# Programmable synthesis of difluorinated hydrocarbons from alkenes through a photocatalytic linchpin strategy†

Zhi-Qi Zhang,<sup>abc</sup> Cheng-Qiang Wang,<sup>c</sup> Long-Ji Li,<sup>ac</sup> Jared L. Piper,<sup>d</sup> Zhi-Hui Peng,<sup>\*d</sup> Jun-An Ma,<sup>ib</sup> Fa-Guang Zhang<sup>ib</sup> and Jie Wu<sup>ib</sup>

The introduction of difluoromethylene moieties into organic molecules has garnered significant attention due to their profound influence on the physicochemical and biological properties of compounds. Nonetheless, the existing approaches for accessing difluoroalkanes from readily available feedstock chemicals remain limited. In this study, we present an efficient and modular protocol for the synthesis of difluorinated compounds from alkenes, employing the readily accessible reagent,  $\text{ClCF}_2\text{SO}_2\text{Na}$ , as a versatile “difluoromethylene” linchpin. By means of an organophotoredox-catalysed hydrochlorodifluoromethylation of alkenes, followed by a ligated boryl radical-facilitated halogen atom transfer (XAT) process, we have successfully obtained various difluorinated compounds, including *gem*-difluoroalkanes, *gem*-difluoroalkenes, difluoromethyl alkanes, and difluoromethyl alkenes, with satisfactory yields. The practical utility of this linchpin strategy has been demonstrated through the successful preparation of  $\text{CF}_2$ -linked derivatives of complex drugs and natural products. This method opens up new avenues for the synthesis of structurally diverse difluorinated hydrocarbons and highlights the utility of ligated boryl radicals in organofluorine chemistry.

## Introduction

The incorporation of difluoroalkyl groups into organic molecules has garnered significant and sustained attention due to their impact on the physicochemical and biological properties of these molecules.<sup>1–6</sup> To date, most efforts to construct difluorinated scaffolds rely on deoxyfluorination of carbonyl compounds<sup>7–9</sup> or transition metal or Lewis acid-catalysed/mediated difluoroalkylation and difluorination reactions,<sup>10–13</sup> with a particular focus on aryl- $\text{CF}_2$  systems. However, synthetic approaches to access *gem*-difluoroalkanes  $\{\text{C}(\text{sp}^3)\text{-CF}_2\text{-C}(\text{sp}^3)\}$  from abundant feedstock chemicals remain scarce.<sup>14–20</sup> Although a few examples have been reported to form aliphatic

difluorinated moieties from unactivated alkenes, these approaches have been limited to using alkyl  $\text{CF}_2\text{-Br/I}$  as the starting  $\text{CF}_2$  precursors.<sup>21,22</sup> Thus, there is a pressing need for novel, efficient, and robust methods to expand the diversity of *gem*-difluorinated compounds, particularly those derived from unactivated aliphatic systems.

Ligated boryl radicals, denoted by the general formula  $\text{L}^+\text{-R}_2\text{B}^{\bullet-}$ , are stabilized by coordination to amines, phosphines, sulphides, or *N*-heterocyclic carbenes (NHCs) and share seven electrons in their valence shell.<sup>23–25</sup> Notably, ligated boryl radicals exhibit a strong nucleophilic character and offer considerable potential for halogen atom transfer (XAT) and hydrogen atom transfer (HAT) processes by tuning the Lewis base motifs.<sup>26–30</sup> For instance, the Ye group successfully activated electron-deficient C–H bonds by employing a quinuclidine-borane (**LB 1**) as the HAT reagent to realize a radical hydroalkylation reaction of unactivated alkenes in 2021 (Fig. 1a).<sup>31</sup> However, the XAT process triggered by ligated-boryl radicals was only known to activate alkyl iodides and bromides for decades,<sup>32–36</sup> until recently, when our group successfully activated the C–Cl bond ( $\text{BDE}_{\text{cal.}} = 87 \text{ kcal mol}^{-1}$ ) from chlorodifluoromethane ( $\text{ClCF}_2\text{H}$ , Freon-22) under blue light irradiation, using commercially available and inexpensive trimethylamine-borane (**LB 2**) as the XAT reagent (Fig. 1b).<sup>37</sup> At the same time, the Wang group reported a three-step process for sequential C–Cl bond functionalization of activated trichloromethyl groups

