The electrochemical reduction of carbon dioxide (CO₂RR) holds great promise for sustainable energy utilization and combating global warming. However, progress has been impeded by challenges in developing stable electrocatalysts that can steer the reaction toward specific products. This study proposes a carbon shell coating protection strategy by an efficient and straightforward approach to prevent electrocatalyst reconstruction during the CO₂RR. Utilizing a copper-based metal–organic framework as the precursor for the carbon shell, we synthesized carbon shell-coated electrocatalysts, denoted as Cu-*x*-*y*, through calcination in an N₂ atmosphere (where *x* and *y* represent different calcination temperatures and atmospheres: N₂, H₂, and NH₃). It was found that the faradaic efficiency of ethanol over the catalysts with a carbon shell could reach ~67.8%. In addition, the catalyst could be stably used for more than 16 h, surpassing the performance of Cu-600-H₂ and Cu-600-NH₃. Control experiments and theoretical calculations revealed that the carbon shell and Cu–C bonds played a pivotal role in stabilizing the catalyst, tuning the electron environment around Cu atoms, and promoting the formation and coupling process of CO*, ultimately favoring the reaction pathway leading to ethanol formation. This carbon shell coating strategy is valuable for developing highly efficient and selective electrocatalysts for the CO₂RR.

Introduction

Electrocatalytic carbon dioxide reduction (CO₂RR), powered by clean and renewable energy resources, is a widely explored reaction due to its promise as a sustainable approach to mitigating global warming and promoting sustainable energy utilization.^{1–3} Among the various CO₂RR products, the production of high-value multicarbon (C₂₊) compounds has garnered significant attention from researchers. However, most of these

technologies still require better catalysts to support electrochemical reactions. In particular, there is a lack of in-depth understanding of a catalyst's dynamic structure under reaction conditions, which is however critically needed to inform rational catalyst design.^{4–6}

Copper (Cu) has been extensively studied in the CO₂RR due to its ability to induce CO* dimerization (where * represents the adsorption state), especially towards deep-reduction products (*e.g.*, eight-electron transfer for methane (CH₄) and twelve-electron transfer for ethylene (C₂H₄) and ethanol (C₂H₅OH)).^{7–9} Various methods, such as modifications of the microstructure,^{10,11} hydrophobicity,¹² defects,¹³ facets,^{14–16} and heteroatom doping,^{17,18} have been applied to enhance C₂₊ product selectivity and catalytic activity. However, there is also increasing evidence that significant catalyst restructuring can already occur as soon as the Cu-based catalysts are placed into an electrolyte, and these changes impact the subsequent catalyst activity and selectivity during the reaction.⁴⁷ Despite the increasing utilization of heteroatom-induced modification of copper catalysts as an electrode preparation method to enhance catalyst stability, there have been limited investigations into the detailed analysis of morphological transformations and the exploration of strategies for controlled synthesis of the most

advantageous nanostructures for a specific electrocatalytic process.

Carbon shells serve as effective physical barriers between nanocatalysts to address catalyst restructuring, reducing particle aggregation, and preventing oxidation. In the past decade, carbon-shell-encapsulated nanoparticles have shown great potential as electrocatalysts for electrochemical energy applications. For example, in the Pt–aniline complex, carbon shells are simply encapsulated on Pt nanoparticles to enhance the long-term stability of proton exchange membrane fuel cells,¹⁹ and carbon-encapsulated ordered PtFe nanoparticles exhibit exceptional activity and durability as electrocatalysts for fuel cell applications.²⁰ Additionally, several studies have indicated that the interface hybridization between carbon matrices and transition metals significantly influences the activity and selectivity of electrocatalysts.²⁰ This is attributed to the modulation of the electronic structure of the external carbon shell by the core metal particles, which leads to significant changes in the electron density of the carbon shells.^{21,22}

In this study, we present a novel carbon shell (C shell) coating protection strategy, employing an efficient and straightforward approach, aimed at preventing electrocatalyst reconstruction during the CO₂RR. A copper-based metal–organic framework (Cu-MOF) was selected as the precursor for the C shell, and the carbon shell was realized through calcination in an N₂ atmosphere. Furthermore, Cu-MOFs were also exposed to different gas atmospheres, such as H₂ and NH₃, at various temperatures to demonstrate the significance of the C shell. The resulting catalysts were labeled as Cu-*x*-*y*, where *x* and *y* represent the calcination temperature and atmosphere, respectively. It was found that Cu-600-N₂ consisted of Cu nanoparticles with a 2 nm thick carbon shell and Cu–C bonds, and it showed excellent stability and efficiency for the CO₂-to-ethanol reaction. The faradaic efficiency (FE) of ethanol could be as high as 67.8%, much better than that of Cu-600-H₂ and Cu-600-NH₃. The carbon shell and Cu–C bonds played a crucial role in stabilizing the catalyst, tuning the electron environment around Cu atoms, promoting the formation of CO*, and following C–C coupling to generate ethanol.

