Formation of giant plasma membrane vesicles for biological and medical applications: a review

 Yang Li, Songyang Liu, Wanyu Xu, Kemin Wang,  Fengjiao He* and Jianbo Liu *

Giant plasma membrane vesicles (GPMVs) are micron-sized biomembrane vesicles that are isolated directly from living cells. They retain the lipid and protein complexity of the plasma membrane of the parent cell while lack the energy-mediated pathway of the cell; therefore, PMVs provide an alternative to vesicles constructed from synthetic or purified lipids as an experimental model system for use in a wide range of biomedical applications. In this review, we provide an overview of recent research on the formation of PMVs and on their unique structure and functional properties. We then discuss efforts to exploit them in biological and biomedical applications. For example, PMVs have been developed as cell mimics and plasma models to study the structure and composition of the plasma membrane and its interactions with other molecules, as drug carriers for targeted delivery and as probes for disease diagnostics. Finally, we provide some perspectives on the challenges and future developments of PMV research in biomimetic science and biomedical applications. GPMVs discussed in this review are restricted to those produced from mammalian cells.

1. Introduction

A cell membrane plays an indispensable and vital role in cells.¹ Specifically, cells maintain their structural stability due to the rigidity of the cell membrane. In addition, the cell membrane not only acts as a barrier to separate the internal and external spaces of the cell but also plays an important role in cell-to-cell communication.^{2,3} The cell membrane is an inextricable topic in the mystery of life because the cell membrane is such a loyal guardian of the cell. Studies involving cells always have some degree of connection with the cell membrane. However, it is not easy to study the cell membrane in living cells directly because of its compositional and topographical complexity.⁴

“Giant plasma membrane vesicles” (GPMVs) were first proposed in the 1970s by Scott, who provided a new technique for the isolation of plasma membranes.⁵ GPMVs are cell-derived vesicles that largely retain the compositional lipid and protein complexity of the parent cell plasma membrane but lack cortical actin cytoskeletons and intracellular processes.⁴ Thus, a substitute research object for living cells has been found. GPMVs are perfect cell mimics for studying the membrane organization and biophysical

properties of the cell membrane without disturbances from intracellular dynamics. In addition, GPMVs are important biomimetic models for the study of the interactions between substances and plasma membranes and can be exploited as drug carriers for disease treatment.

GPMVs are emerging as potential and promising experimental tools, but related reviews are limited. Existing reviews have focused on the use of GPMVs for understanding plasma membrane structures and dynamics, while lack a more comprehensive overview of GPMVs.⁴ In this review, we provide an overview of GPMVs, which includes their formation methods, their unique structural and functional properties, and their biomedical applications (Fig. 1). We discuss efforts to exploit them as cell mimics, plasma membrane models and drug carriers for biomedical applications in particular. It's worth noting that the GPMVs discussed in this review are restricted to those produced from mammalian cells.

2. Formation of GPMVs and experimental factors

GPMVs are micrometre-scale spherical protrusions from the surface of parent cells (Fig. 2A). Protocols have been established to chemically induce the shedding of a substantial proportion of the plasma membrane in the form of GPMVs.⁶ Recently, a series of new simulation approaches have been reported. For example, Liu *et al.* observed plasma membrane vesiculation under light irradiation in their

research and subsequently developed a nanomaterial-assisted strategy to generate GPMVs (Fig. 2B).⁷ This method has the advantage of involving no toxic chemical agents. A pulse laser irradiation strategy was found to induce the generation of GPMVs due to intracellular cavitation.^{8,9} A method of producing GPMVs using a hypertonic vesiculation buffer containing chloride salts was also described.^{10,11} This method can vesiculate Chinese hamster ovary cells.

However, at present, the most widely used method of GPMV preparation is to expose cells to aldehydes and disulfide blocking agents (vesiculation agents). Vesiculation agent-mediated GPMV formation includes several different procedures. After removing the culture medium and washing, a buffer solution containing vesiculation (see below for specific components) agents is added to cells. The cells are cultured at 37 °C for several hours, during which GPMVs are automatically produced and shed into the supernatant. The production of GPMVs may be due to the combination of vesiculation agents with free amino or sulfhydryl groups in

cells, weakening the binding between the cytoskeleton and plasma membrane, followed by expansion of the plasma membrane caused by intracellular pressure.^{5,12} To summarize the above methods of GPMV formation, we present Table 1 to show the details.

