Highly selective CO₂ photoreduction to CO on MOF-derived TiO₂†

Matthew Garvin,^a Warren A. Thompson,^a Jeannie Z. Y. Tan,^a Stavroula Kampouri,^b Christopher P. Ireland,^b Berend Smit,^b Adam Brookfield,^c David Collison,^c Leila Negahdar,^{d,e} Andrew M. Beale,^{d,e} M. Mercedes Maroto-Valer,^a Ruairaidh D. McIntosh^f and Susana Garcia^{*a}

Metal–Organic Framework (MOF)-derived TiO₂, synthesised through the calcination of MIL-125-NH₂, is investigated for its potential as a CO₂ photoreduction catalyst. The effect of the reaction parameters: irradiance, temperature and partial pressure of water was investigated. Using a two-level design of experiments, we were able to evaluate the influence of each parameter and their potential interactions on the reaction products, specifically the production of CO and CH₄. It was found that, for the explored range, the only statistically significant parameter is temperature, with an increase in temperature being correlated to enhanced production of both CO and CH₄. Over the range of experimental settings explored, the MOF-derived TiO₂ displays high selectivity towards CO (98%), with only a small amount of CH₄ (2%) being produced. This is notable when compared to other state-of-the-art TiO₂ based CO₂ photoreduction catalysts, which often showcase lower selectivity. The MOF-derived TiO₂ was found to have a peak production rate of $8.9 \times 10^{-4} \mu\text{mol cm}^{-2} \text{h}^{-1}$ ($2.6 \mu\text{mol g}^{-1} \text{h}^{-1}$) and $2.6 \times 10^{-5} \mu\text{mol cm}^{-2} \text{h}^{-1}$ ($0.10 \mu\text{mol g}^{-1} \text{h}^{-1}$) for CO and CH₄, respectively. A comparison is made to commercial TiO₂, P25 (Degussa), which was shown to have a similar activity towards CO production, $3.4 \times 10^{-3} \mu\text{mol cm}^{-2} \text{h}^{-1}$ ($5.9 \mu\text{mol g}^{-1} \text{h}^{-1}$), but a lower selectivity preference for CO (3 : 1 CH₄ : CO) than the MOF-derived TiO₂ material developed here. This paper showcases the potential for MIL-125-NH₂ derived TiO₂ to be further developed as a highly selective CO₂ photoreduction catalyst for CO production.

Sustainability spotlight statement

Historically, most of our daily chemicals have been synthesised from syngas (CO & H₂) via the Fischer–Tropsch process. Fossil fuels are the main carbon-based feedstocks in the process, making them responsible for a large amount of the GHG emissions from the chemical sector. Alternative renewable and sustainable sources of CO and H₂ would allow for the development of fossil fuel-free and carbon neutral chemicals and products without replacing existing infrastructure. This work investigates the potential of a MOF-derived TiO₂ photocatalyst for CO₂ photoreduction that is selective for CO production. This reaction utilises light, water and CO₂ and offers a sustainable route to CO production. Hence, this work aligns with several UN SDGs, namely, 7, 12, and 13.

Introduction

The increased pressure on governments and industries to commit to sustainable energy and production practices has generated a lot of interest in technologies that can address greenhouse gas emission reduction targets.¹ Carbon Capture Utilisation and Storage (CCUS) is one of those technologies, where the utilisation of CO₂ has the potential double benefit of not only reducing greenhouse gas emissions but also providing a financial incentive to do so through the production of commodity chemicals.^{2–8} Many different approaches have been trialed in order to convert CO₂ to fuels or other value-added products, including catalytic, electrocatalytic, photocatalytic and photoelectrocatalytic reactions.^{9–16} In each of these cases, the high stability of the C=O bond ($\Delta G^\circ = -394.36 \text{ kJ mol}^{-1}$)

and linear geometry of CO₂ poses a thermodynamic challenge, which needs to be overcome before it can be transformed to valuable compounds. Photocatalytic processes offer a low cost and carbon neutral pathway to overcoming these challenges, as sunlight will be the primary energy source to convert CO₂ into fuels or other high-value hydrocarbons. Of note is the conversion of CO₂ to form methane and carbon monoxide, as the former can feed into already established energy systems and the latter can act as a sustainable C1 building block for several products derived from Fischer–Tropsch processes, when partnered with a sustainable source of hydrogen.