Results and discussion

Synthesis and characterization of C shell-protected Cu

First, Cu-MOFs were synthesized using a solvothermal approach based on a bottom-up procedure, which followed a previously reported procedure with certain modifications.^{48,49} Terephthalic acid (H₂BDC), 1,4-diazabicyclooctane (DABCO), and copper nitrate Cu(NO₃)₂ were utilized for the synthesis of the Cu-MOFs, as illustrated in Fig. 1a. Each Cu²⁺ cation in the Cu-MOFs is coordinated with four oxygen atoms from H₂BDC and one nitrogen atom from DABCO molecules within a single building unit. The resulting Cu-MOFs had a size of approximately 2 μm (Fig. S1†), and nitrogen adsorption experiments reveal a Brunauer–Emmett–Teller (BET) surface area of 223.5967 m² g^{−1} (Fig. S2†). The X-ray diffraction (XRD) pattern displayed a well-crystallized structure of Cu-MOFs, consistent with the previous results (Fig. S3†).^{48,49} To produce the Cu-*x*-N₂ catalysts, the

precursor Cu-MOFs were pyrolyzed at various temperatures (400, 500, 600, 700, 800 and 900 °C) in an N₂ environment. Using the same approach, reference compounds Cu-*x*-H₂ and Cu-*x*-NH₃ were also produced under H₂ and NH₃ atmospheres, respectively. As shown in Fig. S4a,† the XRD patterns of all three catalysts Cu-600-N₂, Cu-600-H₂, and Cu-600-NH₃ displayed three distinct diffraction peaks at approximately 43.3°, 50.5°, and 74.1°, which correspond to Cu (111), Cu (200), and Cu (220) faces of metallic Cu (JCPDS no. 04-0836), respectively. The results of inductively coupled plasma (ICP) analysis are presented in Table S1,† which indicates that there was hardly any difference in copper loading between the three catalysts.

The TEM and SEM images showed that Cu²⁺ was converted into monodispersed copper nanospheres with a polycrystalline structure after heat treatment (Fig. 1b–d and S4b–d†). The morphology of the three catalysts calcined in different atmospheres differed significantly. First, as can be seen from Fig. 1b–d and S4b–d,† Cu-600-N₂ and Cu-600-NH₃ were composed of nanoparticles with an average size of less than 100 nm, while Cu-600-H₂ was composed of larger-sized sintered particles (Fig. S5–S7†). TEM characterization (Fig. S5†) indicates that the particle size of Cu nanoparticles (Cu NPs) deposited on carbon ranged from 20 to 50 nm in the Cu-600-N₂ catalyst. In addition, the combination of carbon and Cu-NPs depended on atmospheric conditions in the calcination process. As shown in Fig. 1b and e, the interplanar spacings of the carbon layers and the Cu NPs were 0.34 nm and 0.210 nm, respectively, consistent with the C (002) and Cu (111) crystal planes.^{20–22} The Cu NPs, covered with an about 3 nm-thick carbon shell, were seamlessly incorporated into the C framework in Cu-600-N₂. Previous research has demonstrated that thin carbon shells possess permeability for small molecules and do not impede the mass transport of reactants.^{23–25} The elemental mapping also indicated the tight binding of Cu and carbon in Cu-600-N₂ (Fig. S9–S11†). In contrast, due to the reducibility of H₂, the carbon is squeezed out of the Cu-MOF precursor, resulting in the apparent separation of carbon and Cu-NPs in Cu-600-H₂ (Fig. 1c). Additionally, in Cu-600-NH₃ (Fig. 1d), NH₃ inhibited the sintering of carbon particles, resulting in an incomplete and fragmented carbon layer.²⁶

Raman spectroscopy was used to determine the reason for the discrepancy. As shown in Fig. 1f, the two broad peaks at 1348.2 and 1596.1 cm^{−1} correspond to the D and G bands, respectively. The D band refers to sp² hybridized carbon and material defects, while the G band is related to an ideal graphitic lattice. Therefore, the intensity ratio between the D and G bands (*I*_D/*I*_G) can be used to determine the degree of graphitization of carbon materials.^{23,24} The smaller the ratio is, the higher the degree of graphitization. By comparing the intensity ratios of several Raman bands, we found that the *I*_D/*I*_G ratios increased from Cu-600-H₂ (0.64) to Cu-600-N₂ (0.91) and Cu-600-NH₃ (1.04). This suggests that Cu-600-NH₃ had a more disordered carbon support, and Cu-600-H₂ had the most significant graphitization degree. Thus, different atmospheres resulted in various states of carbon layers, with ordered organization resulting in carbon separation, and disordered carbon may result in diminished conductivity and confinement ability.