A variety of mammalian cell types have been developed to produce GPMVs.⁶ However, adherent cells are often better choices since the generation of GPMVs involves the detachment of vesicles from cells and separation from parent cells. If suspended cells are used, this process is not easy to achieve. Many factors affect the preparation efficiency of GPMVs.

Vesiculation agents

Vesiculation agents play important roles in the formation of GPMVs. In addition to low concentrations of formaldehyde (or polyformaldehyde), other chemical agents can also induce vesiculation, such as *N*-ethylmaleimide, iodoacetate, cacodylate and *p*-chloromercuribenzoate.¹³ Dithiothreitol has been proven to be an effective auxiliary agent to promote vesiculation. Vesiculation agent concentrations will also affect the vesiculation efficiency of GPMVs, as proven by relevant studies.¹⁴ Other researchers have compared the difference in GPMVs when polyformaldehyde/dithiothreitol and calmidazolium are used as vesiculation agents.¹⁵ Different vesiculation agents produce different particle size distributions of GPMVs produced.

Cations

The presence of cations is necessary for vesiculation, including both divalent cations and monovalent cations; calcium ions are the best divalent cations to promote vesiculation.¹³

Temperature and pH

The influence of temperature and pH is very easy to understand. GPMVs are produced from parent cells, and factors affecting the conditions of parent cells will certainly affect the formation of GPMVs. Maximum vesiculation occurs at an optimum

Fig. 2 Formation and characterization of GPMVs. A) Diagram of GPMV formation. B) Flow cytometry analysis and morphological characterization of GPMVs acquired by the nanomaterial-assisted strategy. Scale bar, 20 μm (adapted with permission from ref. 7. Copyright 2019, AAAS).

Table 1 Different methods of GPMV formation

Method	Vesiculation procedure	Ingredients	Size of GPMVs	Parent cells	Ref.
Nanomaterial-assisted strategy	Cells are incubated with carboxylfullerenes then irradiated with white light for 30 min	0.5 mg mL ⁻¹ carboxylfullerenes	5–22 μm	HeLa, HepG2, MCF-7, HEK-293, DC2.4, and CCRF-CEM cells	7, 57
Pulsed-laser irradiation strategy	Femtosecond laser pulses are used to stimulate GPMV formation on individual living cells	3 nJ per pulse 90 MHz 60 fs duration	0.5–5 μm	KB, FaDu, A431, MCF-7, MCA207, jar, and Jeg-3, UMSCC-22A, Rat2, and mouse red blood cells	8, 9
Osmotic buffer strategy	Osmotic buffer is added to cells and the cells are incubated for 13 h at 37 °C	200 mM NaCl 5 mM KCl 0.5 mM MgCl ₂ 0.75 mM CaCl ₂ 100 mM bicine pH = 8.5	17.2 ± 4.4 μm	CHO cells	10, 11
Vesiculation agent-mediated strategy	A buffer solution containing vesiculation agents is added to cells. The cells are cultured at 37 °C for 2 h	10 mM HEPES 150 mM NaCl 2 mM CaCl ₂ 2 mM dithiothreitol 25 mM polyformaldehyde pH = 7.4	13.8 ± 3.7 μm	HEK-293 cells, HepG2 cells, CHO-K1 cells and HeLa cells	15, 16, 20, 21, 38, 45, 63

temperature of 37 °C and pH of 7–7.5. When the pH is above 8 or below 6, vesiculation is hardly observed.¹³

Time

There has been much discussion about vesiculation time. The number and size of GPMVs increase with time in a certain range, but the optimal vesiculation time should be adjusted according to the specific research situation.

Cell density

Cell density also affects the vesiculation of GPMVs, and the recommended cell density is 70%.⁶

3. Structural and functional properties of GPMVs

These prepared GPMVs are filled with cytoplasm associated with the parent cells but lack large organelles (*e.g.*, nuclei, Golgi apparatus) and other intracellular structures. Their membrane is rich in lipids and proteins from the plasma membrane of the parent cells, and exactly mirrors the composition of the cells from which they originate while providing the experimental flexibility of synthetic vesicles.^{16,17} The proteomic analysis carried out by Bauer *et al.* identified 313 proteins from the GPMVs of NG108-15 cells.¹² Their research results showed that 43 proteins were anchored on the membrane, of which 40 proteins were unique to the plasma membrane, whereas 221 proteins were from the cytoplasm.

