Few-layer MoS₂ nanosheets with and without silicon nanoparticles as anodes for lithium-ion batteries†

Ifra Marriam,^{ID}*^{ab} Mike Tebyetekerwa,^{ID}^c Hao Chen,^a Hiran Chathuranga,^{ab} Nunzio Motta,^{ID}^{bd} Jose A. Alarco,^{ID}^{bd} Zhen-Jiang He,^{ID}^e Jun-Chao Zheng,^{ID}^e Aijun Du,^{ID}^{bd} and Cheng Yan,^{ID}*^{ab}

Few-layer two-dimensional (2D) molybdenum disulfide (MoS₂) nanosheets are potential anode materials for lithium-ion batteries due to their stable electrochemical performance. On the other hand, silicon (Si) is attracting the attention of battery research due to its high specific capacity, but its problem of volume expansion remains a challenge. Hence, rationally designed MoS₂ nanosheets with Si may take the synergy between these materials, which can not only mitigate the volume expansion but also maintain excellent electrochemical properties. Therefore, we have successfully synthesized few-layer MoS₂ nanosheets on water-soluble, naturally abundant, and cost-effective recrystallized three-dimensional sodium chloride (NaCl) crystals. The obtained free-standing few-layer MoS₂ nanosheets are utilized to form a MoS₂@Si heterostructure. It has been confirmed that the layered MoS₂ nanosheets can accommodate the volume expansion of Si and provide channels for lithium-ion transport during electrochemical cycles. After 500 cycles, the volume expansion is reduced to 68%, a remarkable improvement compared to 430% in pristine Si. Exceptional rate and cycling performance have been achieved in the composite anode, with a capacity retention of 60% compared to 0.3% for pristine Si at a high current density of 500 mA g⁻¹. This work provides a rational design for Si and 2D material composites as anode materials for improved electrochemical performance.

Introduction

Two-dimensional (2D) layered materials are currently being considered for energy storage applications, commonly in batteries and supercapacitors, due to their unique electrochemical properties.^{1,2} These materials are from various sources with several properties. They include carbonaceous materials such as graphite (graphene), transition metal dichalcogenides (MoS₂, WS₂, MoSe₂, WSe₂, etc.), mono-element 2D materials (such as silicene, phosphorene, etc.), transition metal carbide- and carbon nitride-based MXenes, and many other materials

such as metal-organic frameworks.³⁻⁶ This is because 2D materials have unique 2D intrinsic surface areas, which can easily facilitate fast and superior charge storage in batteries when exposed to electrolyte ions.^{7,8} In lithium-ion batteries (LiBs), graphite with a theoretical specific capacity of 372 mA h g⁻¹ is popular and is currently employed as the commercial anode material.⁹⁻¹¹ However, the limited capacity of graphite is a challenge, prompting research to hunt for new materials like silicon (Si) and metal oxides, which demonstrate higher storage capacities due to their alloying mechanism of charge storage.¹² Si anodes are well known for their high initial capacities of ~3500 mA h g⁻¹ when tested at low current densities, but they retain minimal capacity at higher current densities. Also, notably, Si undergoes large volume fluctuation during the lithiation/delithiation, which can cause the pulverization of electrode materials resulting in severe capacity decay and unstable cycling performance.^{13,14} One approach to solving this problem is introducing other materials with the Si anode to suppress its volume expansion. Ideally, the added material should be electrochemically active, which can simultaneously contribute to the overall capacity.

The addition of existing 2D materials can enhance the capacity of LiBs, given their good electrochemical properties and the tendency to suppress the volume expansion of Si

particles, thus facilitating long cycle life.^{15,16} Among other 2D materials, MoS₂ 2D nanosheets are quite promising as an anode for LiBs. The experimental reversible specific capacity of the MoS₂ anode reaches 1290 mA h g⁻¹, and it exhibits excellent rate performance and lower cycling degradation.^{17,18} It has the capability of being cycled at high current densities with significantly less volumetric expansion upon lithiation.^{19,20} Hence, we designed a layer-by-layer heterostructure with MoS₂ 2D nanosheets and Si nanoparticles (MoS₂@Si), *i.e.*, MoS₂-Si-MoS₂, where few-layer MoS₂ nanosheets wrap Si nanoparticles to suppress its volume expansion and improve the cycling stability of the anode during lithiation/delithiation.

