential. This work represents the first direct detection of OH<sup>−</sup> on a metal electrode produced during HER and provides important insights into the surface reactions that mediate selectivity between HER and CO<sub>2</sub>R in aqueous solution.

## 1 Introduction

The hydrogen evolution reaction (HER) is of great importance in electrocatalysis and sustainable energy production, and a large number of experimental and theoretical studies have sought to unravel the mechanisms of HER.<sup>1–3</sup> Another important reaction

for energy storage and greenhouse gas remediation is CO<sub>2</sub> reduction (CO<sub>2</sub>R). However, during electrocatalytic CO<sub>2</sub>R in aqueous electrolyte, HER competes with CO<sub>2</sub>R limiting the faradaic efficiency of CO<sub>2</sub> conversion. Therefore, to design systems to optimize the selectivity for CO<sub>2</sub>R, it is necessary to understand the mechanism of HER. Much effort has been devoted to control the catalyst surface properties that promote activity and selectivity for CO<sub>2</sub>R while suppressing HER.<sup>4–12</sup> However, by comparison, less attention has been devoted to understand the role of the various interfacial species (H<sub>2</sub>O, CO<sub>2</sub>, H<sub>2</sub>CO<sub>3</sub>, HCO<sub>3</sub><sup>−</sup> and OH<sup>−</sup>) on the competition between CO<sub>2</sub> R and HER. One of the main questions is: among H<sub>2</sub>O, H<sub>2</sub>CO<sub>3</sub> and HCO<sub>3</sub><sup>−</sup>, which is the proton source for HER during CO<sub>2</sub>R? Recently, much effort has been dedicated by Koper and co-workers to study the mechanism of HER in bicarbonate solutions by electrokinetic measurements.<sup>13–16</sup> They conclude that at

increasingly negative potentials, the proton donor for HER changes from  $\text{H}_2\text{CO}_3$  to  $\text{HCO}_3^-$  to  $\text{H}_2\text{O}$ .<sup>15</sup> However, because these species invariably equilibrate, direct spectroscopic evidence is still needed to confirm the actual species produced at the electrode/electrolyte interface in order to distinguish between these surface reactions.

Vibrational spectra of interfacial water can be a sensitive indicator of structure and composition of the electrochemical double layer.<sup>17–24</sup> Various methods for interface-specific vibrational spectroscopy, including VSFG, surface enhanced Raman spectroscopy (SERS), and shell-isolated nanoparticle enhanced Raman spectroscopy (SHINERS) has been shown to be a powerful technique to understand interfacial water structure at solid/liquid interfaces. Focusing here on electrochemical HER, it was demonstrated that the structure of the interfacial water molecule can vary with the potential on the electrode surfaces.<sup>20–23,25–27</sup> A strong correlation between the interfacial water structure and the HER activity on a Pt surface was demonstrated by Shen *et al.* with *in situ* Raman spectroscopy.<sup>26</sup> They find that the first layer of water molecules changes from proton acceptors to proton donors with increasing pH and the reactivity of the interfacial water varied its structure. In a more recent study, using SHINERS, Wang *et al.* also showed that structurally ordered interfacial water facilitated high efficiency electron transfer across the interface, resulting in increased HER rates.<sup>25</sup> However, despite the importance of this electrochemical reaction, direct detection of the HER products at the electrode/electrolyte interface is still missing. Specifically,  $\text{OH}^-$  is the direct product of water reduction, but to date no spectroscopic detection of this species on an electrode surface has been reported. In this study, we employ *in situ* VSFG to measure the interfacial water spectra during active HER in  $\text{Na}_2\text{SO}_4$  and  $\text{NaHCO}_3$  solutions using a Au electrode. By directly observing the interfacial water spectrum as the system is pushed away from equilibrium under applied potential, we seek to differentiate between water and bicarbonate reduction and to understand the related effects of proton source and interfacial pH buffering on the kinetics of HER.

## 2 Results and discussion

VSFG is a second order nonlinear technique with surface/interface specificity, which has been widely used to investigate molecular orientation, dynamics, and chemical reactions on surfaces.<sup>28–31</sup> The details of the instrument, including the VSFG electrochemical cell, which provides *in situ* measurements of the Au/electrolyte interface at current densities exceeding 1 mA  $\text{cm}^{-2}$  in the absence of mass transport limitations,<sup>32,33</sup> can be found in the ESI.† Using this instrument, we have quantified the *in situ* detection limit on a Au electrode to be better than 1% of a surface monolayer.<sup>32,33</sup> Fig. 1a shows the VSFG spectra of interfacial water for 0.05 M  $\text{Na}_2\text{SO}_4$  saturated with Ar as a function of applied potential. Before the onset of HER at approximately  $-0.8$  V vs. Ag/AgCl, there is only one sharp peak observed at  $3730$   $\text{cm}^{-1}$ . This peak corresponds to  $\text{H}_2\text{O}$  that is not H-bonded with other water molecules and is assigned to free OH.<sup>34–37</sup> Using VSFG, a number of groups have reported the

free OH stretch of interfacial water at the aqueous dielectric interface,<sup>38,39</sup> but only recently has this feature been observed at the Au/electrolyte interface under applied potential.<sup>37,40</sup> This feature is best described as interfacial water with one non-H-bonded OH group pointing toward the Au electrode.<sup>37</sup>

When the potential reaches  $-0.8$  V near the onset of HER, another sharp peak appears around  $3650$   $\text{cm}^{-1}$ , which increases in intensity as the applied potential becomes more negative, eventually becoming the dominate feature in the spectrum at potentials below  $-1.0$  V. This feature is similar to the free OH stretch, and due to its narrow line width, indicating that this feature is also from non-H-bonded OH. Based on the shift in peak position and fact that this feature only appears near the onset potential of HER, we assign this feature to the free OH stretch of surface hydroxide ( $\text{OH}^-$ ).