GPMVs have been used to evaluate the permeability of proteins, small molecules and drug-like molecules through the plasma membrane. It is noteworthy that the vesicles are not completely sealed. According to the research of Skinkle

et al., GPMVs show passive permeability to hydrophobic molecules as large as 40 kDa, in contrast to synthesized unilamellar lipid vesicles, probably as a result of the rupture of GPMVs forming large and stable holes (Fig. 3A).¹⁷ GPMVs demonstrate cell-like mechanical properties. Dimova found that the mechanical properties of GPMVs correlate with lipid order, viscosity and cell density.¹⁸ When exposed to lipopolysaccharides, the membrane of GPMVs began to wrinkle unevenly and generated buds.¹⁹ The shape change of GPMVs is irreversible, in contrast to that of giant unilamellar vesicles.

Some changes or enhancements can be made to GPMVs to make them more suitable for the expected applications. Palivan enhanced the mechanical properties and stability of GPMVs by modifying them with a specially designed diblock copolymer, cholesteryl-poly[2-aminoethyl methacrylate-*b*-poly(ethylene glycol) methyl ether acrylate].²⁰ In addition, the pH responsiveness of the copolymer layer allows controlled cargo loading and release (Fig. 3B). This approach can be used for drug release in slightly acidic environments for cancer therapy. The transformation of GPMVs can also start with parent cells because GPMVs retain the membrane composition of the parent cells. When GPMVs are separated from parent cells expressing specific membrane proteins, these proteins are also present on the membrane of GPMVs (Fig. 3C).²¹

4. Biological and biomedical applications of GPMVs

4.1. GPMVs as cell mimics

In recent years, cell mimics have attracted increasing attention (terms such as “artificial cell”, “synthesized cell” and “protocell” are often mentioned). Scientists are trying to

Fig. 3 Properties and functionalities of GPMVs. A) GPMVs show passive permeability to dextran as large as 40 kDa (adapted with permission from ref. 17. Copyright 2020, Elsevier). B) After the preparation and separation of GPMVs, the copolymer is inserted into their membrane, and finally, a cross-linked polymer shell is formed around them to enhance their stability and functionality (reproduced with permission from ref. 20. Copyright 2022, Wiley). C) Targeted proteins are also present on the membrane of GPMVs produced by cells expressing targeted proteins (EGF). Adapted from Fig. 3 in ref. 17. Fig. 1 in ref. 20 and Fig. 1 in ref. 21. Scale bar, 10 μm (adapted with permission from ref. 21. Copyright 2016, Wiley).

achieve the complexity of living cells by using cell mimics, although there is still a long way to go. Phospholipid vesicles,²² polymersomes,²³ proteinosomes,²⁴ colloidosomes,²⁵ and coacervate droplets²⁶ are widely used as cell mimics. For example, Chen *et al.* constructed multicompartiment protocells for the spatial organization of enzymatic reactions using coacervate microdroplets.²⁷ Zhang *et al.* designed a new cytomimetic model by integrating phospholipid membranes and coacervate microdroplets.²⁸ Liu *et al.* utilized vasoactive erythrocyte membrane-enclosed coacervate protocells to produce nitric oxide for vasodilation by an enzymatic cascade reaction.²⁹ However, there is still a large discrepancy between these mimics and living cells. As we mentioned before, GPMVs retain considerable aspects of the composition and structure of living cells, giving them innate advantages as cell mimics with appropriate modifications.