However, obtaining few-layer MoS₂ nanosheets is not a straightforward approach. Several techniques have been proposed to synthesize MoS₂ nanosheets. They are commonly synthesized on thin substrates/wafers of Si/SiO₂, glass, sapphire, *etc.*²¹⁻²³ But it is challenging to transfer MoS₂ nanosheets from these substrates without damaging their structure. Not only that, but the mass production of mono-to few-layer MoS₂ is not possible because of the limited surface area of these substrates. Hence, we utilized a naturally abundant, cost-effective, water-soluble three-dimensional substrate (*i.e.*, sodium chloride (NaCl) crystals) to synthesize few-layer MoS₂ 2D nanosheets *via* the chemical vapor deposition (CVD) technique. NaCl crystals are known to be highly effective in promoting the growth of MoS₂ during the CVD process²⁴⁻²⁷ and are water soluble and environment friendly, allowing the easy removal of the salt substrate by simply dissolving in water to obtain neat MoS₂ 2D nanosheets. This avoids unnecessary contamination and irreversible damage to 2D nanosheets.

In this work, we synthesized continuous few-layer MoS₂ 2D nanosheets on a NaCl substrate, which are used to fabricate the MoS₂@Si heterostructure *via* a vacuum filtration technique. The pristine MoS₂ 2D nanosheets and MoS₂@Si heterostructure were then tested as anode materials for LiBs. The electrodes prepared with MoS₂@Si demonstrated excellent electrochemical performance, greatly improved cycling stability after 500 cycles, and suppressed volume expansion of Si.

Experimental

Synthesis of MoS₂ 2D nanosheets

10 g of commercial NaCl (sodium chloride) (99%, $M_w = 58.44$ g mol⁻¹, Sigma-Aldrich) were dissolved in 40 ml of distilled water to form a saturated solution and filtered through vacuum filtration. Then, 20 ml of ethanol was added to the filtered solution to promote the crystallization of NaCl crystals. The solution was stirred well and filtered again. Then, the filtered NaCl crystals were dried in an oven at 80 °C overnight, and the micron-sized NaCl cubes were obtained. The MoS₂ 2D nanosheets were then synthesized on NaCl cubes *via* the CVD technique. It begins by mixing MoO₃ (molybdenum trioxide, 99.97%, $M_w = 143.94$ g mol⁻¹, Sigma-Aldrich) with a trace amount of NaCl (20 wt%) as a growth promoter to promote the volatilization of Mo precursor at low temperatures. The growth is performed in a two-zone furnace at a low-pressure (0.05 MPa) equipped with a 15 cm quartz tube. Zone 1 contained sulfur as

a precursor (99.97%, $M_w = 32.07$ g mol⁻¹, Sigma-Aldrich) with a temperature of 150 °C. At the same time, the MoO₃ + NaCl mixture and crystallized NaCl (as a substrate) were placed in zone 2 with a temperature of 700 °C. Noble gas (Ar) with the 80 sccm flow was introduced in the CVD chamber tube. The chamber was then heated at 70 °C min⁻¹. Three different growth times, 3, 5, and 10 min were set to observe their effect on the growth of MoS₂.

Fabrication of the MoS₂@Si heterostructure

A sandwich heterostructure of MoS₂ 2D nanosheets with 0D Si nanoparticles (MoS₂@Si) was prepared *via* vacuum filtration. First, MoS₂@NaCl was dissolved in distilled water and centrifuged at 13 000 rpm until the NaCl was completely dissolved. Simultaneously, Si was prepared in solution by mixing Si powder (98%, ≤50 nm, Sigma-Aldrich) with distilled water, followed by stirring until a uniform dispersion was achieved. The MoS₂ and Si solutions with a ratio of 1 : 1 were poured to form a layer-by-layer assembly of MoS₂@Si through the vacuum filtration process.