The success of any photocatalytic reaction relies on the efficiency of the photocatalysts available. There are three critical steps that govern the efficiency of a photocatalyst; (1) light absorption to generate charge carriers (electrons (e⁻) and holes (h⁺)), (2) charge separation and migration of charges to the active sites, and (3) the redox reaction itself.^{17,18} Each of these steps is heavily influenced by the physical and electronic properties of the photocatalyst, with improvements made in any of the steps being impactful on the overall performance.¹⁹ There are a number of materials that have been used as photocatalysts for CO₂ photoreduction *e.g.*, semiconductors, Metal–Organic Frameworks (MOFs), and organometallic complexes.^{18–26} Semiconductors are the most prominent class of photocatalysts, with TiO₂ being the most studied of these due to its high photostability, low cost, high natural abundance and low toxicity.²⁷ Since its first demonstrated use, in water splitting by Fujishima and Honda in 1972, TiO₂ has been studied extensively and has found success as a catalyst for CO₂ photoreduction.^{27–30} The latest state of the art TiO₂ based photocatalysts focus on minimising the charge recombination to maximise their efficiency, and there are a number of strategies that are employed to achieve this.^{31–33} One such method is to use the pores of a MOF as a chamber to grow TiO₂ particles.³⁴ This allowed for synergy between the light absorbing/electron generating TiO₂ and the catalytic metal clusters of the MOF to enhance CO₂ reduction.³⁴ Noble metal co-catalysts are commonly introduced as a method to enhance light absorption as well as reducing electron–hole recombination.^{35,36} Another method, described in Angulo-Ibáñez *et al.*'s work involves the synthesis of a TiO₂ based metal–organic aerogel which results in a highly active photocatalyst for methanol production.³⁷ These methods focus on improving light conversion to charge carriers and prioritise facilitating the photoreduction reaction. Great improvements have been made in these areas, however, the lack of selectivity in the products produced is still a challenge that has yet to be overcome.

Previous work by Kampouri *et al.* prepared mixed-phase TiO₂ nanoparticles through calcination of a MOF, MIL-125-NH₂, and showcased enhanced activity for hydrogen production *via* photocatalytic water splitting.³⁸ The MOF structure acted as a sacrificial template to form rectangular parallelepipeds particles of TiO₂ as the organic components were burned away. Through strict control of the calcination temperature they were able to alter the ratio of anatase and rutile in the resultant TiO₂ nanoparticles. Subsequent study of the MOF-derived TiO₂ for photocatalytic hydrogen generation was promising with the material exhibiting high H₂ production rates outperforming

P25 (Degussa) – a common commercial TiO₂ benchmark. They attribute the excellent performance of the MOF-derived TiO₂ the formation of longer lived charge carriers due to reduced electron–hole recombination afforded by charge transfer between the anatase and rutile phases in the TiO₂ nanoparticles within the MOF-templated crystals. Given the reduced electron–hole recombination and enhanced activity, compared to P25 (Degussa), this material looks to be well suited to catalysing CO₂ photoreduction. As such, this work examines the potential of this material as a photocatalyst for CO₂ reduction, exploring the impact of temperature, irradiance, and partial pressure of water (*P*_{H₂O}) on CO₂ conversion.

Experimental

Photocatalyst preparation

The MOF derived TiO₂ was synthesised according to work of Kampouri *et al.*, the details can be found in the ESI† along with the characterisation used to confirm its successful synthesis (SI. 1†).³⁸

Once acquired, the MOF-derived TiO₂ was loaded onto a glass fiber disc support using the following protocol: approximately 10 mg of the photocatalyst was added to 1 mL of ultrapure water in a 10 mL glass sample vial. The suspension was then agitated in an ultrasonic bath for 3 minutes and the resultant slurry was applied to a 47 mm glass fiber disc (Whatman) by drip coating before drying in an oven at 120 °C for two hours. The same protocol was followed using a commercial P25 photocatalyst, which was used for benchmarking purposes.