This is consistent with previous assignments for the free  $\text{OH}^-$  stretch observed in the gas phase<sup>41</sup> as well as in alkali hydroxide solutions.<sup>42–45</sup> To confirm this assignment, VSFG spectra of NaOH solutions at varying concentration between 1 and 100 mM were also measured on Au under open circuit potential as shown in Fig. 1b. In addition to the free OH stretch of interfacial water around  $3730$   $\text{cm}^{-1}$ , these solutions show another sharp peak around  $3635$   $\text{cm}^{-1}$  at increasing NaOH concentrations, which supports the assignment of this feature as interfacial  $\text{OH}^-$ . Additional control experiments using isotope exchange, which further confirm this assignment, are described in the ESI Section 2 (Fig. S1–S2).†

Similar sharp peaks resulting from non-H-bonded/weakly coupled  $\text{OH}^-$  have been observed by VSFG at the  $\text{CaF}_2$ /liquid interface.<sup>46–48</sup> Based on these observations, we hypothesize that the  $\text{OH}^-$  anion measured here resides directly on the Au surface inside of the Stern layer with the H atom oriented toward the Au electrode and the O atom possibly coordinated to a  $\text{Na}^+$  cation. To test whether this species is directly interacting with the Au surface, we treated a Au electrode with UV-generated ozone to form a hydrophilic surface oxide layer. The purple curve in Fig. 1b shows the SFG spectrum of the electrode/electrolyte interface using this oxidized Au electrode. As shown, the peak at  $3650$   $\text{cm}^{-1}$  disappears even for 100 mM NaOH solution. It should be noted that the open circuit potential (OCP) for ozone-treated Au surface is 210 mV which is higher than that of normal Au surface ( $-100$  mV). However, the 300 mV difference of OCP should not account for the absence of the  $\text{OH}^-$  peak. When a positive potential of 0.4 V was applied for a normal Au electrode, the  $\text{OH}^-$  peak still shows in the spectrum (Fig. S3†). The peak begins to decrease substantially when the applied potential reaches 0.6 V. At this potential the gold electrode begins to oxidize and form hydrogen bonds with  $\text{OH}^-$  causing the peak intensity to decrease. Thus, we attribute the loss of this free OH stretch to H-bonding of the interfacial  $\text{OH}^-$  anion with the oxidized Au electrode, which cannot occur on a metallic Au surface. Note that the  $\text{OH}^-$  anion should be repelled from the negatively charged electrode during HER, indicating that detection of  $\text{OH}^-$  on Au at negative potential represents a transient, surface species formed *in situ* as a product of HER. The transient nature of this species is confirmed by a potential jump experiment (see Fig. S4†), where the intensity of the  $\text{OH}^-$  peak

Fig. 1 (a) VSFG spectra of  $\text{Na}_2\text{SO}_4$  (0.05 M) purged with Ar as a function of potential vs. Ag/AgCl. (b) VSFG spectra of NaOH solutions (red: 1 mM, blue: 10 mM, and green: 100 mM) at open circuit potential. The purple curve in panel b shows the spectrum of 100 mM NaOH on Au following ozone treatment resulting in slight surface oxidation of the Au electrode.

immediately decreases to near zero once the potential is stepped more positive, and active HER stops. This finding is consistent with recent theoretical predictions by Li *et al.* of non-H-bonded  $\text{OH}^-$  produced at the metal/electrolyte interface inside the outer Helmholtz plane during HER.<sup>49</sup> To our knowledge, this is the first direct observation of  $\text{OH}^-$  produced inside the Helmholtz plane during HER. Blue shift of the  $\text{OH}^-$  peak around  $3650\text{ cm}^{-1}$  is observed as shown in Table S1.† The shift is only  $2\text{ cm}^{-1}$  from  $-0.85\text{ V}$  to  $-1.1\text{ V}$ , which is smaller than the spectral resolution of our instrument ( $\sim 10\text{ cm}^{-1}$ ). The absence of a significant Stark shift for this species is consistent with a previous study by Tong *et al.*<sup>37</sup> The reason that  $\text{OH}^-$  shows such a small Stark shift may be due to direct interactions of  $\text{OH}^-$  with alkali cations in the Stern layer such that it probes local rather than average electric fields. However, confirming this hypothesis will require further investigation.

Since the  $\text{OH}^-$  peak around  $3650\text{ cm}^{-1}$  represents the local concentration of  $\text{OH}^-$ , it is related to the local pH. In fact, it may be possible in the future to use this  $\text{OH}^-$  signature as an indicator to quantitatively measure the local pH of the electrode surface. At present, as demonstrated above the surface  $\text{OH}^-$  resides in the first molecular layer at the electrode surface. After the surface  $\text{OH}^-$  diffuses away from the surface, it forms hydrogen bonds with the surrounding water molecules, and the feature around  $3650\text{ cm}^{-1}$  disappears. A number of other techniques have been used to study the local pH near the electrode/electrolyte interface, such as SEIRAS,<sup>50</sup> and RRDE based local pH measurements.<sup>51,52</sup> Although each of these techniques measures related signals, they each sample different regions away from the actual interfaces (approximately 10 nm for SEIRAS and  $\mu\text{m}$  to mm scale for RRDE) and provide different but complementary information.