Einfalt *et al.* designed GPMV-based artificial cells containing nanosized polymersomes as intracellular artificial organelles.¹⁶ On the one hand, GPMVs retain the components of the cytoplasm and plasma membrane of donor cells. On the other hand, the adjustable components of artificial organelles (enzymes, proteins, *etc.*) allow the controllability of intracellular reactions, thus realizing customizable cell mimics. The adjustable artificial organelles provide the possibility of diverse artificial cells, enabling more extensive applications in the field of cell mimics (Fig. 4A). Furthermore, researchers transferred polystyrene

carboxylated nanoparticles into GPMVs, laying a foundation for further application of GPMVs in the field of cell mimics (Fig. 4B).³⁰ However, it should be noted that although they have potential to be excellent models, GPMVs have not been studied extensively as cell mimics, leaving much room for further exploration. The reason for this may be that GPMVs retain the relative integrity of the membrane when they are prepared, requiring additional effort to achieve combination with other new components, which can be completed during the preparation process if synthesized phospholipid vesicles are used.

Sedgwick *et al.* revealed the relationship between the production of GPMVs and the efflux of cholesterol from cells.³¹ Specifically, the molecules that promote the efflux of cholesterol can promote the formation of GPMVs, while those that inhibit the efflux of cholesterol hinder GPMV formation. Thus, the formation of GPMVs is a means to monitor the cholesterol content of cells to better understand the pathology of some diseases related to the abnormal accumulation of cholesterol in cells, such as Niemann–Pick type C and Alzheimer's disease.

4.2. GPMVs as plasma membrane models

4.2.1. GPMVs as models for studying membrane properties. GPMVs can serve as plasma membrane models to study the structure, composition, dynamic fluidity, and stimulus response. In contrast to the traditional view of the

Fig. 4 GPMVs as cell mimics. A) Cell mimics consisting of GPMVs produced from parent cells with internalized polymer artificial organelles also contain artificial organelles (reproduced with permission from ref. 16. Copyright 2020, Wiley). B) A similar method can be used to internalize nanoparticles into GPMVs (adapted with permission from ref. 30. Copyright 2021, American Chemical Society).

cell membrane structure, the membrane raft hypothesis assumes that there is a domain called a “raft” on the plasma membrane of cells.³² The existence of a “raft” plays an important role in cell function (both in membrane transport and membrane signalling).³³ However, this heterogeneity in the living cell membrane is difficult to observe by optical microscopy.³⁴

Baumgart *et al.* proved in their research that the vast majority of GPMVs can form optically distinguishable domains when the temperature is below approximately 25 °C. They found that the lipid distribution in GPMVs was similar to that in model membrane systems with the coexistence of liquid-order and liquid-disorder fluid phases and imaged GPMVs to characterize the distribution of proteins in different membrane phases.³³ For example, the transmembrane IgE receptor FcεRI was preferentially separated into a liquid-disordered-like phase, and the separation of other common membrane-related receptors was also reported. Here, GPMVs provided an effective method to characterize the heterogeneity of biomembranes. At the same time, this discovery verified the central principle of the membrane raft hypothesis, that is, the ability of eukaryotic membranes to form coexisting liquid domains, thus proving the rationality of the membrane raft hypothesis. In addition, nanodomains were observed at higher temperatures (physiological temperatures), and lipid replacement in the plasma membrane can regulate the tendency of the plasma membrane to form ordered domains.³⁵

Levental *et al.* further clarified that the properties of the coexisting phases formed in GPMVs depended on the conditions for separating GPMVs, especially the vesiculation agents.³⁶ Different separation conditions affected the phase separation temperature, the protein distribution among phases and the relative order between coexisting phases. The cholesterol-rich domain in the plasma membrane is considered to exclude many transmembrane proteins. GPMVs were used to quantitatively prove that the helical tetraspan peripheral myelin protein22 (PMP22) showed an obvious

preference for the ordered membrane domain, which promoted the formation of the ordered membrane domains and stabilized the ordered membrane domains.³⁷ Furthermore, Fricke *et al.* built a high-content platform that can be used to discover the chemical substances regulating plasma membrane rafts.³⁸ The platform proved its reliability by verifying existing valve regulators, such as C6- and C8-ceramides, miltefosine, and epigallocatechin gallate (Fig. 5A).