Materials characterization

Raman spectra were recorded at room temperature using a RENISHAW inVia Raman spectroscope with a 532 nm edge filter laser beam as the excitation source. X-ray photoelectron spectroscopy (XPS) analysis was carried out using a Kratos AXIS supra photoelectron spectrometer with a monochromatic Al K α source (1486.7 eV) at a power of 225 W and 15 mA emission current, and the obtained data were analyzed using the CasaXPS software version 2.3.24. The SEM morphology and EDS mapping of the samples were obtained using field-emission scanning electron microscopy (SEM, Tescan MIRA) at an acceleration voltage of 5 kV in secondary electron mode. Nitrogen adsorption/desorption isotherms were obtained on a Tristar II 3020 physisorption analyzer at 77 K. Prior to measurement, samples were degassed at 120 °C for 7 h.

Electrochemical measurement

To check the electrochemical performance, the synthesized MoS₂ 2D nanosheets, the MoS₂@Si composite, and Si powder were used as active materials to fabricate the electrodes for Li-ion batteries. The slurry was prepared by manual mixing of the active materials, carbon black (electrical conductor), and binder (carboxymethyl cellulose (CMC)) with a mass ratio of 6 : 2 : 2 in a solvent (distilled water). All the ingredients were mixed carefully with a hand grinder. The as-prepared electrode films were punched into 12 mm diameter circular disks and directly used as the working electrode in coin cells. The average areal mass loading of the active materials is around 1.6 mg cm⁻². The standard coin cells (CR2032) were assembled in an argon-filled glovebox (O₂ ≤ 0.1 ppm and H₂O ≤ 0.1 ppm), using MoS₂@Si, MoS₂, and Si electrodes as working electrodes and lithium metal chips (0.45 × 15.6 mm, Gelon Energy Corp) as the counter-electrode. An insulating separator (2325 Celgard PP membrane) was used to prevent short-circuiting of the cell and 1.0 M LiPF₆ in EC/DEC (LP40, BASF) with 50/50 (v/v) was used as

the electrolyte. The electrochemical measurements (galvanostatic charge/discharge experiments) were performed on a Battery Testing System (CT-4008 NEWARE). The assembled cells were cycled over a potential range of 0.01–3 V (for MoS₂ and MoS₂@Si) and 0.01–1 V (for Si) vs. Li/Li⁺. The specific capacity was calculated on the basis of the active material only. The lithiation process was named the discharge process, and the delithiation process was indexed as the charge process. For the rate performance test, the anodes were first cycled at a lower current density of 20 mA g⁻¹ for 10 cycles. The cyclic voltammetry (CV) behavior was tested on an EC-Lab potentiostat/galvanostatic instrument (VMP-300 BioLogic) with a scan rate of 0.1 mV s⁻¹ in a voltage window of 0.01–3 V vs. Li/Li⁺.

Results & discussion

Materials analysis

The MoS₂ nanosheets with 2D morphology offer high surface area and provide additional reactive sites for Li-ion storage.²⁸ Also, large defect sites and void spaces between the 2D nanosheets allow the fast diffusion of Li-ions. Therefore, to synthesize the 2D MoS₂ nanosheets, we used the CVD technique as illustrated in the schematic in Fig. 1A with temperature control

according to Fig. S1,† with 3D crystallized NaCl cubes (Fig. 1B) employed as the substrate. NaCl is readily soluble in water; therefore, pristine MoS₂ nanosheets can be obtained without damaging their structure. Fig. 1C–D show the MoS₂ grown on the NaCl crystal surface. The color of the NaCl crystal turned from the original white to dark green after CVD growth (Fig. S2†) due to the presence of MoS₂. The thickness and layer number were varied by controlling the time of MoS₂ growth in the CVD chamber ranging from 2 to 10 minutes. Raman spectroscopy was employed to confirm the successful growth of MoS₂ and to probe the relative difference between the layer numbers. As shown in Fig. 1E, the MoS₂ on NaCl crystals (MoS₂@NaCl) showed typical MoS₂ Raman modes of E_{2g}¹ and A_{1g} at ~384 cm⁻¹ and ~409 cm⁻¹, respectively. The E_{2g}¹ mode signifies the in-plane and A_{1g} defines out-of-plane opposite vibrations of the Mo and S atoms.^{25,29} The opposing vibrations of the Mo and S atoms but parallel to each other are explained as the in-plane vibration mode, whereas the vibrations of the two S atoms in opposite directions are known as the out-of-plane mode.^{30,31} The Raman intensity of both vibration modes is proportional to the layer number, which can be achieved by increasing the growth time, as shown in Fig. 1E and S3.† The growth time, therefore, influences the amount and size of the

(E) Raman and (F–H) XPS spectra of MoS₂.