The experiments above represent direct observation of HER in the absence of  $\text{CO}_2\text{R}$ . We now consider the interfacial water spectrum measured in  $\text{CO}_2$ -purged  $\text{Na}_2\text{SO}_4$  electrolyte where HER is in competition with  $\text{CO}_2\text{R}$ , and  $\text{H}_2\text{CO}_3$  and  $\text{HCO}_3^-$  represent additional proton donors, which are not present in the Ar-purged electrolyte. VSFG spectra of 0.05 M  $\text{Na}_2\text{SO}_4$  solution saturated with  $\text{CO}_2$  are shown in Fig. 2a as a function of potential. At potentials more positive than  $-0.6\text{ V}$ , we observe two main features: free OH at  $3730\text{ cm}^{-1}$  and a broad peak around  $3630\text{ cm}^{-1}$ , which is assigned to a weakly hydrogen-bonded or singly hydrogen-bonded water.<sup>36,40</sup> The absence of peaks at lower frequency, which are usually observed at air/liquid<sup>34,36,53</sup> or solid/liquid interface<sup>54–56</sup> indicates a relatively disordered water structure at the Au electrode surface.<sup>18</sup> As more negative potential is applied, an additional peak around  $3400\text{ cm}^{-1}$  appears that increases with negative potential. This peak can be assigned either to liquid-like water<sup>34</sup> or to a H-bonding water network with a net lower coordination compared to tetrahedral water around  $3200\text{ cm}^{-1}$ .<sup>53,55,56</sup> Overall, the spectra of  $\text{Na}_2\text{SO}_4$  solution saturated with  $\text{CO}_2$  exhibit very different features compared to Ar-saturated electrolyte. Specifically, the sharp peak corresponding to surface  $\text{OH}^-$  at  $3650\text{ cm}^{-1}$  is not observed in  $\text{CO}_2$ -saturated electrolyte, and the peak around  $3400\text{ cm}^{-1}$ , which is absent for Ar-purged electrolyte, becomes significant under catalytic potentials in  $\text{CO}_2$ -saturated electrolyte.

The feature at  $3400\text{ cm}^{-1}$  cannot be attributed solely to the influence of  $\text{Na}^+$  or  $\text{SO}_4^{2-}$  on the interfacial water structure because these species are present in both Ar- and  $\text{CO}_2$ -purged electrolyte. In addition to  $\text{Na}^+$  and  $\text{SO}_4^{2-}$ ,  $\text{CO}_2$ -saturated electrolyte contains  $\text{H}_2\text{CO}_3$ ,  $\text{HCO}_3^-$ , and  $\text{CO}_3^{2-}$ , which is absent in Ar-purged electrolyte, and the equilibrium concentration of

Fig. 2 (a) VSFG spectra of  $\text{Na}_2\text{SO}_4$  (0.05 M) purged with  $\text{CO}_2$  as a function of potential vs. Ag/AgCl. (b) VSFG spectra of 50 mM  $\text{Na}_2\text{CO}_3$  solutions as a function of pH.

these species varies as a function of pH. To identify the origin of this feature, we explored the effects of various electrolyte compositions on the interfacial water spectrum. Results show that this peak is weak in Ar-purged NaCl, but is much more prominent in  $\text{CO}_2$ -purged NaCl as well as Ar- or  $\text{CO}_2$ -purged  $\text{NaHCO}_3$  electrolytes (see Fig. S5†), confirming a correlation between this feature and the presence of carbonate species at the interface. Additionally, we show that at fixed potential the intensity of this feature tracks closely with the  $\text{NaHCO}_3$  electrolyte concentration (see Fig. S6†). Based on these observations, we attribute this feature to water structure induced by carbonate species present in the electrochemical double layer.

To evaluate the relative contributions of  $\text{H}_2\text{CO}_3$ ,  $\text{HCO}_3^-$ , and  $\text{CO}_3^{2-}$  to this feature, Fig. 2b plots the VSFG spectra in 0.05 M  $\text{Na}_2\text{CO}_3$  electrolyte at  $-1.0$  V as a function of pH. The spectrum with pH = 11.3 (green curve) represents pure 0.05 M  $\text{Na}_2\text{CO}_3$  solution. To prepare the solution with pH = 6.7 (blue curve), this same solution is purged with  $\text{CO}_2$ , which converts the majority of  $\text{CO}_3^{2-}$  anions into  $\text{HCO}_3^-$  (see ESI Fig. S7†). To prepare the pH = 2.5 solution (red curve), HCl is added to 0.05 M  $\text{Na}_2\text{CO}_3$  solution. At pH = 2.5,  $\text{CO}_3^{2-}$  is almost completely converted to  $\text{H}_2\text{CO}_3$  as show in Fig. S7.† Fig. 2b shows that the spectrum obtained at pH = 11.3 includes a strong feature at  $3400\text{ cm}^{-1}$ , as well as a peak at  $3640\text{ cm}^{-1}$  corresponding to free  $\text{OH}^-$ . As pH is decreased to 6.7, we observe that the  $\text{OH}^-$  peak disappears, and the  $3400\text{ cm}^{-1}$  feature decreases in intensity. At pH = 2.5 the peak at  $3400\text{ cm}^{-1}$  entirely disappears, suggesting that this feature can be attributed to  $\text{CO}_3^{2-}$  with perhaps a minor contribution from  $\text{HCO}_3^-$ , but that neutral  $\text{H}_2\text{CO}_3$  does not contribute. While additional work is required to understand the actual water structure associated with these specific ion effects, here we use this feature as a spectral indicator of  $\text{HCO}_3^-$  and  $\text{CO}_3^{2-}$  at the