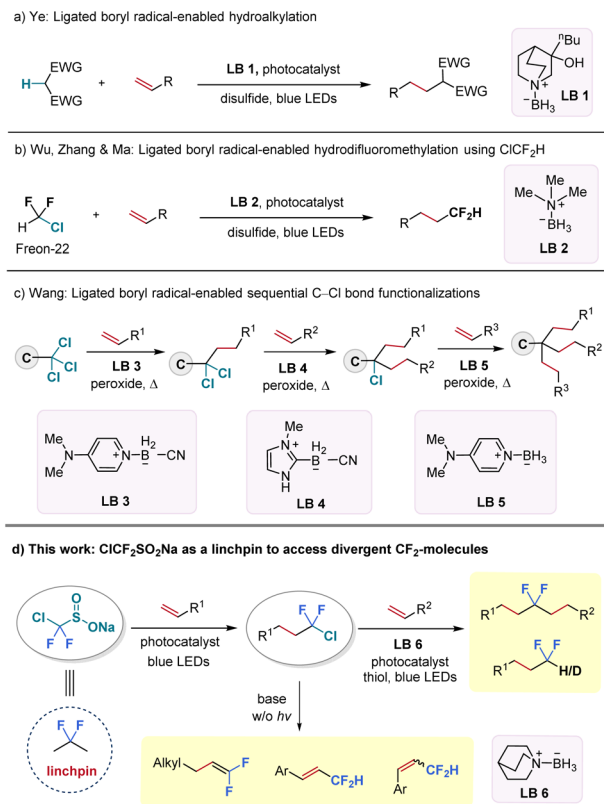

Fig. 1 Ligated borane-enabled HAT and XAT processes.

with the choice of an appropriate ligated borane reagent in each step (LB 3–5) (Fig. 1c).<sup>38</sup>

Encouraged by these recent scientific advancements, we aimed to establish a protocol for ligated boryl radical-promoted C–Cl bond functionalization of C(sp<sup>3</sup>)–CF<sub>2</sub>–Cl substrates to provide a novel and streamlined method for accessing *gem*-difluorinated aliphatic backbones, which were previously challenging to obtain. Along this endeavour, we turned our attention to an easily accessible reagent—sodium chlorodifluoromethylsulfonate (ClCF<sub>2</sub>SO<sub>2</sub>Na) as the CF<sub>2</sub>-precursor.<sup>39–41</sup> The proposed sequence involves two radical carbon–carbon bond formation transformations and has the potential to connect two alkene fragments through the valuable CF<sub>2</sub>-unit (Fig. 1d). If successful, this protocol would open an interesting avenue for synthesizing structurally divergent difluorinated hydrocarbons, with ClCF<sub>2</sub>SO<sub>2</sub>Na serving as a practical “linchpin”.<sup>42–48</sup> While the “linchpin” strategy has been explored in recent years to link two molecular skeletons through linkers such as alkyne, alkene, and sulfone groups, its application in organofluorine chemistry remains underdeveloped.<sup>49–51</sup> Herein, we collaborated with colleagues from Pfizer to prepare ClCF<sub>2</sub>SO<sub>2</sub>Na in kilogram-scale. By merging radical chlorodifluoromethylation of alkenes with a subsequent ligated boryl radical-facilitated hydrodifluoroalkylation of different alkenes, we were able to easily access a wide variety of internal *gem*-difluoro alkanes under mild visible-light irradiation conditions. Furthermore, photo-induced hydrodechlorination and base-promoted elimination

reactions enabled the synthesis of a broad range of terminal *gem*-difluorinated alkanes and alkenes (Fig. 1d).