MoS₂ nanosheets, similar to previous reports.³² We also attempted to grow MoS₂ nanosheets directly onto the Si nanoparticles but could not obtain well-defined 2D structures, despite being able to obtain MoS₂ on Si (Fig. S4†). Further, the chemical composition of prepared MoS₂ on NaCl was studied with the XPS technique (Fig. 1F–H). The wide XPS spectra of the MoS₂ nanosheets in Fig. 1F show the prominent peaks of Mo and S elements which further proves the successful synthesis of MoS₂. In the high-resolution XPS spectrum of Mo 3d, the two main peaks, Mo 3d_{5/2} and Mo 3d_{3/2}, are observed at the binding energies of ~229 eV and ~232 eV (Fig. 1G) and confirm the presence of Mo⁴⁺ atoms. A minor peak at ~226 eV next to the Mo 3d region corresponds to S 2s.^{33,34} Meanwhile, the double 2p peaks of S at ~162 eV and ~163 eV (Fig. 1H), which are recognized as the S 2p_{3/2} and S 2p_{1/2}, respectively, indicate the S²⁻ state of MoS₂.³⁵

The morphology of the synthesized MoS₂@NaCl samples corresponding to different growth times was examined using SEM images, as shown in Fig. 2A–F. A continuous thin layer of MoS₂ is formed on the NaCl surface, and extra 2D randomly sized sheets start to grow on top with increased growth time (above 5 minutes). Fig. 2A and D clearly show continuous and finely wrinkled MoS₂ sheets obtained with a growth time of 3 min. The optimized few-layer MoS₂ 2D nanosheets can be observed after 5 min of growth with some thin monolayer triangle MoS₂ sheets (Fig. 2B and E). Hence, the 5 min of growth time was selected for further characterization, which will allow the easy intercalation of Li-ions compared to the bulk MoS₂ after 10 min, as observed in Fig. 2C and F. The SEM results coincide well with the Raman results and prove that the amount and size of the nanosheets increased with growth time. The longer growth time allows the MoS₂ nanosheets to enlarge in size and eventually form a pseudo-continuous sheet.³² The larger sheets in the background were observed to have covered the whole surface of the NaCl crystals and then overlapped on each other. Additionally, with the energy-dispersive X-ray spectroscopy (EDS) element mapping analysis, the presence of Mo,

Na, and Cl as the main components in a MoS₂@NaCl composite was confirmed (Fig. 2 G–J).

The synthesized MoS₂@NaCl was then dissolved in water, and the pristine few-layer MoS₂ 2D nanosheets were obtained *via* a vacuum filtration technique. The pristine MoS₂ was selected as an active material for the LiB anode. In the next part, a sandwich heterostructure of MoS₂ 2D nanosheets with 0D Si nanoparticles (MoS₂@Si) was prepared *via* vacuum filtration as illustrated in the schematic in Fig. 3A. The main purpose of fabricating the sandwich structure is to trap Si particles in between 2D nanosheets to avoid its volume expansion during lithiation/delithiation and to create void spaces between the 2D nanosheets for better diffusion of Li⁺. The structure can be seen in the SEM images of the prepared MoS₂@Si heterostructure electrode in Fig. 3B–D together with its EDS mapping in Fig. 3E–G which clearly shows the presence of Si and MoS₂.

Raman, XPS, and porosity analyses were conducted on the obtained MoS₂@Si heterostructure samples. The Raman results in Fig. 4A show three peaks at 381.22 cm⁻¹, 407.5 cm⁻¹, and 518.56 cm⁻¹ ascribed to E_{2g}¹ and A_{1g} of MoS₂ and Si, respectively.³³ Moreover, the XPS spectra in Fig. 4B reveal the presence of Mo, S, and Si elements in the MoS₂@Si composite. The two Mo 3d peaks at 229.04 eV and 232.18 eV correspond to the Mo 3d_{5/2} and Mo 3d_{3/2} (Fig. 4C), validating the presence of Mo⁴⁺ in MoS₂ and the S 2s peak is observed at 226.35 eV.^{33,34} The S²⁻ 2p_{3/2} and S²⁻ 2p_{1/2} peaks of MoS₂ are centered at 162.2 eV and 163.4 eV (Fig. 4D), respectively.³⁵ The Si 2p peak is observed at

(B) Wide scan XPS and its high resolution fitted (C) Mo 3d, (D) S 2p, and (E) Si 2p core level XPS spectra. (F) Nitrogen adsorption and desorption isotherms of MoS₂@Si heterostructure, MoS₂, and Si samples obtained at 77 K.