Photoreduction test

The photoreduction of CO₂ was investigated in a purpose-built gas phase system (Fig. 1) using water as the reducing reagent, used previously by our group.^{39,40} The photocatalyst coated glass fibre disc was placed in the middle of the photoreactor and, to eliminate residual air contamination, the system was evacuated *via* three swing purge-vacuum steps placing the system under vacuum and then purging with CO₂ (99.995%). The flow rate of CO₂ was set to 0.35 mL min⁻¹ and was passed through the temperature controlled (±0.1 °C) aluminium body saturator for at least 16 h to allow the system to equilibrate. To record the partial pressure of H₂O, relative humidity (±1.8% RH) was measured using an inline Sensirion SHT75 humidity sensor placed (MG Chemicals 832HD) into a Swagelok 1/4" T-piece. The photoreactor was heated using a hotplate and after at least 16 h equilibration, the surface temperature of the coated photocatalyst was measured using a Radley's pyrometer (±2.0 °C). To prevent condensation at higher relative humidity, the lines from the outlet of the impinger, up until the inlet of the H₂O trap, were heated and temperature controlled (±0.1 °C) with a heating cord and thermocouple (Fig. 1).

An OmniCure S2000 (300–600 nm) was used as the light source and the irradiance set according to the experimental design (Table 1). The light source was placed 30 mm above the surface of the coated glass fibre disc and irradiance, at the exit

Fig. 1 Overview of the experimental setup used for the CO₂ photoreduction tests (Not to scale).³⁴

of the fibre optic light guide, was measured before each experiment by using an OmniCure R2000 radiometer ($\pm 5\%$). An inline GC (Agilent, Model 7890B series) with a Haysep Q column (1.5 m), 1/16 inch od, 1 mm id, MolSieve 13X (1.2 m), 1/16 inch od, 1 mm id, thermal conductivity detector (TCD), nickel catalysed methanizer and flame ionization detector (FID) was used to analyse the output of the photoreactor every four minutes. The GC was calibrated using 1000 ppm calibration gas (H₂, CO, O₂ and CH₄) in a balance of Ar gas that was further diluted with Ar (99.995%). Cumulative production ($\mu\text{mol cm}^{-2}$) was calculated by integrating the area under the production rate ($\mu\text{mol cm}^{-2} \text{ h}^{-1}$) vs. time (h) curve using the trapz MATLAB function.

Design of experiments

The impact of irradiance, temperature, and partial pressure of H₂O on photoreduction was tested for the MOF-derived TiO₂ photocatalyst within the following experimental ranges: irradiance (150–300 mW cm⁻²), temperature (38–56 °C) and P_{H₂O} (2.50–3.00 kPa). In order to properly explore the large experimental space with the minimum number of experiments a two-

level full-factorial experimental design with three central points was used to systematically investigate the experimental space shown in Table 1. Additional details of the experimental design can be found in the ESI.†

To allow for a more appropriate comparison to other systems and photocatalysts, additional photoreduction experiments were carried out using the best performing conditions and a commercially available P25 (Degussa) sample, as a reference material.

Results and discussion

The experimental space investigation in Table 1 revealed that MOF-derived TiO₂ produced both, CH₄ and CO (Fig. 2), with a significant selectivity towards CO production which was, on average, an order of magnitude greater than CH₄ production. Both CH₄ and CO production profiles peak between 1–1.5 hours before exhibiting a deactivation profile. This deactivation trend is a common observation for TiO₂ based catalysts for CO₂ photoreduction and may be attributed to a loss of oxygen vacancies or accumulation of reaction intermediates on the

catalyst surface.^{41–44} The reproducibility and consistency of our experimental design was confirmed through triplicate tests at the central points (SF. 8†). For CH₄, the three central points yielded an average cumulative production of $3.70 \times 10^{-4} \mu\text{mol cm}^{-2} \pm 1.39 \times 10^{-4} \mu\text{mol cm}^{-2}$. For CO production the central points yielded good reproducibility with an average cumulative production of $1.85 \times 10^{-2} \mu\text{mol cm}^{-2} \pm 2.46 \times 10^{-3} \mu\text{mol cm}^{-2}$. The conditions used in Exp 8 (Table 1) were found to have the greatest production rate of CO, peaking at a rate of $8.9 \times 10^{-4} \mu\text{mol cm}^{-2} \text{ h}^{-1}$ ($2.6 \mu\text{mol g}^{-1} \text{ h}^{-1}$) and cumulatively producing $2.1 \times 10^{-2} \mu\text{mol cm}^{-2}$ ($64.0 \mu\text{mol g}^{-1}$) of CO over 4 h. Exp 7 was found to have the greatest production rate of CH₄ peaking at $2.6 \times 10^{-5} \mu\text{mol cm}^{-2} \text{ h}^{-1}$ ($0.1 \mu\text{mol g}^{-1} \text{ h}^{-1}$) and cumulatively producing $6.28 \times 10 \mu\text{mol cm}^{-2}$ ($2.5 \mu\text{mol g}^{-1} \text{ h}^{-1}$) of CH₄.