## Results and discussion

### Development of hydrochlorodifluoromethylation of alkenes

Our investigation began with the development of a radical chlorodifluoromethylation protocol for alkenes with ClCF<sub>2</sub>–SO<sub>2</sub>Na. A screening of photocatalysts, thiols, and solvents established that the desired product **1j** was obtained in up to 86% isolated yield by conducting the reaction with Mes-Acr-Me<sup>+</sup>ClO<sub>4</sub><sup>–</sup> as the photocatalyst and methyl thiosalicylate as the HAT mediator in a mixed solvent of CHCl<sub>3</sub>/CF<sub>3</sub>CH<sub>2</sub>OH (9/1, 0.2 M, see the ESI Table 1† for optimization details). As shown in Fig. 2A, this protocol accommodated a wide range of unactivated mono-, di-, and trisubstituted alkenes (**1a–1s**) with good to high yields. Notably, the reaction conditions tolerated various functional groups, including those bearing silicon (**1b**), phosphine (**1c**), amine (**1d**), silyl ether (**1k** and **1m**), free hydroxyl group (**1l**), aldehyde (**1i**), tosylate (**1n**), hetero/aliphatic-cyclic rings (**1f**, **1g**, and **1r**), alkyne (**1k**), and bromide (**1p**). Additionally, a substrate bearing two olefin motifs was fully chlorodifluoromethylated at both sites in a 71% yield (**1t**). Notably, selected complex alkenes derived from natural products or drug molecules were found to be well-tolerated under standard conditions, affording the corresponding difluorinated derivatives (**1u–1ae**) in good yields.

When the scope of this protocol was extended to styrenes, however, low yields were observed for the target chlorodifluoromethylation products due to undesired polymerization side reactions in the presence of the acridinium photocatalyst. Notably, cyanoarenes have been previously shown to serve as effective organophotocatalysts for the hydrofluoroalkylation of styrenes, with the solvent choice playing a critical role.<sup>52</sup> Taking this into account, we investigated various organic photocatalysts and solvents, ultimately finding that the desired reaction could be achieved using 1,2,3,5-tetrakis(carbazol-9-yl)-4,6-dicyanobenzene (4CzIPN) in DMSO (Fig. 2B, see the ESI Table 2† for screening details). The protocol was shown to be effective for a range of styrenes substituted at *ortho*-, *meta*-, or *para*-positions of the phenyl ring, yielding the desired products in moderate to good yields (**1af–1ao**). Furthermore, the protocol successfully delivered chlorodifluoromethylation products from substrates including 2-naphthyl (**1ap**), heteroaromatic (**1aq**), cyclic internal alkene (**1ar**), 1,2-disubstituted (**1ar–1at**) and 1,1-disubstituted (**1au**) styrene derivatives. Importantly, the reaction could be easily scaled up to gram-scale with minimal loss (**1k**, **1af**, **1ag**, and **1aj**), highlighting the practical synthetic utility of this protocol. In addition, relatively complex styrenes derived from estrone or phenylalanine are also accommodated in this reaction to give **1av** and **1aw** in moderate yields.

### Synthesis of *gem*-difluorinated alkanes from alkenes

With a series of chlorodifluoromethyl alkanes in hand, our study then focused on the selective activation of the C–Cl bond by choosing compound **1k** as the model substrate with