~99.5 eV (Fig. 4E) assigned to the Si bonding in the MoS₂@Si, whereas a native oxide layer (SiO₂) is detected at 103.9 eV in the Si 2p region, which describes the oxidation of the pure Si to form SiO₂.^{12,36} The pore structures of pristine Si, MoS₂, and MoS₂@Si were also investigated with the help of the nitrogen adsorption and desorption isotherms (Fig. 4F). From the isotherms, the obtained Brunauer–Emmett–Teller (BET) specific surface area of MoS₂@Si (45 m² g⁻¹) was higher than that of Si (33 m² g⁻¹) and MoS₂ (13 m² g⁻¹). The large specific surface area obtained for MoS₂@Si is mainly due to some MoS₂ isolated nanosheets at the edges of the MoS₂@Si as observed in the SEM images in Fig. 3. The pore size distribution based on the Barrett–Joyner–Halenda (BJH) method is also shown in Fig. S5.† The average diameter of pores decreases when the Si is sandwiched between MoS₂ nanosheets confirming a well-made sandwich composite. These can offer a greater number of active sites which is beneficial for ion storage if such a structure is used as a battery electrode.

Electrochemical performance

Next, MoS₂@Si and MoS₂ nanosheets were used as anodes to prepare LIBs in a half-cell configuration (Fig. S6†). The cyclic voltammetry (CV) and long-term galvanostatic charge/discharge

(GCD) cyclic measurements were conducted to understand the electrochemical properties and the possible reaction mechanisms. Fig. 5A and B show the CV curves of the MoS₂@Si and MoS₂ cells measured in a potential window between 0.01 and 3 V at a scan rate of 0.1 mV s⁻¹. Upon the first discharge, the MoS₂@Si electrode depicts cathodic peaks at ~0.01, ~0.4, and 0.9 V. The broad peak at 0.9 V is associated with the lithiation of MoS₂, where Li-ions intercalate into MoS₂ nanosheets to form Li_xMoS₂, and it shifts to 1.1 V in the subsequent cycles. This is followed by the conversion reaction at ~0.4 V, where the reduction of Li_xMoS₂ to Mo metal and Li₂S takes place.^{37,38} The irreversible peaks in the first cycle are due to the solid electrolyte interphase (SEI) formation in the initial lithiation process.³⁹ The sharp peak at ~0.01 V is a typical Si peak caused by the conversion of Si to the Li_xSi alloy (Fig. S7A†).⁴⁰ In the subsequent cycles, the reversible reduction peak 1.8 V is associated with the reduction of S atoms and is predominant in the pristine MoS₂ CV curve in Fig. 5B. Similarly, during charging, the prominent anodic peak at 2.3 V and a weak peak at 1.6 V are related to the oxidation of Li₂S and metallic Mo to S and the MoS₂,⁴¹ respectively, which is not present in the Si CV curve in Fig. S7A.† This reversible lithium–sulfur reaction contributes to the Li-ion storage capacity of MoS₂.⁴² The sharp anodic peaks at ~0.5 V are associated with the delithiation process of the Li_xSi alloy which is very prominent in the Si CV curves.^{43,44} The shape of the CV curve and the oxidation/reduction peaks in the latter cycles are almost overlapped with a slight increase in the redox peak area which can reflect the good electrochemical stability and the activation process of the electrode.