The specific surface area and the pore-size distribution of the catalysts are further investigated using the N_2 adsorption-desorption isotherm at 77 K which is shown in Fig. S12a.† The isotherms are classified as the type IV category, displaying an H3 hysteresis loop, which indicates a mesoporous structure.⁵⁰ The pore size distribution estimated by the nonlocal density functional theory method shows that the primary pore sizes are 4–6 nm for Cu-600-N₂, 1.5 nm for Cu-600-NH₃, and 1.6 nm for Cu-600-H₂ (Fig. S12b†). Furthermore, mesoporous Cu-600-N₂ exhibits a notably high BET surface area of 1004.63 m² g⁻¹ and a sufficient pore volume of 2.96 cm³ g⁻¹ (Table S2†). This extensive surface area offers a greater number of active sites and reactant transmission channels. To further evaluate the adsorption strength of CO₂ on the catalyst surface, CO₂ temperature-programmed desorption (CO₂ TPD) has been conducted under identical mass loading conditions (Fig. S13a†). The results indicate that the desorption temperature and peak intensity of chemically adsorbed CO₂ on Cu-600-N₂ are higher than those of Cu-600-H₂ and Cu-600-NH₃, indicating

stronger adsorption capability of Cu-600-N₂ for CO₂.⁵¹ Furthermore, the result of CO₂ adsorption isotherms in Fig. S13b† is corroborated with the CO₂ TPD analyses.

Control experiments were conducted to investigate the initial impact of different carbon layer states on the CO₂RR, and the results are presented in Fig. 1g. Compared to samples Cu-600-H₂ and Cu-600-NH₃, Cu-600-N₂ consisting of Cu nanoparticles encapsulated in a thin and complete carbon shell, exhibited significantly enhanced ethanol selectivity. This improvement is possibly attributed to the synergistic effect between Cu nanoparticles and the carbon shell in Cu-600-N₂, and a detailed analysis will be provided below.

Structural characterization

To investigate the impact of various calcination atmospheres on the performance of the catalysts, a series of Cu-based catalysts pyrolyzed under different atmospheres were characterized as follows. First, it is evident from the results discussed above that