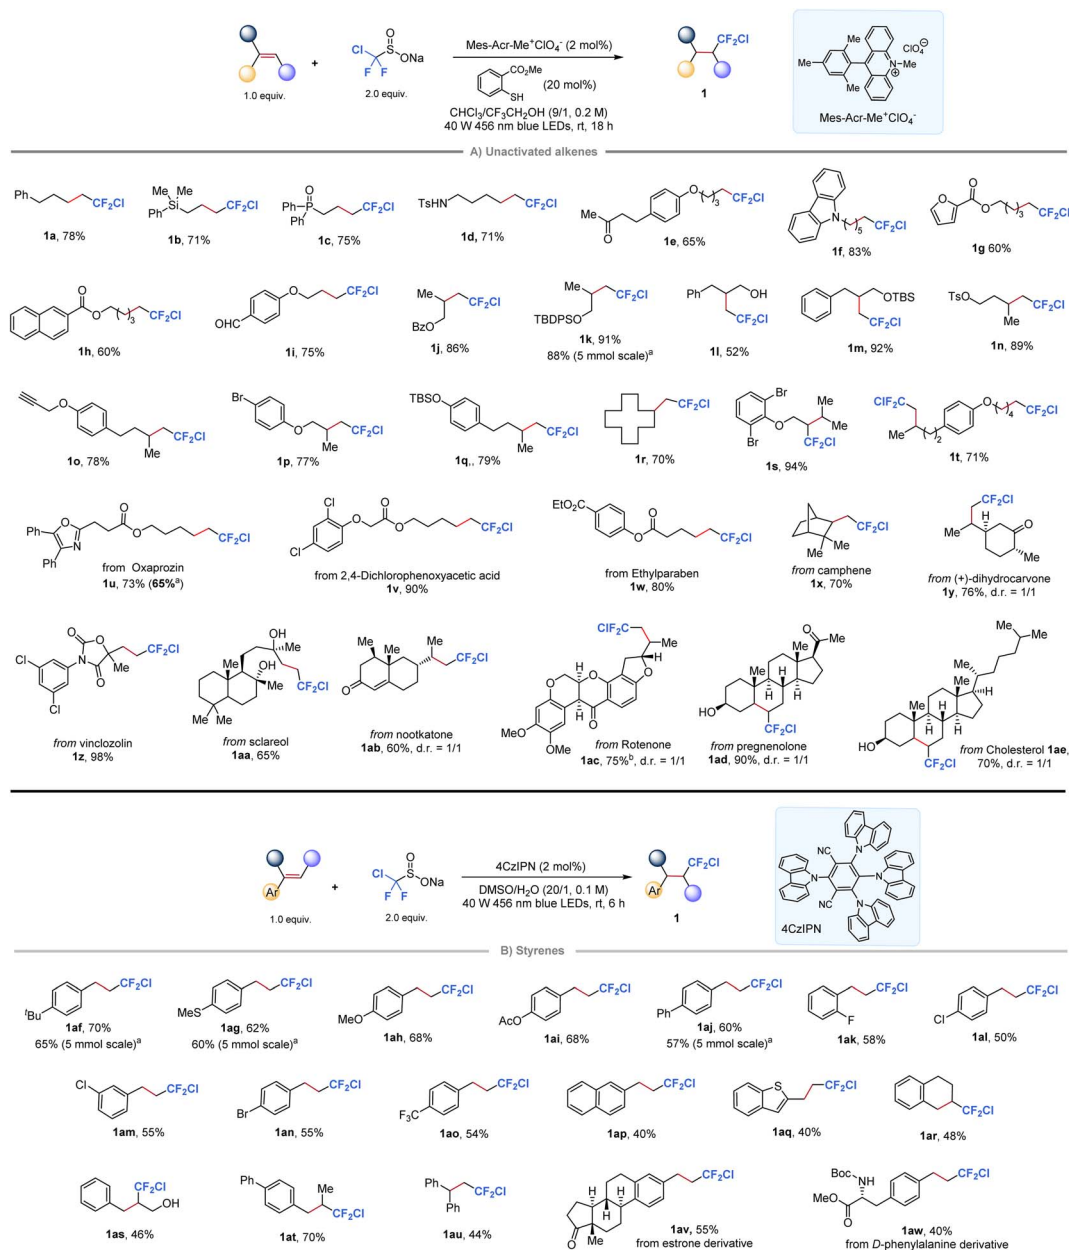

Fig. 2 Hydrochlorodifluoromethylation of alkenes with  $\text{ClCF}_2\text{SO}_2\text{Na}$ . <sup>a</sup>5.0 mmol of alkenes, 3.0 equiv. of  $\text{ClCF}_2\text{SO}_2\text{Na}$ ; <sup>b</sup>3.0 equiv. of  $\text{ClCF}_2\text{SO}_2\text{Na}$ .