The results of the DoE shown in Fig. 3 indicate that for cumulative production of both CH₄ and CO, temperature is the only statistically significant parameter. This can also be observed in Fig. 2b where Exp 3, 4, 7 and 8, which have the highest temperature settings in the design, exhibit increased production of CO. The increase in performance with increasing temperature has been documented in a number of studies,

wherein it is believed to contribute to the initial breaking of C–O bonds in CO₂ adsorbed to the surface of TiO₂.^{45–47} For instance, Liu *et al.* report a 10-fold increase in performance when the temperature was gradually increased from 50 to 150 °C. However, there does appear to be an optimum temperature window with further increases to 170 °C showing a decrease in activity.⁴³ In a separate study, it is proposed that elevated temperatures aid in the desorption of intermediates and products making the active sites available for CO₂ adsorption.⁴⁸

In this work, the range of explored irradiance values ($1480\text{--}2980 \text{ W m}^{-2}$) displayed no statistically significant impact on the production of CO or CH₄ (Fig. 3). This is consistent with work by Dilla *et al.* which examines the irradiance relationship in P25 (Degussa) and finds that at high irradiances ($230\text{--}1700 \text{ W m}^{-2}$) there is a minimal increase in the rate in rate of production, whereas at low irradiances ($<230 \text{ W m}^{-2}$) there is a much larger increase in the rate of production, although the overall rate remains low.⁴⁹ The authors explain that at higher irradiances the higher concentration of charge carriers lead to an increase in charge transfer to adsorbed species, but also increase the thermodynamically preferred charge-recombination events hence leading to an overall minimal increase in the rate.

Fig. 3 (a) CH₄ and (b) CO main effects plots to visually highlight the strength of each reaction parameter.

Similarly, the work by Olivo *et al.* also finds that low irradiance ($40\text{--}60\text{ W m}^{-2}$) is a statistically significant parameter, attributing this to an insufficient number of photons to activate all available photocatalytic sites.³⁹ However, they find that at high irradiances ($60\text{--}2400\text{ W m}^{-2}$) there is a minor dependence on irradiance for CH₄ production, attributing this to fewer incident photons being required to activate the photocatalytic sites. These reports are consistent with our findings and indicate that the active sites on the MOF-derived TiO₂ are also fully saturated at irradiances as low as 1480 W m^{-2} , and likely even as low as 230 W m^{-2} . This is notable for potential commercialization of this photocatalyst, as the average solar irradiance on earth's surface is $\sim 325\text{ W m}^{-2}$ of which $\sim 8\%$ is made up of UV light, meaning that solar concentrators would be required to artificially boost irradiance if the light source being used is natural solar light.^{50,51} This is also highly dependent on the location and

the set-up of any future plant as surface solar irradiance varies significantly based on location, for example in the UK the highest average annual solar irradiance was in the range of $123.4\text{--}126.0\text{ W m}^{-2}$.⁵²

The range of H₂O partial pressures ($2.48\text{--}3.05\text{ kPa}$) explored here do not have a statistically significant relationship with CO/CH₄ production (Fig. 3). The effect of H₂O is important to monitor as it is an integral parameter to facilitate the reaction. Without the presence of water the reaction cannot proceed, however, at elevated levels it has been shown to inhibit the reaction due to blocking the active sites or weakening CO₂ adsorption.⁴² Previous investigations by others into the effect of water concentration on the production of CH₄/CO give contradictory results. Molins *et al.* find a statistically significant increase in photocatalytic production of methane with increasing water mole fraction ($x_{\text{H}_2\text{O}} = 0.25\text{--}0.75$) across Pt/TiO₂

(P25) photocatalysts, whereas Dilla *et al.* found that a continuous flow of H₂O inhibited CH₄ formation due to competition with CO₂ over active sites.^{47,49}