Furthermore, the GCD test was performed at a current density of 100 mA h g⁻¹ in the voltage window of 0.01–3.0 V for MoS₂@Si and MoS₂. The voltage profiles of the first five cycles of MoS₂@Si and MoS₂ are shown in Fig. 5C and D and for Si in Fig. S7B.† Commonly, the discharge capacity between 0.01 V and 3 V is considered to be able to compare with similar values

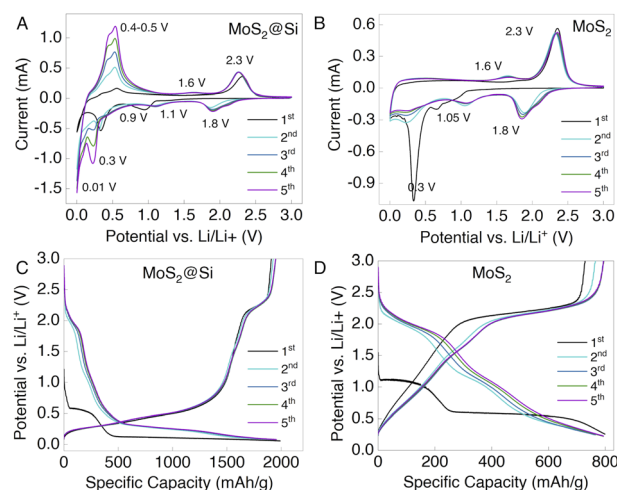

Fig. 5 The electrochemical results. (A) CV curves of MoS₂@Si and (B) MoS₂ at a scan rate of 0.1 mV s⁻¹ within the potential window of 0.01–3.0 V. GCD profiles of the initial five cycles of (C) MoS₂@Si and (D) MoS₂ at 100 mA g⁻¹.

obtained in the literature. However, the practical range lies between 0.01 and 0.5 V, at which the anode potential does not deviate from zero above 0.5 V.⁴⁵ Whereas, for MoS₂@Si, the discharge capacity remains very high, above 1500 mA h g⁻¹, with very good capacity retention and cycle life (Fig. 5C). The three plateaus in the MoS₂@Si discharge profile are observed at ~0.9 V, ~0.4 V, and ~0.01 V, describing the combined plateaus of MoS₂ and Si electrodes. Thus, the corresponding charge plateaus are consistent with those of cathodic and anodic peaks in cyclic voltammetry (Fig. 5A). The trends of the charge/discharge profiles of the second, third, fourth, and fifth cycles gradually become stable, which further demonstrates that the MoS₂@Si electrode has excellent stability.

For the practical applications of LiBs, it is essential for an electrode to have an excellent reversible rate performance. The rate capability of both MoS₂ and MoS₂@Si electrodes was measured, ranging from low to high current densities, *i.e.*, 100, 200, 300, 500, and 1000 mA g⁻¹, as illustrated in Fig. 6A. The synthesized MoS₂ nanosheets demonstrated an exceptional specific capacity of 890 mA h g⁻¹ at 100 mA g⁻¹, which gradually decreased with increasing current density to 508 mA h g⁻¹ at 1000 mA g⁻¹. When the current density increased back to 100 mA g⁻¹, the specific capacity reached up to 911 mA h g⁻¹ with a coulombic efficiency of 98% and remained stable for 20 cycles which proves that the MoS₂ 2D nanosheets had remarkable rate performance. For MoS₂@Si, the capacity at 100 mA g⁻¹ was 2331 mA h g⁻¹ and dropped to 625 mA h g⁻¹ at a very high current density of 1000 mA g⁻¹. On returning to 100 mA g⁻¹, its specific

capacity and coulombic efficiency reached 1707 mA h g⁻¹ and 98%, respectively. The charge/discharge capacities of MoS₂ and MoS₂@Si at different current densities are given in Table S1.†

The long-term cycling performance of the electrodes was evaluated at 100 and 500 mA g⁻¹, as shown in Fig. 6B and C. The initial discharge capacities of MoS₂, MoS₂@Si, and Si electrodes at 100 mA g⁻¹ were 1812, 2825, and 3466 mA h g⁻¹, respectively. The discharge capacities dropped in the second cycle to 739, 2033, and 2551 mA h g⁻¹, respectively (Fig. 6B). Further, the coulombic efficiencies of MoS₂ and MoS₂@Si anodes were 70% and 73% in the first cycle. The low initial coulombic efficiency can be due to the SEI formation which decomposes the electrolyte in the first cycle. To reduce the initial capacity loss and increase the initial coulombic efficiency of Si, some strategies including optimization of electrolyte, prelithiation, structure and morphology design, defects engineering, and binder optimization can be utilized.^{46–49} Nevertheless, in our half cells, the coulombic efficiencies increased to 91% and 96% in the second cycle. MoS₂ and MoS₂@Si electrodes showed excellent reversible cycling performance maintaining the specific capacity of 624 and 1223 mA h g⁻¹ after 300 cycles with 99% coulombic efficiency. The improved capacity, cycling stability, and high coulombic efficiency are due to the unique structure of MoS₂@Si. Though the Si electrode shows a higher capacity at low current density but becomes unstable as the capacity drops to 959 mA h g⁻¹ at ~300 cycles.