Au/electrolyte interface. It is important to note that, although negatively charged,  $\text{HCO}_3^-$  and  $\text{CO}_3^{2-}$  can approach the Au surface under negative potential due to ion pairing interactions with the  $\text{Na}^+$  cations comprising the Stern layer.<sup>57–60</sup>

Before further discussion, we consider the  $\chi^{(3)}$  bulk contribution in the spectra measured here. As demonstrated by several previous studies,<sup>23,61–64</sup> the  $\chi^{(3)}$  bulk contribution in interfacial water spectra is common at charged interfaces:  $\chi_{\text{eff}}^{(2)} = \chi_s^{(2)} + \chi_B^{(3)}\Phi$ , in which  $\chi_{\text{eff}}^{(2)}$  is the total SFG response,  $\chi_s^{(2)}$  is the surface contribution,  $\chi_B^{(3)}$  is the bulk contribution induced by the interfacial electric field and  $\Phi$  is the surface potential. As shown in Fig. S8,† the  $\chi_B^{(3)}$  bulk contribution in our spectra is less than 20% due to the 467 fs delay time of IR and 800 nm beams (see the details in ESI Section 6†). The absence of interference effects between bulk contribution and free-OH peaks also suggest that the  $\chi_B^{(3)}$  contribution does not significantly influence the shape or intensity of the free OH stretch reported here (Fig. S9†). Lastly, the peak around  $3200\text{ cm}^{-1}$  which is very pronounced in  $\chi_B^{(3)}$  bulk contribution<sup>61,62</sup> is not seen for all the spectra in this work (Fig. S9 & S10†). This further indicates that the  $\chi_B^{(3)}$  contribution is small. Although the  $\chi_B^{(3)}$  bulk contribution in interfacial water spectra presented in this work is small, disentangling the  $\chi_B^{(3)}$  bulk contribution is very important to gain a detailed physical picture of the Stern layer, and further work is required for a quantitative analysis.

Having identified these spectral signatures, we now consider the influence of  $\text{CO}_2$ -purging on the kinetics of HER and  $\text{CO}_2\text{R}$  at the Au/electrolyte interface. The linear sweep voltammograms of Ar- and  $\text{CO}_2$ -saturated  $\text{Na}_2\text{SO}_4$  solution are shown in Fig. 3a. The current densities agree with ones extracted during SFG measurement as shown in Fig. S11.† The onset potential for HER in Ar saturated  $\text{Na}_2\text{SO}_4$  solution is around  $-0.8$  V, but changes to  $-0.6$  V for  $\text{CO}_2$ -saturated  $\text{Na}_2\text{SO}_4$  solution. Fig. 3a is

Fig. 3 (a) Linear sweep voltammograms of Ar- (red curve) and CO<sub>2</sub>- (blue curve) saturated 0.05 M Na<sub>2</sub>SO<sub>4</sub> solution. The scan rate of the linear sweep voltammograms is 50 mV s<sup>-1</sup>. The current is normalized to the geometric area. (b). H<sub>2</sub> and CO faradaic efficiencies (left axis) for Ar/CO<sub>2</sub> saturated Na<sub>2</sub>SO<sub>4</sub>/NaHCO<sub>3</sub> solutions measured at -1.2 V vs. Ag/AgCl. The blue curves are the yield for H<sub>2</sub> (blue cube) and CO (purple dot).

replotted vs. RHE as shown in Fig. S12† given that the pH of Ar- and CO<sub>2</sub>-saturated Na<sub>2</sub>SO<sub>4</sub> solution are 7 and 5.6 respectively. The potential difference vs. RHE due to this change in electrolyte pH is only 0.08 V as shown in Fig. S12.† Apparently, the lower onset potential observed in CO<sub>2</sub>-saturated electrolyte cannot be explained solely by the change in bulk pH. Additionally, the current density is much higher for CO<sub>2</sub>-saturated Na<sub>2</sub>SO<sub>4</sub> solution at higher overpotentials indicating an increased rate of HER. Alternatively, CO<sub>2</sub>R, which can occur only in CO<sub>2</sub>-saturated Na<sub>2</sub>SO<sub>4</sub> solution, could lower the onset potential and increase the current density by creating an additional reaction channel for CO<sub>2</sub>R. In order to distinguish between currents generated by HER and CO<sub>2</sub>R, faradaic efficiencies (FE) for both reactions are measured in various Ar- and CO<sub>2</sub>-saturated electrolytes at an applied potential of -1.2 V vs. Ag/AgCl. As shown in Fig. 3b, the measured FE of CO for Ar- and CO<sub>2</sub>-saturated Na<sub>2</sub>SO<sub>4</sub> solutions are only 0% and 18.1% respectively. This indicates that the ~5-fold increase in current density observed for CO<sub>2</sub>-saturated Na<sub>2</sub>SO<sub>4</sub> electrolyte cannot be solely attributed to CO<sub>2</sub>R. Rather, CO<sub>2</sub> purging significantly enhances the rate of HER as measured here by direct detection of H<sub>2</sub>.