Moreover, Levental *et al.* used GPMVs to evaluate the plasma membrane structure and protein distribution.³⁹ Cells realize their biological functions by regulating their shape and the lateral organization of membrane-related proteins, and the recruitment of proteins to specific areas of the membrane can promote regulation. Moreno-Pescador *et al.* used GPMVs derived from transfected cells to study the response of different types of membrane proteins to curvature changes and lipid phases. Nanoscale membrane curvature was generated by extracting nanotubes from these vesicles with optical traps.⁴⁰ Chiang *et al.* developed a method for studying plasma membrane proteins using the air–water interface to rupture GPMVs and deposited them on a planar support to form a nanoscale supported membrane with natural plasma membrane proteins (Fig. 5B).⁴¹

GPMVs serve as tools to study the factors affecting membrane fusion.⁴² In the research of Kalyana *et al.*, GPMVs were used to form cell membranes in a developed suspension lipid bilayer system to study the assembly of lipids and proteins.⁴³ GPMVs are also used as sources of membrane and protein materials for building vesicle–nanotube networks. The vesicle–nanotube network system constructed by Bauer *et al.* requires obtaining membrane proteins and lipids from natural sources with high yield and functionality retention, making GPMVs become perfect precursors.⁴⁴

4.2.2. GPMVs as models for the study of interaction with plasma membranes. Owing to the inconvenience of directly researching the plasma membrane of living cells, GPMVs can serve as plasma membrane models for the study of interactions with the plasma membrane. Endocytosis should

Fig. 5 GPMVs as plasma membrane models for the study of the plasma membrane. A) Construction of a high-content imaging platform to discover chemical modulators of plasma membrane rafts (reproduced with permission from ref. 38. Copyright 2022, American Chemical Society). B) Rupturing GPMVs by air–water interface compression to form a microscale support membrane for plasma membrane protein study (adapted with permission from ref. 41. Copyright 2017, Springer).

be avoided as much as possible when drugs are transported to cells so as not to affect the efficacy, which is a subject explored by many researchers. Dubavik *et al.* improved the synthesis of amphiphilic CdTe@mPEG-SH nanocrystals and used GPMVs as endocytosis-free membrane models to prove their ability to escape the endocytic pathway (Fig. 6A).⁴⁵

The interaction of the cell membrane and lipoprotein particles, whose task is to exchange cell membrane components and participate in cell lipid metabolism, maintaining lipid balance, is generally considered to be related to specific receptors on the cell membrane. The receptor-independent interaction pathway has been noted and confirmed in some studies through the interaction between lipoprotein particles and GPMVs, where lipoprotein particles can still transfer cargoes to the plasma membrane (Fig. 6B).^{46,47} These findings may help to better understand the biology of lipoprotein granules and to guide the treatment of dyslipidaemia diseases.

By adjusting the composition of the membrane, GPMVs can also be used to clarify the mechanism and behaviour of different kinds of cell-penetrating peptides in crossing the plasma membrane.⁴⁸ For example, arginine-rich cell-penetrating peptides require nucleolin- and cholesterol-poor subdomains for translocation across membranes,⁴⁹ glycosaminoglycans are required for the translocation of amphipathic cell-penetrating peptides across membranes,⁵⁰ and the translocation of cell-penetrating peptides across the plasma membrane is controlled by cholesterol and the microenvironment created by membranous proteins.⁵¹

With insights into GPMVs, Steinkuhler *et al.* found that the interaction between lipid domains and membrane curvature produced a “superelastic” response, which represents the large deformation ability of the living cells’ plasma membrane.⁵² Applying the curvature parameters that allow the superelastic behaviour, a vesicle analogue containing only lipids was designed through the simulation

Fig. 6 GPMVs as plasma membrane models for the study of interactions with the plasma membrane. A) GPMVs are used to study the interaction between amphiphilic CdTe@mPEG-SH nanoparticles and the plasma membrane. The nanoparticles enter the cell by the endocytic-escape pathway, thus filling the whole cell. of GPMVs, with the denaturation ability three times that of traditional lipid vesicles, which made the bottom-up designed artificial cells more likely to approach the properties of living cells.

4.3. GPMVs as drug carriers

To date, liposomes,^{53,54} nanoparticles^{55,56} and exosomes^{57,58} have been widely studied and discussed as drug carriers. Compared with the above traditional drug carriers, the advantages of better biocompatibility, lower toxicity, accessible preparation and low immunogenicity imply that GPMVs also have potential as drug carriers.