In Fig. 6C, MoS₂@Si showed excellent capacity retention of ~60% after 500 cycles at a high current density of 500 mA g⁻¹

Fig. 6 (A) The rate capability of MoS₂@Si and MoS₂ at 100, 200, 300, 500, and 1000 mA g⁻¹. (B–C) Cyclic behaviors of MoS₂@Si, MoS₂, and Si at 100 and 500 mA g⁻¹. (D–F) Cross-sectional SEM images of delithiated electrodes after 500 cycles at 500 mA g⁻¹ (scale bar = 20 μm).

with a coulombic efficiency of 99%. However, we note that its specific capacity at a low current density of 100 mA g^{-1} was lower than that of pure Si, up to ~ 260 cycles. We believe this is related to the unique structure of few-layered MoS_2 2D nanosheets sandwiching the Si nanoparticles in the heterostructure. In all experiments, we observed that Si always has a higher capacity in the initial cycles than $\text{MoS}_2@$ Si. However, the capacity of Si drops gradually below that of $\text{MoS}_2@$ Si due to increased instability. At a high current density, $\text{MoS}_2@$ Si performs better even at earlier cycles as MoS_2 is able to mitigate Si volume expansion and particle pulverization, considered as the synergistic interaction between 2D sheets and Si.^{50–52} At low current density, the volume expansion of Si becomes less significant and it can last for ~ 260 cycles before its capacity drops below $\text{MoS}_2@$ Si due to the low current density-driven lithiation and delithiation, in which we expect a less adverse expansion of Si electrodes and tampering of the electrode structure. It is worth noting that pristine Si in all our experiments showed a higher specific capacity than the composite, albeit with poor stability. The composite despite lower specific capacity (mainly due to the presence of MoS_2 , with low specific capacity) in comparison to pristine Si consistently showed reliable stability even at a higher density which we attributed to the improved volume expansion. It is well known that the stresses caused by the repetitive volume expansion and contraction of Si can lead to cracking and pulverization of the electrode resulting in capacity loss.⁵³ Hence, it can be concluded that MoS_2 acts as a buffer as it sandwiches the Si nanoparticles between its nanosheets, limiting the extent of repetitive volume expansion and contributing to improved cycling stability.

To understand the role of MoS_2 nanosheets in the lithiation/delithiation, the volume change of the anodes after a certain number of cycles was examined. We further analyzed the SEM images of the cross-section of $\text{MoS}_2@$ Si, MoS_2 , and Si electrodes at a fully delithiated state after 500 cycles at 500 mA g^{-1} as given in Fig. 6D–F in comparison to the initial measurements prior to cycling in Fig. S8.† It can be clearly observed that the thickness of the Si electrode expanded from $10 \mu\text{m}$ to $53 \mu\text{m}$ after 500 cycles which is $\sim 430\%$ volume expansion. In comparison, the thickness of $\text{MoS}_2@$ Si increased from $19 \mu\text{m}$ to $32 \mu\text{m}$ after 500 cycles with around 68% of volume expansion. Therefore, introducing MoS_2 nanosheets into the overall electrode significantly reduces the volume expansion (Fig. 7A).^{51,52,54,55} This performance is superior compared to past reported results given in Table S2.† The surface morphology of the $\text{MoS}_2@$ Si and Si anodes can be observed from the SEM images before and after 500 cycles of lithiation/delithiation in Fig. 7B and C and S9.† For the $\text{MoS}_2@$ Si electrode, Si particles almost maintained their structure (Fig. 7B) with few cracks after 500 cycles (Fig. S9A†). However, the round-like crystalline Si particles in the Si electrode transformed into larger irregular shapes after lithiation/delithiation cycles (Fig. 7C) with various cracks around the electrode (Fig. S9B†). The expansion of Si nanoparticles is limited by the MoS_2 nanosheets. The pores within the MoS_2 can also accommodate some volume expansion of Si. In addition, the presence of MoS_2 2D nanosheets is observed to improve the formation of the SEI layer (Fig. S10†). Also, our