These measurements demonstrate that the presence of HCO<sub>3</sub><sup>-</sup> and CO<sub>3</sub><sup>2-</sup> formed from CO<sub>2</sub> purging significantly improves HER kinetics. This enhancement cannot be simply explained by the change in bulk pH. Instead, there are two possible mechanisms for HER enhancement by CO<sub>2</sub> purging: the first is interfacial pH buffering, and the second is the direct reduction of H<sub>2</sub>CO<sub>3</sub>/HCO<sub>3</sub><sup>-</sup> to produce H<sub>2</sub>. Considering the first mechanism, as shown by eqn (1)–(4), when water serves as the primary proton donor, the resulting OH<sup>-</sup> anion produced at the Au electrode diffuses out of the Stern layer and reacts with H<sub>2</sub>CO<sub>3</sub>/HCO<sub>3</sub><sup>-</sup>/CO<sub>2</sub>. Consequently, the presence of H<sub>2</sub>CO<sub>3</sub>/HCO<sub>3</sub><sup>-</sup>/CO<sub>2</sub> may help avoid the accumulation of OH<sup>-</sup> by serving as a buffer of the interfacial pH during active HER. Considering the second mechanism, as shown by eqn (5)–(6), H<sub>2</sub>CO<sub>3</sub> and HCO<sub>3</sub><sup>-</sup> can also directly serve as the proton donor for HER. This mechanism does not require pH buffering since OH<sup>-</sup> is not directly generated as an intermediate in this reaction. However,

OH<sup>-</sup> can be indirectly produced during this process by subsequent equilibration of HCO<sub>3</sub><sup>-</sup> and CO<sub>3</sub><sup>2-</sup> with water (*i.e.*, reverse reaction of eqn. (2)–(4)). Because these two pathways will eventually achieve the same equilibrium distribution of interfacial species regardless of the actual proton source for HER, these mechanisms can only be distinguished by monitoring surface speciation as the electrochemical double layer is pushed out of equilibrium during active HER.

Above we showed the interfacial water spectrum as a function of potential in Ar- and CO<sub>2</sub>-purged Na<sub>2</sub>SO<sub>4</sub> electrolyte. In Ar-purged Na<sub>2</sub>SO<sub>4</sub> electrolyte, we observe the production of surface OH<sup>-</sup> resulting from direct water reduction (Fig. 1). In contrast, OH<sup>-</sup> is not observed in CO<sub>2</sub>-purged Na<sub>2</sub>SO<sub>4</sub> electrolyte; instead, we detect the presence of CO<sub>3</sub><sup>2-</sup> in the electrochemical double layer during HER (Fig. 2). In addition to the loss of surface OH<sup>-</sup>, CO<sub>2</sub> purging results in an approximately 5-fold increase in the rate of HER (Fig. 3). It is not initially clear, whether the loss of OH<sup>-</sup> and the associated rate increase for HER is the result of pH buffering by H<sub>2</sub>CO<sub>3</sub>/HCO<sub>3</sub><sup>-</sup>/CO<sub>2</sub> (eqn (2)–(4)) or if H<sub>2</sub>CO<sub>3</sub>/HCO<sub>3</sub><sup>-</sup> serve as the primary proton source for H<sub>2</sub> production (eqn (5) and (6)). We now consider HER in 0.1 M NaHCO<sub>3</sub> electrolyte, which is commonly used for CO<sub>2</sub>R. Understanding the mechanism of H<sub>2</sub> production in this electrolyte is important, where HER is in direct competition with the FE for CO<sub>2</sub>R. Below we show that in this solution HER is governed by two potential-dependent regimes based on direct reduction of HCO<sub>3</sub><sup>-</sup> and water, respectively. Fig. 3b shows the kinetics of HER and CO<sub>2</sub>R in Ar- and CO<sub>2</sub>-purged 0.1 M

$\text{NaHCO}_3$ . In the case of Ar-purged electrolyte, we observe almost unity FE for  $\text{H}_2$  indicating a negligible rate of  $\text{CO}_2\text{R}$ , and this finding is also consistent with a recent study by Dunwell *et al.*<sup>59</sup> With  $\text{CO}_2$ -purging the yield of CO increases and the FE for  $\text{CO}_2\text{R}$  reaches approximately 60%. Focusing on Ar-purged  $\text{NaHCO}_3$  electrolyte, where only HER occurs, we find that the  $\text{H}_2$  yield is almost 3-fold higher compared to Ar-purged  $\text{Na}_2\text{SO}_4$  electrolyte. Again, this enhancement can be either the result of interfacial pH buffering by the much higher concentration of  $\text{HCO}_3^-$  or the result of direct reduction of  $\text{HCO}_3^-$  to produce  $\text{H}_2$ . Below we show that the actual enhancement is a potential-dependent combination of these two effects.