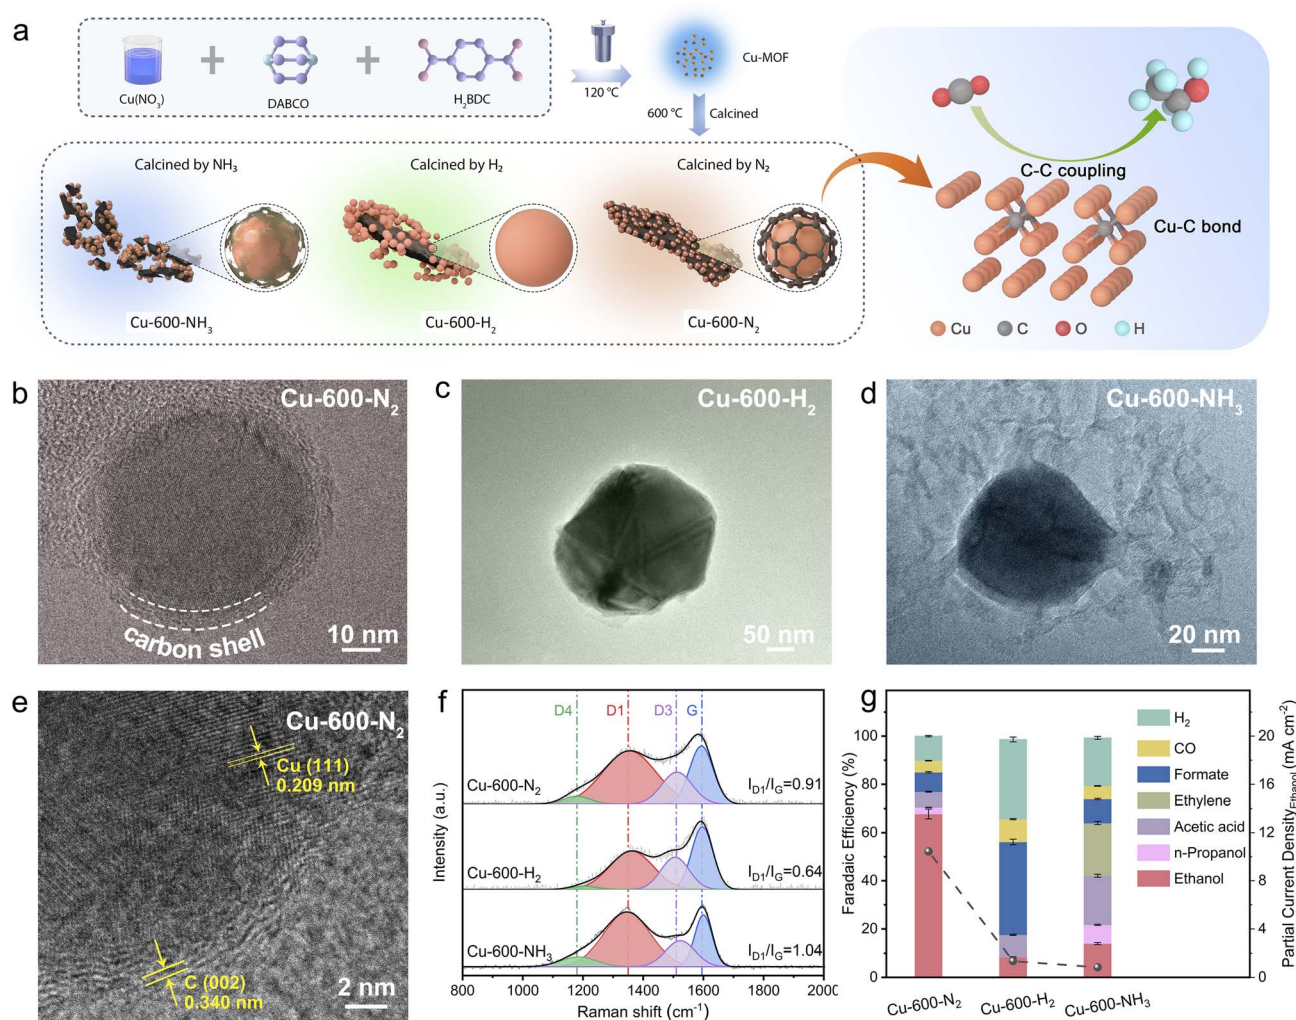

Fig. 1 (a) The schematic illustration of the preparation of catalysts. TEM characterization of (b) Cu-600-N₂ (c) Cu-600-H₂ and (d) Cu-600-NH₃, respectively. (e) HR-TEM images of Cu-600-N₂. (f) Raman spectra and (g) FE over Cu-600-N₂, Cu-600-H₂ and Cu-600-NH₃ in CO₂-saturated 0.1 M KHCO₃ aqueous solutions using an H-cell at -0.8 V (vs. RHE).

Fig. 2 (a) High-resolution Cu 2p XPS spectra and (b) C 1s XPS spectra of Cu-600-NH₃, Cu-600-N₂, and Cu-600-H₂. (c) Normalized Cu K-edge XANES spectra and (d) Cu K-edge FT-EXAFS spectra in the *R*-space of Cu-600-NH₃, Cu-600-N₂, Cu-600-H₂, Cu foil, CuO, and Cu₂O.

different atmospheres resulted in varying degrees of graphitization, with the degree of graphitization being Cu-600-H₂ > Cu-600-N₂ > Cu-600-NH₃. In the high-resolution Cu 2p X-ray photoelectron spectra (XPS) (Fig. 2a), the peaks with a binding energy (BE) of around 952.2 and 932.3 eV are assigned to Cu(I)/Cu(0) species, whereas the peaks at 954.3 and 934.5 eV should be attributed to Cu(II).^{25,26} Cu-600-N₂ and Cu-600-NH₃ exhibited shifted metallic Cu(0) peaks compared with Cu-600-H₂, indicating a higher valence state of Cu in the former. This also signifies that the interfacial charge may be transferred from Cu nanoparticles to the carbon support.^{27,28} Based on the relative intensities of the C 1s peaks in Fig. 2b, the C 1s XPS spectrum was fitted with six peaks. The deconvoluted C 1s peaks at 283.2, 284.6, 285.5, 286.8, and 288.5 correspond to Cu-C, sp²-C, sp³-C, C-O, and C=O groups,^{29–31} respectively. Notably, the defective sp³ carbon atoms were introduced into Cu-600-NH₃. This coincides with the Raman and SEM results that Cu-600-NH₃ had the least graphitized carbon support. The percentage of sp² and sp³-hybridized C atoms was estimated as shown in Table S3.† Moreover, due to charge transfer at the interface, a typical “shoulder” appears at the low binding energy of C 1s. A spilled peak at 283.2 in Cu-600-N₂ and Cu-600-NH₃ indicates a strong interaction between metal and carbide (M-C bond).²⁹ Additionally, the Cu-C levels caused by N₂ are about one-fold larger than those induced by NH₃. Our research revealed that the nitrogen environment might create a certain content of carbon defects and enhance the synergy between the M-C bonds. The effect of other gases on the properties of the catalysts was also investigated. NH₃ hindered the sintering of carbon particles, resulting in the carbon support with poor graphitization and electroconductivity. On the other hand, in an H₂ environment, Cu-MOF precursors tend to produce a high degree of graphitization.^{26,27}