To allow for an appropriate comparison to other systems and photocatalysts, additional photoreduction experiments were carried out using the conditions in Exp 8 and the commercially available P25 (Degussa) as a reference material (Fig. 4). P25 exhibits a greater overall activity towards CO₂ photoreduction than the MOF-derived TiO₂, producing appreciable amounts of both CO and CH₄, and reaching an average maximum production rate of $1.4 \times 10^{-3} \mu\text{mol cm}^{-2} \text{h}^{-1}$ ($2.5 \mu\text{mol g}^{-1} \text{h}^{-1}$) and $5.0 \times 10^{-3} \mu\text{mol cm}^{-2} \text{h}^{-1}$ ($8.9 \mu\text{mol g}^{-1} \text{h}^{-1}$) for CO and CH₄, respectively. P25 cumulatively produced $0.044 \mu\text{mol cm}^{-2}$ ($0.078 \mu\text{mol g}^{-1}$) and $0.14 \mu\text{mol cm}^{-2}$ ($0.24 \mu\text{mol g}^{-1}$) on average for CO and CH₄, respectively. Both photocatalysts follow similar deactivation profiles after peaking at ~ 1 h. The selectivity of P25 leans towards CH₄ (3 : 1 CH₄ : CO) which is in accordance with literature.^{41,53–55} Conversely, MOF-derived TiO₂ has almost complete selectivity towards CO (1 : 49 CH₄ : CO) albeit with a lower total activity. This lower activity was unexpected as the MOF-derived TiO₂ was shown to have a longer charge lifetime when compared to P25, which is an integral part of the photoreduction process therefore we were anticipating enhanced activity.³⁸

It is an interesting and important observation that the MOF-derived TiO₂ produces almost exclusively CO. There are several factors that could cause this; the surface of the photocatalyst could be more prone to desorbing CO intermediates, or the reduced surface area of the MOF-derived TiO₂, when compared to P25, results in fewer surface bound hydroxyls available to participate in the reaction.³⁸ Typically, purely TiO₂ based semiconductors have exhibited poor control over the products of the photoreduction leading to inefficient reactions. The selectivity of photocatalysts is strongly influenced by the surface of the material and how it interacts with adsorbed species.¹⁸ For example, in a work by Li *et al.* the introduction of dual-metal sites shifted the selectivity to almost 100% CH₄ through stabilisation of C–O intermediates preventing their desorption prior to reduction.⁵⁶

When comparing MOF-derived TiO₂ to other state-of-the-art CO₂ photocatalysts, in terms of selectivity, the potential of this material is highlighted (Fig. 5).^{34–36,57–59} Being able to achieve a 98% selectivity towards CO without a co-catalyst is very significant, as typically TiO₂ photocatalysts are coupled with expensive noble metal co-catalysts to alter the surface in such a way as to direct the selectivity.^{30,60} When compared to other photocatalysts (Fig. 5), the MOF-derived TiO₂ is only out-competed in selectivity by the molecular photocatalyst grafted to TiO₂, CpRu_{0.6}/TiO₂, and SBNT-HR-0.5, Sr₂Bi₂Nb₂TiO₁₂ nanosheets, which are 100% selective for CH₄ or CO, respectively (experimental and production details can be found in S3 of the ESI†).^{57,58} When taking into consideration the relatively simple synthesis and abundance of the required materials, MOF-derived TiO₂ is an attractive catalyst for CO₂ photoreduction. Currently there are areas for improvement/development before this photocatalyst can match the other state of the art catalysts. For instance, the activity of the MOF-derived TiO₂ is quite low compared to current top performers, such as those reported by recent work from Jiang *et al.*, where they observe a production rate of $12 \text{ mmol g}^{-1} \text{h}^{-1}$ without a decay in performance across 60 h.³⁴ The second area for further development is enhancing the visible-light absorption. MOF-derived TiO₂ is still a form of TiO₂ that does not absorb significantly in the visible light region of the solar spectrum, which affects its potential to generate charges to take part in the reaction. However, addressing these issues is quite feasible through further optimisation or modification of the catalyst.

Cycle tests were carried out to investigate the longevity and stability of MOF-derived TiO₂. These show a decline in performance after two cycles (SF. 9†), which may be due to accumulation of intermediates on the active sites.⁴² The performance may potentially be recovered through regeneration of the catalyst through a heat cycle to desorb the intermediates.