Fig. 4a shows the water spectra taken in Ar-purged  $\text{NaHCO}_3$  solution as a function of potential. At potentials more positive than  $-0.8$  V, these spectra are quite similar to those of  $\text{CO}_2$ -saturated  $\text{Na}_2\text{SO}_4$  solution shown in Fig. 2a. As more negative potential is applied, we observe the appearance of a strong feature at  $3400\text{ cm}^{-1}$ . Note that this peak is assigned to  $\text{CO}_3^{2-}$  since this feature only appears at the onset potential for HER despite the high concentration of  $\text{HCO}_3^-$  in this electrolyte. When the applied potential reaches  $-0.9$  V the  $\text{OH}^-$  peak at  $3650\text{ cm}^{-1}$  also appears. The interfacial product distribution has negligible contribution from  $\text{CO}_2\text{R}$  because the FE of CO is only about 1.2% (Fig. 3b) in Ar-saturated  $\text{NaHCO}_3$  solution. From these observations we conclude that surface  $\text{OH}^-$  is produced either by direct water reduction or by  $\text{HCO}_3^-$  reduction to  $\text{CO}_3^{2-}$  followed by equilibration with water to produce  $\text{OH}^-$  and  $\text{HCO}_3^-$  (eqn (2)). If the latter is true, we would also see the  $\text{OH}^-$  peak at  $3650\text{ cm}^{-1}$  for  $\text{Na}_2\text{CO}_3$  solution (0.1 M) since the  $\text{CO}_3^{2-}$  concentration in  $\text{Na}_2\text{CO}_3$  solution is much higher than in  $\text{NaHCO}_3$  solution (0.1 M). As shown in Fig. S13,<sup>†</sup> there is no apparent peak for  $\text{Na}_2\text{CO}_3$  solution. This indicates that the

surface  $\text{OH}^-$  observed in Fig. 4a is produced by direct water reduction. Consequently, the observation of the surface  $\text{OH}^-$  in  $\text{NaHCO}_3$  solution provides strong evidence that the proton source of HER in  $\text{CO}_2$ -saturated  $\text{Na}_2\text{SO}_4$  solution is not water. As demonstrated above, during electrochemical water reduction, surface  $\text{OH}^-$  is a transient, non-equilibrium species that resides at the very first layer of the electrode surface. Due to the repulsive Coulomb force,  $\text{OH}^-$  is repelled by the negatively charged Au electrode and is expected to diffuse rapidly into the electric double layer. Based on our previous works, the electric field for 0.1 M  $\text{NaHCO}_3$  at the electrode surface at  $-1.0$  V is as high as  $\sim 4 \times 10^7\text{ V cm}^{-1}$ .<sup>40,65</sup> The intense electric field represents a strong driving force for free  $\text{OH}^-$  to desorb and diffuse away from the surface. Outside of the outer Helmholtz plane (OHP),  $\text{OH}^-$  will form H-bond with surrounding water, and we can no longer observe the characteristic stretch of free  $\text{OH}^-$  at  $3650\text{ cm}^{-1}$ . Consequently, we only detect free  $\text{OH}^-$  generated by water reduction inside the OHP, while  $\text{OH}^-$  produced indirectly *via* eqn (2) and (3) occurs in the diffuse layer and beyond and will not be detected as free  $\text{OH}^-$  as shown in Fig. S13.<sup>†</sup> Therefore, without sufficient hydroxide ions generated at the surface, the hydroxide peak around  $3650\text{ cm}^{-1}$  is not observed for the  $\text{CO}_2$ -saturated  $\text{Na}_2\text{SO}_4$  solution. If buffering by the  $\text{HCO}_3^-/\text{H}_2\text{CO}_3$  equilibrium (eqn (2) and (3)) for the  $\text{CO}_2$ -saturated  $\text{Na}_2\text{SO}_4$  solution is sufficient to consume all the surface  $\text{OH}^-$  prior to desorption we would not be able to detect the free  $\text{OH}^-$  peak for 0.1 M  $\text{NaHCO}_3$  solution (Fig. 4) since the  $\text{HCO}_3^-$  concentration is much higher than  $\text{HCO}_3^-/\text{H}_2\text{CO}_3$  in  $\text{Na}_2\text{SO}_4$  solution (Fig. 2). The concentrations of  $\text{H}_2\text{CO}_3$  and  $\text{HCO}_3^-$  in  $\text{CO}_2$ -saturated  $\text{Na}_2\text{SO}_4$  solution are only  $\sim 5.6 \times 10^{-5}\text{ M}$ ,  $4.9 \times 10^{-6}\text{ M}$  respectively. The actual concentration of  $\text{HCO}_3^-$  in Ar-purged 0.1 M  $\text{NaHCO}_3$  is close to the 0.1 M formal

Fig. 4 (a) VSFG spectra of  $\text{NaHCO}_3$  (0.1 M) purged with Ar as a function of potential vs. Ag/AgCl. (b) Relative amplitudes of  $\text{CO}_3^{2-}$  feature at approximately  $3400\text{ cm}^{-1}$  (red curve) and  $\text{OH}^-$  feature at  $3640\text{ cm}^{-1}$  (blue curve) as a function of potential. The amplitudes are extracted from fitting results of the curves (Table S2<sup>†</sup>). Amplitudes of both peaks are independently normalized to their maximum intensity observed in the potential range between  $-0.2$  to  $-1.4$  V.