The research of Zemljic *et al.* demonstrated that calcein AM and dextran (10 000 MW) can penetrate the membrane of GPMVs and remain in the membrane after washing, which is different from their behaviour in synthetic vesicles, and further, GPMVs can deliver dextran to cells grown *in vitro*.¹⁹ Their research shows that GPMVs are potentially useful as drug delivery systems. How to target is an important issue when using any material as a drug carrier. The conjugation of ligands to traditional drug carriers (as we mentioned before) is not easy to control, which often limits the consistency and complexity of ligands and thus limits the application of such drug carriers. This problem can be solved by extracting GPMVs from donor cells expressing engineered transmembrane targeting proteins because GPMVs retain the plasma membrane composition of their donor cells, as confirmed in the research of Zhao *et al.*²¹ This is undoubtedly another advantage of GPMVs as drug carriers.

Luo *et al.* encapsulated photosensitizers and photothermal therapeutic agents in GPMVs modified with cholesterol-labelled aptamers on the surface for targeted drug delivery and synergistic photodynamic/photothermal therapy.⁵⁹ GPMVs release therapeutic drugs by membrane fusion-mediated therapeutic transportation to kill targeted cancer

cells with no obvious toxicity to normal cells (Fig. 7A). Nanoparticle or liposome drug carriers enter cells through endocytosis and are often trapped in the endosomal lumen.^{60,61} Ineffective endoplasmic escape limits the efficiency of cytoplasmic delivery and increases the concentration of drugs needed to kill cancer cells.⁶² When two neighbouring cells meet, they can exchange cargoes (metabolites, second messengers, peptides and siRNA) through the gap junctions on their membrane, which provides a way to avoid endocytosis. Gadok *et al.* extracted GPMVs from donor cells that overexpressed gap junctions and developed the so-called connectosomes for directly delivering drugs to the cytoplasm of cancer cells without endocytosis.⁶³ The results showed that compared with either free or liposomal doxorubicin, this method reduced the therapeutic effective dose (LD₅₀) by more than one order of magnitude. The drugs entered the connectosomes by the pretreatment of donor cells with a drug-containing medium (Fig. 7B).

5. Challenges and prospects

This review has summarized the formation methods, properties, and biomedical applications of GPMVs. We emphatically discuss the biological and medical applications of GPMVs as cell mimics, plasma membrane models and drug carriers. Currently, the most widely used method to produce GPMVs is the vesiculation agent-mediated strategy, which can produce a large number of GPMVs in a matter of hours, but also causes the cross-linking of the plasma membrane proteins and destroys the asymmetry of the membrane, interfering with the study of the plasma membrane.^{4,6} Compared with synthetic phospholipid vesicles, GPMVs show better stability and biocompatibility. Compared with extracellular vesicles or cell membrane-derived vesicles, GPMVs require no complex procedures for

preparation or isolation, making GPMVs promising drug carriers. Besides, the ability to retain proteins on the parent cell membrane makes GPMVs worth exploring as targeted drug carriers. But there are also some problems that need to be solved, such as leakage when loading small molecules.²⁰ Programmed methods for loading cargoes also need to be developed.

The potential of GPMVs as cell mimics has not yet been fully explored, probably as a result of difficulty of loading biomacromolecules into GPMVs. Cell communication, one of whose ways is with the help of small molecules, is one of the key focuses in the field of cell mimicking. In previous studies, giant monolayer vesicles have been used more frequently for biomimetic cell communication.⁶⁴ GPMVs are well worth exploring as their alternatives. There have been a lot of research studies on GPMVs as plasma membrane models. But an underappreciated fact is that GPMVs can also be used as sources of plasma membranes; after all, GPMV vesiculation was originally proposed as a method of plasma membrane isolation. For example, plasma membrane vesicles are widely used for the coating of nanoparticles, where the plasma membranes are obtained through a series of procedures starting with cell lysis.^{65,66} GPMVs, which exclude structures such as large organelles of cells, can be used as an alternative method of obtaining plasma membranes.

In short, GPMVs are experimental tools with unique, even irreplaceable, advantages in certain fields. The ability of GPMVs to display a diverse range of unique structural and functional properties will enable the development of these biomimetic systems for a broad range of biological and biomedical applications.