unactivated alkenes. A systematic optimization of the reaction parameters, including photocatalysts, ligated boranes (XAT reagents), disulfides (HAT reagents), solvents, and light source, revealed that the desired product **2a** could be obtained in 90% yield by utilizing quinuclidine-ligated borane **LB 6** in combination with a simple phenyl thiol under blue light irradiation conditions (see the ESI Table 3† for optimization details). Fig. 3 illustrates the assembly of  $\text{CF}_2$ -linked aliphatic hydrocarbons through an organophotoredox-catalysed radical chlorodifluoromethylation coupled with ligated boryl radical-enabled hydrodifluoroalkylation, starting from  $\text{ClCF}_2\text{SO}_2\text{Na}$ . As a proof of concept study, we briefly explored the scope of  $\text{ClCF}_2$ -alkanes (**1k**, **1af**, **1ag**, and **1aj**) to connect with unactivated alkenes. The

study found that a wide range of mono-substituted alkenes with various functional groups, such as tosylate (**2b**), free hydroxyl group (**2c**), ester (**2e** and **2k**), amide (**2f**), carbonyl group (**2j** and **2x**), chloride (**2t**), and free carboxylic acid (**2p**), were all compatible to deliver the corresponding difluorinated products in moderate to high yields. Phosphorus (**2d**), nitrogen (**2i**), oxygen (**2u**), and silicon (**2o** and **2v**) atom-tethered alkenes were also competent reaction partners. Furthermore, cyclic structures, including carbazole (**2g** and **2l**), furan (**2m**), oxetane (**2n**), cyclododecane (**2r**) and adamantane (**2y**), underwent the reaction smoothly. It should be noted that the reaction between ethylene, the largest-volume and cost-effective industrial chemical that has an annual production of over 150 million

Fig. 3 Synthesis of internal *gem*-difluoro alkanes from two alkenes and  $\text{ClCF}_2\text{SO}_2\text{Na}$ . <sup>a</sup>1a (0.2 mmol, 1.0 equiv.), 1 atm balloon of ethylene. <sup>b</sup>50 equiv. of  $\text{H}_2\text{O}$  was added.

tons, and **1y** led to the formation of *gem*-difluoroalkane (**2q**) with a yield of 46%. Additionally, the linchpin strategy demonstrated effective utilization in the late-stage functionalization of complex alkenes derived from pharmaceutical

molecules and natural products. Unactivated alkenes containing the core structures of norbornene (**2z**), camphene (**2aa**), carprofen (**2ab**), or sclareol (**2ac**) smoothly reacted with **1y** with good yields. Importantly, it was feasible to use the linchpin

strategy to connect two bioactive olefins derived from oxaprozin and *L*-menthol (**2ad**), or *L*-(-)-borneol (**2ae**), or ibuprofen (**2af**) or 2,4-dichlorophenoxyacetic acid (**2ag**), which clearly indicates the broad applicability of this strategy. Among the tested alkenes, relatively lower yields were observed for substrates containing allylic alcohols or silanes (*i.e.*, **2u**, **2v** and **2x**) due to the simultaneous formation of C=C bond-reduced by-products. Lower conversions accounted for the moderate yields of some substrates (*i.e.*, **2b**, **2i** and **2y**), and dechlorination of intermediate **1** would be the major process after prolonging the reaction time. Alternatively, low solubility of some alkene starting materials or alkyl-CF<sub>2</sub>Cl intermediates in <sup>t</sup>BuCN might result in moderate yields of some products (*i.e.*, **2ab**, **2ad–2ag**).