To understand the observed selectivity additional investigations into the electronic properties were conducted. Fig. 6A shows the photocurrent response for MOF-derived TiO₂ under UV-visible ($\lambda = 320\text{--}1000 \text{ nm}$) light irradiation at a constant potential 0.5 V (vs. SCE). The MOF-derived TiO₂ exhibits a sharp

Fig. 4 MOF-derived TiO₂ and P25 production rates of (A) CH₄ and (B) CO using the best performing conditions found from the design of experiment (Table 1, Exp 8).

Fig. 5 Comparison of the selectivity of the MOF-derived TiO₂ (Exp 8) compared to P25 and other state-of-the-art CO₂ photoreduction catalysts.

response to light, reaching a peak photocurrent density of $-18.33 \mu\text{A cm}^{-2}$ before equilibrating at $-12.70 \mu\text{A cm}^{-2}$ before sharply returning to the baseline upon the light being turned off. There is an increase in photocurrent density (-8.51 to $-12.70 \mu\text{A cm}^{-2}$) over time first giving a peak response of $-8.51 \mu\text{A cm}^{-2}$ before gradually increasing to $-12.70 \mu\text{A cm}^{-2}$ where it appears to reach a plateau. This is an interesting result for two reasons, firstly the MOF-derived TiO₂ shows a lower photocurrent density compared to that of P25, which would contribute to the higher activity shown by P25 towards CO₂ photoreduction. The second reason is that the MOF-derived TiO₂ has a negative photocurrent density. This is indicative of p-type semiconductor behaviour, which is typically not observed in undoped TiO₂-based materials where typically n-type semiconductor behaviour is observed. The p-type behaviour in undoped TiO₂ species has been suggested linked to Ti vacancies present within the

material.^{61,62} To investigate this hypothesis, Electron Paramagnetic Resonance (EPR) spectra were collected to determine if these p-type Ti vacancies were present in the MOF-derived TiO₂. As reported in the literature, p-type vacancies usually present as relatively strong signals with g -values ≈ 1.998 and are typically measurable at both cryogenic temperatures and higher (towards room temperature) in contrast to the anatase/rutile defects present in commercial TiO₂, where cryogenic temperatures are vital for adequate sensitivity of detection.^{63,64}

Variable temperature EPR spectra of the MOF-derived TiO₂ were collected at both X-band (SF. 3†) (≈ 9.4 GHz) and Q-band (≈ 34 GHz) frequencies and confirm the presence of the Ti vacancies with $g = 2.002$ (Fig. 6B). The higher frequency of Q-band was particularly useful to unpack the spectra by separating the resonances of the trace copper impurities (one component is at $g = 2.069$ and is confirmed by XRF, arising

Fig. 6 (A) Photocurrent response for MOF-derived TiO₂ & P25 (B) Q-band continuous wave EPR spectra of the MOF derived TiO₂ at 150 K. Microwave frequency 34.023535 GHz, microwave power 0.1 mW, modulation amplitude 5 G.

from starting materials, SF. 5†) away from the signal of interest. The *g*-value obtained differs slightly to the literature value but is within the range of uncertainties present when carrying out field correction against a standard sample, and the shape of the resonance is as reported previously.⁶³

The effect of titanium vacancies on the electronic properties have been reported by Bak *et al.*⁶⁵ They note that charge transfer is enhanced for electrons and decreased for holes, as a result charge recombination is reduced. This phenomenon is observed in MOF-derived TiO₂ through the photoluminescence experiments carried out in the original work by Kampouri *et al.*, where it exhibits lower emissions compared to P25.³⁸ Wang *et al.* therefore attribute the enhancement in organic pollutant degradation performance to these electronic properties arising from the presence of titanium vacancies within the structure of the photocatalyst.⁶³ Although, in this work enhanced activity was not observed *vs.* P25, possibly due to the inherent differences between CO₂ photoreduction reaction and pollutant degradation. To further our understanding of the reaction mechanism *in situ* Diffuse Reflectance Infrared Fourier Transform Spectroscopy (DRIFTS) studies were conducted on P25 and MOF-derived TiO₂.