To further examine the electronic structures and chemical configurations of catalysts Cu-600-N₂, Cu-600-H₂ and Cu-600-

NH₃, X-ray absorption near-edge structure (XANES) and extended X-ray absorption fine structure (EXAFS) spectroscopies were performed. Fig. 2c shows the Cu K-edge XANES spectra of Cu-600-N₂, Cu-600-H₂ and Cu-600-NH₃, alongside CuO, Cu₂O, and Cu foil references. Compared to Cu-600-H₂ and Cu-600-NH₃, the absorption edge position of Cu-600-N₂ is positively shifted and virtually identical to that of CuO, suggesting a higher oxidation state of the copper species and a tendency toward a +2 valence state. This is consistent with the XPS results. In addition, the edge positions of the spectra acquired on Cu-600-H₂ and Cu-600-NH₃ are between Cu₂O and Cu, suggesting that the oxidation state of the copper species is between valence states +1 and +2 in these samples, as indicated by the previous XPS results. Due to the reducibility of hydrogen, the valence state of Cu-600-H₂ is more inclined toward Cu⁰, while the valence state of Cu-600-NH₃ is almost +0.5 on average. The Fourier-transformed (FT) *k*³-weighted EXAFS oscillation in Fig. 2d and S15† showed that the three catalysts all demonstrate characteristic peaks similar to those of the Cu foil, with a prominent peak at a distance of approximately 2.1, corresponding to the Cu-Cu coordination in *R* space. Furthermore, scattering was detected at a distance of 1.5 Å, which corresponds to the first coordination shell of Cu-C in Cu-600-N₂. This observation was further confirmed by the appearance of the Cu-C peak at 283.2 eV in the C 1s XPS spectrum, providing additional evidence for the coordination environment of the Cu-C bond in Cu-600-N₂.

CO₂RR activity investigation

The CO₂RR catalytic performances of Cu-600-N₂, Cu-600-H₂ and Cu-600-NH₃ were evaluated in an H-type cell with a CO₂-saturated 0.1 M KHCO₃ electrolyte. Fig. 3a shows the linear sweep voltammetry (LSV) curves for different catalysts in CO₂- and Ar-saturated 0.1 M KHCO₃ electrolytes. The notably higher current density observed in a CO₂-saturated electrolyte in comparison to an Ar-saturated electrolyte indicates the reduction of CO₂. In contrast, the current in the Ar-saturated electrolyte predominantly originates from the hydrogen evolution reaction (HER). Notably, Cu-600-N₂ exhibits a significantly higher current density, indicating that Cu-600-N₂ is more conducive to the CO₂RR rather than the HER.

At a low current density, Cu-600-N₂ with a graphitic C shell produced a substantial amount of CO and acetic acid (Fig. 3b), while a small amount of ethanol was generated, indicating that C-C coupling of Cu-600-N₂ was initiated at a lower overpotential. As the applied potential became more negative, the selectivity of CO and acetic acid decreased while the FE of ethanol increased, exhibiting a volcano-like trend. Notably, the conversion of CO₂ to ethanol exhibited the highest FE of 67.8% at -0.8 V, much higher than that of Cu-600-H₂, Cu-600-NH₃, and other previously reported Cu-based catalysts for converting CO₂ to ethanol.^{32–34} According to previous reports, high selectivity for ethanol suggests a greater amount of surface-bound CO* or CHO*, which is a crucial step in forming C₂ products.³⁵ The number of other hydrocarbons produced was minor compared to that of ethanol; small amounts of n-propanol,