concentration, which is several orders higher than  $\text{HCO}_3^-/\text{H}_2\text{CO}_3$  in  $\text{Na}_2\text{SO}_4$  solution. As shown in Fig. 4a, when the applied potential reaches  $-0.9$  V, the surface  $\text{OH}^-$  peak around  $3650\text{ cm}^{-1}$  appears and becomes more intense as increasingly negative potentials are applied. This suggests that even in  $0.1$  M  $\text{NaHCO}_3$  solution,  $\text{HCO}_3^-$  is not sufficient to consume all the surface  $\text{OH}^-$  generated by water reduction, not to mention  $\text{Na}_2\text{SO}_4$  solution with much lower  $\text{HCO}_3^-/\text{H}_2\text{CO}_3$  concentrations. Thus, the complete disappearance of the hydroxide peak for the  $\text{CO}_2$ -saturated  $\text{Na}_2\text{SO}_4$  solution indicates that the proton source switched from water to  $\text{H}_2\text{CO}_3$  and  $\text{HCO}_3^-$  otherwise the hydroxide peak should be observed. As pointed out in a recent work by Liu *et al.*<sup>52</sup> the equilibrium between  $\text{HCO}_3^-$  and  $\text{CO}_3^{2-}$  should be established within microseconds, while it takes on the order of  $10$  s to reach equilibrium for the  $\text{CO}_2/\text{HCO}_3^-$  buffer at pH 5.35–7.35 due to the slow hydration of  $\text{CO}_2$ . In our work, the relatively fast buffer by  $\text{HCO}_3^-$  is not sufficient to consume the surface  $\text{OH}^-$  (Fig. 1a). The much slower equilibration for the  $\text{CO}_2/\text{HCO}_3^-$  buffer certainly cannot be responsible for the complete disappearance of the surface  $\text{OH}^-$  peak of the  $\text{CO}_2$ -saturated  $\text{Na}_2\text{SO}_4$  solution. All these observations suggest that in  $\text{CO}_2$ -saturated  $\text{Na}_2\text{SO}_4$  solution the proton source is  $\text{HCO}_3^-/\text{H}_2\text{CO}_3$  rather than  $\text{H}_2\text{O}$ .

As for  $\text{NaHCO}_3$  solution, to resolve between the two above mentioned mechanisms, we plot the intensity of the features corresponding to  $\text{OH}^-$  and  $\text{CO}_3^{2-}$  as a function of potential (Fig. 4b), showing two regions with different trends. In the potential window between  $-0.8$  V and  $-1.0$  V, the intensity of  $\text{OH}^-$  remains low while  $\text{CO}_3^{2-}$  increases significantly with applied potential. In contrast, at higher overpotential beyond  $-1.0$  V, the intensity of  $\text{OH}^-$  increases rapidly while the intensity of  $\text{CO}_3^{2-}$  decreases. The distinct behaviour in these two regions suggests that the mechanism of HER is potential dependent with  $-1.2$  V as the approximate crossover point where the intensity of  $\text{OH}^-$  becomes the dominate feature in the interfacial water spectrum.

Considering the relative intensities of these two features, we evaluate the two possible mechanisms for enhanced HER in  $\text{NaHCO}_3$  electrolyte. First we consider the pH buffering mechanism. As long as the consumption of  $\text{OH}^-$  *via* eqn (2) and (3) are faster than  $\text{OH}^-$  production, no experimental technique is expected to unequivocally prove the presence of direct reduction of bicarbonate to carbonate. But as we demonstrated above, the consumption of  $\text{OH}^-$  *via* eqn (2) and (3) is slower than  $\text{OH}^-$  production, otherwise the  $\text{OH}^-$  peak should be observed in Fig. 2a in  $\text{CO}_2$ -saturated  $\text{Na}_2\text{SO}_4$  solution and the  $\text{OH}^-$  peak should not be observed for Ar-saturated  $0.1$  M  $\text{NaHCO}_3$  solution in Fig. 4a. If we assume that enhanced HER is the result of interfacial pH buffering, then as the potential is increased and the buffering kinetics of  $\text{HCO}_3^-$  can no longer keep up with the rate of water reduction, we expect to see  $\text{CO}_3^{2-}$  and  $\text{OH}^-$  features grow in intensity together and saturate as the interface becomes increasingly basic. However, this is not what we observe. Instead, we observe a crossover at approximately  $-1.2$  V where  $\text{CO}_3^{2-}$  has decreased in intensity as the surface-bound  $\text{OH}^-$  feature has increased significantly. This cannot be explained by an equilibrium reaction where the

concentration of  $\text{OH}^-$  and  $\text{CO}_3^{2-}$  would trend in the same direction. Fig. 4b shows a measurable decrease in the intensity of the carbonate peak. If this peak is the result of buffering *via* eqn (2) and (3) this peak should increase as potential becomes more negative, and eventually remain constant at the point where all interfacial bicarbonate has been converted to carbonate. However, the decrease of this peak cannot be a result of  $\text{CO}_3^{2-}$  production *via* eqn (2), where this equilibrium should cause the concentration of  $\text{CO}_3^{2-}$  to increase monotonically and then saturate. Rather the decrease in intensity of this feature at potentials beyond  $-1.1$  V is best explained as a crossover from bicarbonate reduction at more positive applied potential to primarily water reduction at more negative applied potential. Thus, Fig. 4b indicates a shift in the non-equilibrium interfacial product distribution as the proton source for HER switches from primarily  $\text{HCO}_3^-$  at low overpotential ( $\text{CO}_3^{2-}$  product) to  $\text{H}_2\text{O}$  at higher overpotential ( $\text{OH}^-$  product). This picture is also consistent with a recent study by Koper and co-workers where kinetic measurements with a rotating ring disk electrode indicate that at increasing overpotential, the primary proton donor for HER in  $\text{CO}_2$  saturated  $\text{NaHCO}_3$  electrolyte switches from  $\text{H}_2\text{CO}_3$  to  $\text{HCO}_3^-$  and finally to water at increasing overpotential.<sup>15</sup> They predicted the crossover from  $\text{HCO}_3^-$  to water occurs at approximately  $-0.5$  V *vs.* RHE, which closely matches the crossover point shown in Fig. 4b (note that  $-0.5$  V *vs.* RHE is equivalent to  $-1.1$  V *vs.* Ag/AgCl for Ar-saturated  $\text{NaHCO}_3$  electrolyte where pH is 8.3). Based on these direct measurements of the Au/electrolyte interface, we conclude that the significantly enhanced rate of HER in  $\text{NaHCO}_3$  electrolyte is the result of  $\text{HCO}_3^-$  reduction for potentials between  $-0.8$  V to  $-1.0$  V. A transition occurs between  $-1.0$  V and  $-1.2$  V where direct water reduction begins to occur. At potentials beyond  $-1.2$  V HER kinetics appear to be dominated by direct water reduction, and any enhancement by  $\text{HCO}_3^-$  on the rate of HER is assumed to be the result of interfacial pH buffering. However, as shown by the crossover in Fig. 4b, pH buffering by  $\text{HCO}_3^-$  (eqn (2)) is unable to keep up with the kinetics of water reduction as the overpotential increases. This finding is also consistent with previous studies by Wuttig *et al.* who have shown that that the  $\text{CO}_2/\text{HCO}_3^-/\text{H}_2\text{CO}_3$  equilibrium suffers from slow kinetics, making it a sluggish buffer to maintain the surface pH.<sup>66</sup>