DRIFT spectra of the MOF-derived TiO₂ at room temperature, at room temperature with CO₂, at 60 °C with CO₂, after 1 minute of light exposure and after 60 minutes of light exposure are shown in Fig. 7. The peaks at 3543 and 1626 cm⁻¹ are assigned to H₂O with the former being broad due to the effects of H-bonding with other molecules or surface hydroxyls. Hydroxyl signals can be observed 3727–3598 cm⁻¹, which can be assigned to non-H-bonded “free” hydroxyls that could be found on the edges of MOF-derived TiO₂ particles.⁶⁶ These signals become more pronounced upon light exposure and temperature increasing. Increasing the temperature from room temperature to 60 °C decreases the signals at 3567 and 3543 cm⁻¹, which further suggests that they are a combination of H-bonded molecular water and hydroxyl groups. The CO₂ ν_{as} (CO) signal can be found at 2347 cm⁻¹ (SF. 6†) which is supported by values found in literature.⁶⁷ The CO signal is broad and is centered around 2048 cm⁻¹ which is relatively low

compared to literature but still within an appropriate range (2200–2050 cm⁻¹).^{68–70} The region from 1800–1200 cm⁻¹ is where the mono- and bi-dentate carbonate (1558 ν_{as} (OCO) b-CO₃²⁻, 1472 m-CO₃²⁻, 1335 b-CO₃²⁻ cm⁻¹), bicarbonate (1431 cm⁻¹) and water (1626 cm⁻¹) signals are found.^{74,72} The broad nature of the signals in this region makes accurate assignment challenging. However, based on the changes with temperature we can assign the signal at 1626 cm⁻¹ to molecular water as it decreases with increasing temperature, and the signal at 1558 cm⁻¹ can be assigned to a carbonate species (ν_{as} OCO) given the slight increase in signal with temperature and light exposure. Similar absorption bands were observed in the P25 sample (SF. 7†), however the 1800–1200 cm⁻¹ region was even more poorly defined, although the same temperature related trends are present.

There were no signals corresponding the presence of formate or methoxy species, which suggests that formic acid and methanol are not formed in the reaction.⁷³ It is possible these products are formed and the intermediates are not observed on this reaction timescale. The *operando* DRIFTS study shows the reaction intermediates and pathways that are important for CO₂ photoreduction to CO over this catalyst. However, based on DRIFTS result, the mechanism for CO formation is suggested to proceed through a reduction of CO₂⁻ with H⁺ (eqn (1)) or potentially through a disproportionation reaction between two CO₂⁻ species (eqn (2)).^{74,75}

Conclusions

This study showcases a promising new photocatalyst for CO₂ photoreduction. The systematic investigation of the reaction parameters – irradiance, temperature, and partial pressure of water – through a two-level design of experiment (DoE) has shown that only temperature is a statistically significant

parameter for CO₂ photoreduction. The MOF-derived TiO₂ was found to produce almost exclusively CO as a photoreduction product. The high selectivity we observe is unusual in purely TiO₂ based photocatalysts and was achieved without the use of a co-catalyst or expensive rare-earth metals. Comparison experiments were carried out with commercially available P25 (Degussa) using the best conditions found through the DoE. This comparison showed that P25 was more active than MOF-derived TiO₂, however, this activity was split across both CH₄ and CO (3 : 1) production. Finally, the selectivity of MOF-derived TiO₂ was compared with other state of the art CO₂ photocatalysts and the MOF-derived TiO₂ compared favourably. The selectivity of the MOF-derived TiO₂ reported here outperforms the majority of the state-of-the-art photocatalysts which employed co-catalysts to enhance performance. The p-type conductivity of the MOF-derived TiO₂ is in contrast to the n-type conductivity of P25. Our empirical observations suggest that this plays a role in the selectivity observed in the CO₂ photoreduction, however further experiments will be required to elucidate the mechanism of this reaction. This catalyst is an exciting prospect and will be the subject of future work that will focus on enhancing its activity whilst maintaining its excellent selectivity.

Acknowledgements

We would like to thank the Engineering and Physical Sciences Research Council, Heriot-Watt University and the CRITICAT Centre for Doctoral Training for financial support (PhD Student M. Garvin, EPSRC Grant: EP/L016419/1). As well as the PrISMa Project (No 299659), which is funded through the ACT programme (accelerating CCS Technologies, Horizon 2020 Project No 294766). We thank the EPSRC National Research Facility for EPR Spectroscopy (NS/A000055/1). UK Catalysis Hub is kindly thanked for resources (DRIFT and XRF) and support provided via the membership of the UK Catalysis Hub Consortium and funded by current EPSRC grants: EP/R026939/1 and EP/R026815/1.