Fig. 3 (a) LSV curves in CO₂- and Ar-saturated 0.1 M KHCO₃ aqueous solutions for Cu-600-N₂, Cu-600-H₂, and Cu-600-NH₃. FE and partial current density for (b) Cu-600-N₂, (c) Cu-600-H₂, and (d) Cu-600-NH₃ in CO₂-saturated 0.1 M KHCO₃ aqueous solutions at different potentials (vs. RHE), and error bars are given by the shaded areas. The error bar indicates the standard deviation of three independent measurements. (e) Comparison of the overall performance of the three catalysts, Cu-600-N₂, Cu-600-H₂, and Cu-600-NH₃. (f) Comparison of stability with other recently reported advanced CO₂RR Cu-based electrocatalysts in an H-type cell.

acetic acid, and formate were generated with FE values of 2.8%, 7.8%, and 9.3%, respectively. The ¹H NMR spectra of the products after the CO₂RR are shown in Fig. S17.† However, the HER gradually became dominant at more negative potentials. Isotope-labelled ¹³CO₂ was used as feed gas to trace the carbon source in ethanol production. The ¹H-NMR analysis also confirmed that ethanol was produced from the CO₂RR and not due to contaminants⁵² (Fig. S18†).

The FEs for Cu-600-H₂ and Cu-600-NH₃ were also determined for comparison (Fig. 3c and d). At 0.8 V vs. RHE, formate was the predominant product (38.6%) for Cu-600-H₂, with an ethanol FE of 10.3%. Because severe Cu reconstruction hindered the realization of the synergy effect, it was difficult to enhance the ethanol product selectivity due to favorable HER. For the Cu-600-NH₃ electrode, the FE of ethanol was only 15.2% at -0.8 V vs. RHE. When the proportion of amorphous carbon was high, the selectivity of ethanol was poor, and the hydrocarbon products were a complex mixture (C₂H₄: 24.9%; *n*-propanol: 8.1%; acetic acid: 20.4%; and formate: 9.9%). At the same potential, the partial current density of Cu-600-N₂ was substantially greater than that of Cu-600-H₂ and Cu-600-NH₃. It should be noted that the onset potential for C₂H₅OH formation on Cu-600-N₂ was approximately -400 mV (vs. RHE), corresponding to an overpotential of ~490 mV, which was lower than

the overpotentials observed for Cu-600-H₂ (~690 mV) and Cu-600-NH₃ (~590 mV) for the reduction of CO₂ to C₂H₅OH (Fig. 3e). These results directly demonstrate the significance of developing an appropriate graphitization degree system to prevent reconstruction of Cu and promote high selectivity for ethanol production.

In addition, temperature is also a crucial factor influencing the graphitization degree of carbon materials. Therefore, a series of Cu-*x*-N₂ catalysts were prepared by altering the Cu-MOF annealing temperature (*x* = 400, 500, 600, 700, 800 and 900 °C). At lower temperatures of 400 or 500 °C (Fig. S19a and b†), Cu NPs are fully encapsulated in a thicker carbon shell, indicating that the bulk MOF has not been effectively delaminated. Increasing the calcination temperature is beneficial for decomposing the metal-organic framework. At 600 °C (Fig. S19c†), the Cu-MOF structure is almost entirely delaminated into layered structures, with partial removal of Cu NPs from the graphene shell, resulting in the formation of a porous structure and graphene nanocages (inset of Fig. S19c†). During the calcination process, Ostwald ripening occurs, and metal nanoparticles tend to reduce the total surface energy by aggregating and forming larger particles, thereby reducing the interfacial surface energy between the particles. Therefore, as the temperature further increases from 700 °C to 900 °C (Fig. S19d-f†), Cu NPs melt and migrate, aggregating into larger particles. Additionally, with the increase of temperature, the metal particles break through the constraints of the carbon shell, resulting in even larger aggregation sizes. Indeed, larger metal particles can lead to a reduced electrochemical active surface area and an increase in electron transfer resistance, ultimately resulting in a decrease in catalytic reaction activity. As shown in Fig. S20,† the FE of ethanol follows a volcano pattern as the applied temperature was increased, reaching a maximum of 67.8% at 600 °C, and the current reached 15.4 mA cm⁻². The catalyst performance of the other two catalysts, Cu-*x*-H₂ and Cu-*x*-NH₃, is also shown in Fig. S21 and S22.†