To further demonstrate the synthetic application of the ClCF<sub>2</sub>-alkane intermediates, various transformations have been explored (Fig. 4). Initially, in the absence of an alkene, hydrodechlorination triggered by quinuclidine-ligated borane

(**LB 6**) was achieved by employing a more sterically hindered hydrogen atom donor, bis(2,4,6-triisopropylphenyl) disulfide (TRIPS)<sub>2</sub> (Fig. 4A). Substrates derived from both unactivated alkenes and styrenes were found to be suitable for this transformation (**3a–3d**). Moreover, ClCF<sub>2</sub>-alkanes obtained from natural products, such as oxaprozin, ethylparaben and sclareol, were also efficiently converted to the corresponding products through hydrodechlorination with moderate yields (**3e–3g**). Furthermore, *gem*-difluoroalkenes (**3h** and **3i**) were obtained in variable yields by simply treating ClCF<sub>2</sub>-alkane **1** with <sup>t</sup>BuOK (Fig. 4B).<sup>53,54</sup> Notably, ClCF<sub>2</sub>-alkanes derived from styrenes reacted with <sup>t</sup>BuOK to give conjugated (*E*)-β-difluoromethyl styrenes (**3j–3l**) in high yields attributed to the C=C bond migration to more conjugated systems (Fig. 4C). In addition, inspired by recent advances in *E* to *Z* photoisomerization of alkenes through an energy transfer process,<sup>55</sup> adding Ir(ppy)<sub>3</sub> as a triplet photosensitizer in a one-pot two-step manner led to the formation of (*Z*)-β-difluoromethyl styrenes as the major products (**3m–3o**) with a *Z/E* ratio of up to 4 : 1 (Fig. 4D).

### Mechanistic considerations

In order to gain a better understanding of the C–Cl bond activation mechanism, a series of experiments were conducted (Fig. 5). First, the isolation of byproduct quinuclidine-BH<sub>2</sub>Cl **4** (confirmed by the X-ray crystallographic analysis) provides support for the proposed key XAT process (Fig. 5a). A radical clock experiment using β-pinene resulted in the formation of the ring-opened product **5** in 57% yield (Fig. 5b). In addition, a radical trapping experiment was also performed using 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO), which completely inhibited the formation of the difluoroalkylation product **2a**. Instead, the TEMPO-intercepted species **6** was detected by high resolution mass spectrometry (HRMS) (Fig. 5c). These results strongly suggest the involvement of alkyl-CF<sub>2</sub> radicals in the reaction process. Furthermore, two parallel reactions were conducted using quinuclidine-BH<sub>2</sub>Cl and quinuclidine-BD<sub>2</sub>Cl (about 60% deuterated) with excess deuterium oxide as an additive (Fig. 5d). The results showed that product **3b**, with much higher deuterium incorporation, was observed in the latter case (36% *vs.* 81% deuterium incorporation, respectively). This finding suggests that the hydrogen atom of the CF<sub>2</sub>H-product was most likely derived from quinuclidine-BH<sub>3</sub> through a HAT process. In addition, the very low value of quantum yield ( $\Phi = 0.0013$ ) supports the possibility of an in-cage mechanism (See the ESI† for details). Stern–Volmer quenching experiments indicated that the excited photocatalyst could be quenched more effectively by PhSSPh than by ligated borane or the alkyl-CF<sub>2</sub>Cl intermediate (See the ESI† for details).

A tentative mechanism is proposed based on all the experimental data and previous literature reports<sup>31,37,38</sup> (Fig. 5e). The excited-state photocatalyst [4CzIPN]\* [ $E_{1/2}(\text{PC}^{+}/\text{PC}^{*}) = -1.18 \text{ V vs. SCE in MeCN}$ ] is presumed to reduce the aryl thiol radical to thiol anion species [ $E(\text{PhS}^{\bullet}/\text{PhS}^{-}) = 0.16 \text{ V vs. SCE}$ ]. Then PC<sup>+</sup> would trigger the formation of the key ligated boryl radical intermediate (L-BH<sub>2</sub>•) through either a single electron transfer (SET)/deprotonation sequence or a concerted proton-coupled