Overall, these observations reflect a competition between the acidity of the various potential proton donors and their potential dependent interfacial concentrations. Specifically, the  $\text{pK}_a$  values of  $\text{HCO}_3^-$  and  $\text{H}_2\text{CO}_3$  are 10.32 and 6.37, respectively, while water has a much higher  $\text{pK}_a$  of 14. Although water ( $55$  M) is 550 times more concentrated than  $\text{HCO}_3^-$  in  $0.1$  M  $\text{NaHCO}_3$  electrolyte,  $\text{HCO}_3^-$  is approximately 4 orders of magnitude more acidic. Thus  $\text{HCO}_3^-$  is observed to be the major proton donor at low overpotential where the electric field is not so strong as to completely repel negatively charged  $\text{HCO}_3^-$  anions from the interface. However, as overpotential increases, direct reduction of water becomes facile, and the increasingly negative electric field repels anions  $\text{HCO}_3^-$  from the interface. As this happens, the availability of  $\text{HCO}_3^-$  cannot keep up with the increasing rate of HER, and water eventually replaces  $\text{HCO}_3^-$  as the

primary proton donor. The  $\text{OH}^-$  produced by water reduction subsequently diffuses out of the Helmholtz plane where it is partially buffered by reaction with  $\text{HCO}_3^-$  and/or  $\text{H}_2\text{CO}_3$ . A similar effect also controls the kinetics for  $\text{CO}_2$ -purged  $\text{Na}_2\text{SO}_4$  (Fig. 2), although in this case the bulk solution pH is more acidic (pH = 5.6) compared to Ar-purged  $\text{NaHCO}_3$  (pH = 8.3). Due to the decrease in pH, the  $\text{HCO}_3^-/\text{H}_2\text{CO}_3$  equilibrium is shifted toward  $\text{H}_2\text{CO}_3$ . Because  $\text{H}_2\text{CO}_3$  is more acidic than  $\text{HCO}_3^-$  and does not carry a negative charge, the direct reduction of  $\text{H}_2\text{CO}_3$  may preclude water reduction out to even more negative potential. We hypothesize that this explains why we do not observe  $\text{OH}^-$  in  $\text{CO}_2$ -purged  $\text{Na}_2\text{SO}_4$  electrolyte out to potentials as negative as  $-1.1$  V (see Fig. 2a).

### 3 Conclusions

In summary, *in situ* VSFG measurements provide direct observation of the Au/electrolyte interface during HER in various electrolytes. The presence of transient surface hydroxide ions ( $\text{OH}^-$ ) formed at electrode surface as the product of water reduction within the outer Helmholtz plane is reported for the first time. This species is indicated by the sharp hydroxide peak at  $3650\text{ cm}^{-1}$ . Notably this peak is absent for the  $\text{CO}_2$ -saturated solution, where instead a peak around  $3400\text{ cm}^{-1}$  is observed and is assigned to the presence of  $\text{CO}_3^{2-}$  in the electrochemical double layer. By directly observing the response of these features as the system is pushed away from equilibrium during active HER, we are able to differentiate between water and  $\text{HCO}_3^-$  reduction and to understand the related effects of proton source and interfacial pH buffering on the kinetics of HER. The results provide important insights regarding how to suppress HER during  $\text{CO}_2\text{R}$ . Specifically, for electrocatalysts with high activity at low overpotential, it is not necessary to reduce interfacial water concentration since water is not the proton donor for HER. Instead, reducing  $\text{H}_2\text{CO}_3$  and  $\text{HCO}_3^-$  while maintaining a high interfacial concentration of  $\text{CO}_2$  is most important for suppressing HER. Alternatively, for electrocatalysts, which require high overpotential for  $\text{CO}_2\text{R}$ , it is critical to reduce the concentration of interfacial water to suppress HER as water serves as the primary proton source below  $-1.2$  V.

### Author contributions

L. R. B. and G.-H. D. conceived the experiments. G.-H. D. conducted SFG and LSV measurements. Q. Z. helped with the SFG experiments. T. N. conducted the FE measurements. G.-H. D., Q. Z., J. R., and L. R. B. analysed the results. G.-H. D. wrote the original draft. G.-H. D., Q. Z. and L. R. B. revised the manuscript. All of the authors reviewed the manuscript.

### Conflicts of interest

The authors declare no competing financial interest.