To explore the origins of enhanced CO₂RR by different carbon shell structures, the influence of various catalysts on the active sites and charge transfer kinetics is examined. The electrochemical active surface area (ECSA) of the catalysts was estimated by measuring the electrochemical double-layer capacitance (Cdl) obtained from the CV curves at different scan rates.³⁶ As shown in Fig. S23,† Cu-600-N₂ can provide the largest ECSA, which facilitates an improved contact interface with the electrolyte and exposes more active sites to enhance the adsorption of various intermediates. The electrochemical impedance spectroscopy (EIS) depicted in Fig. S24† revealed that Cu-600-N₂ exhibits a smaller semicircular radius and charge transfer resistance in the Nyquist plot, indicating a faster charge transfer process occurring on Cu-600-N₂ compared to Cu-600-H₂ and Cu-600-NH₃. It expedites the transfer of electrons to CO₂ to stabilize the reduced CO₂^{•-} intermediate, which is essential for the electroreduction of CO₂.^{37,38} Due to poor graphitization, the Cu-600-NH₃ electrode features the most significant charge transfer resistance and the worst conductivity.²⁷ This phenomenon demonstrates that a suitable degree of graphitization and a high Cu-C combination is advantageous

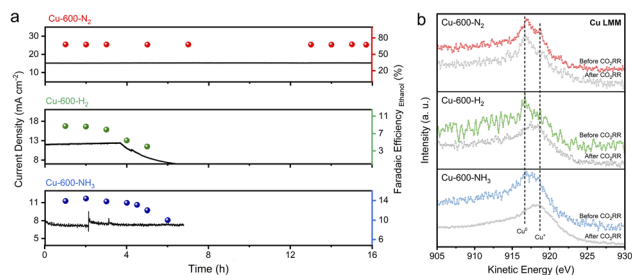

Fig. 4 (a) CO₂ electroreduction stability of Cu-600-N₂, Cu-600-H₂, and Cu-600-NH₃ at a potential of -0.8 V (vs. RHE) in 0.1 M KHCO₃. (b) XPS Cu LMM spectra of Cu-600-N₂, Cu-600-H₂ and Cu-600-NH₃ before and after the CO₂RR. The CO₂RR was conducted at a potential of -0.8 V (vs. RHE) for 3 hours.

for the CO₂RR and that these two parameters may act synergistically to enhance the activity and selectivity of the CO₂RR.

The stability of catalysts for the CO₂RR is of utmost importance for their practical application. As shown in Fig. 4a, Cu-600-N₂ remained stable and had excellent catalytic activity over 16 hours at an applied potential of -0.8 V, which is more stable than the other catalysts. SEM revealed that the C shell-coated Cu nanoparticles maintained their embedded morphology and chemical state even after long reaction times (Fig. 4b and S25[†]). Cu wrapped by a protective shell exhibited significantly improved stability due to the prevention of Cu particle aggregation. For unprotected Cu nanoparticles or disordered carbon, however, the surface changed significantly after a few hours at a high reaction rate (Fig. S26–S28[†]). The Cu nanoparticles on the surface underwent severe surface reconstruction and agglomerated into many micron-sized and rough aggregates, and the ethanol selectivity also decreased rapidly. Furthermore, as depicted in Fig. S29,† the anti-corrosion properties of Cu-600-N₂, Cu-600-H₂, and Cu-600-NH₃ were evaluated by Tafel analysis. Cu-600-N₂ exhibited the best corrosion resistance among the three catalysts due to its more positive corrosion potential than Cu-600-H₂ and Cu-600-NH₃.

The above performance comparison demonstrates that Cu-600-N₂ exhibited superior performance to Cu-600-H₂ and Cu-600-NH₃ in multiple aspects (as depicted in Fig. 3e). The outstanding stability of Cu-600-N₂ could be attributed to the protective effect of the carbon layer encapsulating the Cu nanoparticles. The internal Cu nanoparticles could also collaborate with the surface carbon shell to form stable Cu–C bonds, promoting the catalytic reaction and producing a synergy effect.^{39–41} This synergistic effect enabled Cu-600-N₂ to maintain high FE and current density during continuous electrocatalysis, making it comparable to recently reported Cu-based electrocatalysts for CO₂-to-ethanol conversion in an H-cell setup (as shown in Fig. 3f and Table S4[†]).