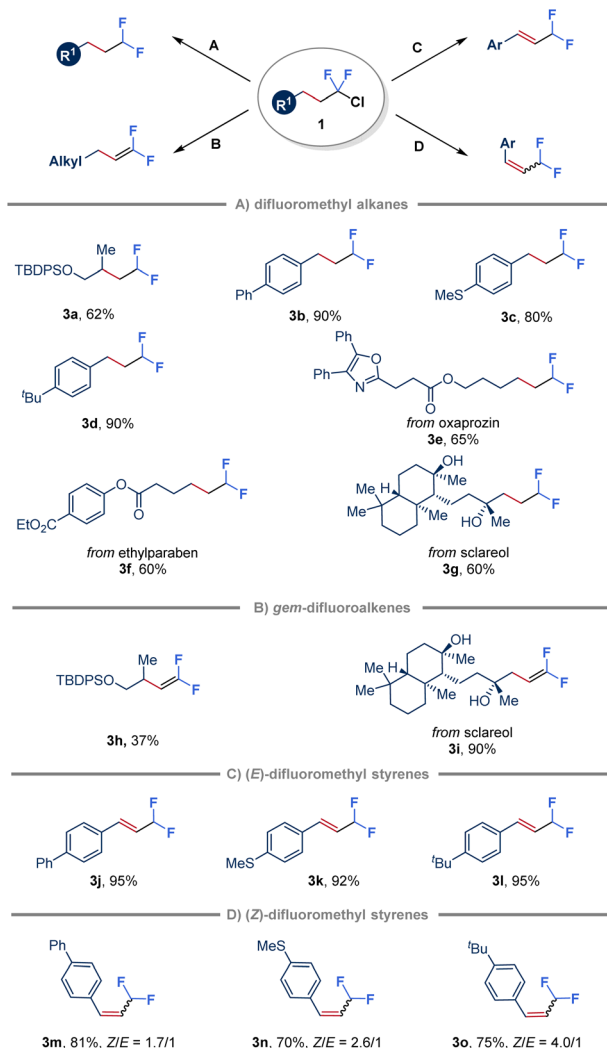

Fig. 4 Divergent synthesis of difluorinated hydrocarbons and alkenes. (Condition A) 4CzIPN (10 mol%), **LB 6** (1.5 equiv.), (TRIPS)<sub>2</sub> (10 mol%), <sup>t</sup>BuCN (0.1 M), 40 W 456 nm blue LEDs, rt, 48 h; (Conditions B and C) <sup>t</sup>BuOK (4.0 equiv.), <sup>t</sup>BuCN (0.1 M), rt, 12 h; (Condition D) Ir(ppy)<sub>3</sub> (1 mol%), <sup>t</sup>BuOK (4.0 equiv.), <sup>t</sup>BuCN (0.1 M), 40 W 456 nm blue LEDs, rt, 12 h.

electron transfer (PCET) process. Subsequently, the nucleophilic boryl radical activates the C–Cl bond of substrate **1** through a XAT process, resulting in the formation of the corresponding CF<sub>2</sub>-alkyl radical (R<sup>1</sup>-CF<sub>2</sub>•). The R<sup>1</sup>-CF<sub>2</sub>• undergoes intermolecular radical addition with the alkene substrate, followed by a HAT process with thiophenol, to generate the desired *gem*-difluoroalkane **2**. Alternatively, the CF<sub>2</sub>-alkyl radical may undergo HAT with amine-borane, leading to the formation of difluoromethyl alkane **3** in the absence of alkenes.

## Conclusions

In summary, we have successfully developed a general and widely applicable method for synthesizing diverse difluorinated alkanes and alkenes by leveraging easily accessible ClCF<sub>2</sub>SO<sub>2</sub>Na as a practical difluoromethylene linchpin. This strategy involves an organophotoredox-catalysed hydrochlorodifluoromethylation reaction, followed by a tertiary amine-borane-triggered XAT

process under blue light irradiation conditions. Our approach offers several advantages, including broad substrate scope, excellent functional group tolerance, metal-free character, mild reaction conditions, and CF<sub>2</sub>-link-derivatization of complex bioactive alkenes, which demonstrate the potential utilities of this linchpin protocol. Our ongoing research involves merging ligated boryl radicals with transition metal catalysis and exploring its potential applications.