Mechanistic study on enhanced C–C coupling

The experiment confirmed that the carbon coating of the Cu nanoparticles played a significant role in ethanol generation. To gain more fundamental insights, DFT calculations were also performed to verify the effect of the Cu–C bond on the

Fig. 5 (a) The proposed dimerization mechanism for ethanol formation involves optimized structures of adsorbed species on the Cu–C surface, shown in the top and side views. Cu: orange, C: gray, O: red, H: white. (b) Free energy diagram for CO dimerization on the pristine Cu–C and bare Cu surface. (c) The calculated d-PDOS of surface Cu and C atoms on Cu–C and bare Cu planes. The two blue lines indicate the d-band center positions with the calculated values. performance of the CO₂RR to ethanol. The Cu–C bond structure model was constructed by doping C on the subsurface of Cu, while bare Cu was used for comparison. The doping sites of C and the adsorbed sites are based on the most energetically stable structures. Fig. 5a illustrates the schematic diagrams for CO₂RR pathways that achieve CO* and CO* dimerization on Cu–C. For bare Cu surfaces, the schematic diagrams of the reaction pathway are illustrated in Fig. S30.† Initially, one CO₂ molecule forms a *CO species on the copper surface through protonation, and then *CHO is formed by one proton transfer process. Subsequently, *CHO undergoes coupling with another CO* by *CHO + CO* → *CHO–CO,^{42,43} which is considered the rate-determining step in the ethanol formation path. The free energy profiles (Fig. 5b) suggest that Cu–C exhibits a low reaction energy barrier (0.02 eV) in the process of CO* formation, significantly lower than that on bare Cu (0.21 eV). Therefore, the Cu–C surface is favorable for the formation of CO*, which can improve the coverage of CO*. It has been reported that the energy barrier for CO dimerization can be lowered by increasing the coverage of CO*, which can improve its dimerization.^{44,45} When CO is further hydrogenated to generate CHO, the energy barrier is as low as 0.12 eV on the Cu–C surface, which reduces the overall reaction energy barrier for subsequent C–C coupling. In addition, the uphill energy for CHO formation on bare Cu is 0.52 eV, which is much higher than that on Cu–C (0.4 eV). The large free energy implies high-energy barriers for the CO₂-to-C₂ process. Therefore, the Cu–C bond can promote the CO₂RR to form CO* and OCCHO* and reduce the energy barrier for CO* dimerization, which leads to higher selectivity for ethanol.

In addition, the charge density difference (CDD) of Cu–C was calculated to study the space charge distribution and influence on the valence state of the Cu and electric properties of the catalyst. Fig. S31–S33[†] shows that based on DFT calculations, Cu–C exhibits charge transfer from Cu to carbon due to the strong electronic attraction properties of the graphic structure;

this was consistent with the XPS fitting results in the experiment. The plots of the d-projected density of states (d-PDOS) of Cu and Cu-C in the unadsorbed state show that the carbon effect upshifts the d-band center of the surface Cu from -2.64 to -2.38 eV, indicating enhanced activity of surface Cu atoms (Fig. 5c). This electronic interaction results in the d orbital electron of Cu atoms being relatively empty, facilitating electron coupling with the p orbital electron of CO₂ adsorbates. Moreover, doped C displays peaks near the Fermi level, which enables electrons with energies close to the Fermi level to participate in bonding during adsorption, thus enhancing the interaction with the adsorbate. As displayed in Fig. 5d-f, comparing adsorption configurations of two CO* reveals a noticeable rightward shift of the d-band of C-doped Cu. The solid red line in the energy range of -8 eV to -6 eV and near the Fermi level shows hybridization between Cu, C, and the adsorbed CO*, indicating that doped C can also hybridize with the electrons of adsorbed CO*, further enhancing the interaction with the catalyst.⁴⁶

Conclusion

In summary, we have designed a highly efficient and stable electrocatalyst, Cu-600-N₂, by forming a carbon shell on Cu nanoparticles for CO₂ electroreduction to ethanol. First, the carbon shell could form Cu-C bonds with Cu nanoparticles, thereby tuning the electron environment around Cu atoms and promoting the formation and coupling process of CO*. At the same time, the carbon shell improved the structural and chemical stability of the catalyst. DFT calculations showed that Cu-C bonds regulated the key intermediate *HOCCH's hydrogenation pathway and favored the ethanol formation reaction pathway. Therefore, the catalyst exhibited a high ethanol FE of 67.8% and excellent stability. Our results and conclusions pave the way for the rational design of efficient and stable catalysts for the CO₂RR.

Author contributions

Y. T. and W. X. proposed the project, designed the experiments and wrote the manuscript; Y. T. performed the whole experiments; S. T. H., X. D., S. Q. J., M. W., D. W. Z. C. J. C. and J. H. Y. assisted in analyzing the experimental data; S. Q. J., W. X., X. Q. X., M. Y. H. and H. H. W. assisted in analyzing the experimental data of XAS; B. X. H. supervised the whole project.