Fig. 7 (A) The schematic showing Si nanoparticles sandwiched between MoS_2 nanosheets improving the volume expansion of the $\text{MoS}_2@$ Si electrode. SEM images of the (B) $\text{MoS}_2@$ Si and (C) Si electrodes before and after 500 cycles. The scale bar is 500 nm.

previous molecular dynamics simulation indicates that wrapping Si particles with 2D nanosheets can reduce mechanical stresses during cycling.⁵⁶ As discussed, MoS_2 is an active material and can achieve stable cycle performance (Fig. 6 A–C). This proves that the fabrication of the heterostructure with $\text{MoS}_2@$ Si is responsible for the excellent performance observed here.

To confirm the excellent electrochemical performance of $\text{MoS}_2@$ Si electrodes, we also analyzed charge transfer and diffusion resistance of the Si, MoS_2 , and $\text{MoS}_2@$ Si electrodes from GCD discharge curves for cycles 1, 2, 5, 50, and 500 (Fig. S11†). The charge transfer resistance of the MoS_2 and $\text{MoS}_2@$ Si electrode decreased after the first cycle in the subsequent second cycle from 266Ω to 246Ω and 1084Ω to 57Ω , respectively, owing to the transformation of MoS_2 into a metallic high conductive phase and formation of the conductive SEI layer during the first discharge process.⁵⁷ The charge-transfer resistance of these electrodes continued to decrease to 240Ω and 55Ω in the 5th cycle before stabilizing to the low resistance of 44Ω and 81Ω in the 50th cycle and finally

increasing to 158 Ω and 126 Ω at 500th cycle, which was very low as compared to the first cycle. However, for Si, the charge transfer resistance for the first cycle started low at 120 Ω but ended at 185 Ω , which we ascribe to be due to the electrode failure and cracks after 500 cycles.

Conclusion

We synthesized MoS₂ 2D nanosheets on a water-soluble NaCl substrate. This enabled us to get few-layer and isolated 2D sheets of MoS₂ which was utilized to prepare a heterostructure with Si nanoparticles in a layer-by-layer assembly. To investigate the working mechanism, the pristine MoS₂ and MoS₂@Si sandwich structures were used as the anodes for Li-ion batteries. The assembled cells demonstrated remarkable rate capability, *i.e.*, 890 and 2331 mA h g⁻¹ at 100 mA g⁻¹ for the MoS₂ and MoS₂@Si anodes, respectively, with the coulombic efficiency of above 98%. The long-term cycling stability of the heterostructure MoS₂@Si electrode was observed to outperform that of MoS₂ and Si to a great extent. Specifically, after 500 cycles, the MoS₂@Si showed excellent cycling stability with capacity retention of 60% compared to 21% from MoS₂ and 0.3% from pristine Si at a high current density of 500 mA g⁻¹. A significant reduction in volume expansion is observed in the MoS₂@Si anode (68%) compared to pristine Si (about 430%). The layered MoS₂ nanosheets in the heterostructure can accommodate the volume expansion of Si particles and contribute to excellent electrochemical performance. The approach to synthesizing MoS₂ 2D nanosheets and their utilization in a sandwich heterostructure add advantage to the already existing promising application of MoS₂ for energy storage applications.

Author contributions

The manuscript was written through the contributions of all authors. I. Marriam performed most of the experiments, collected and analyzed the data, wrote the first draft, and took responsibility for this article overall. C. Yan and A. Du supervised the experiments and writing of the article. M. Tebyetekerwa edited the second draft of the article and provided insights into the growth and Raman spectroscopy of MoS₂. N. Motta provided the CVD equipment and supervised the synthesis of MoS₂. J. A. Alarco provided the glovebox and supervised the battery assembling process. H. Chen, H. Chathuranga, Z. J. He, and J. C. Zheng supported the development of some experiments. All the authors discussed the contents of the manuscript prior to submission and revised the final draft of the manuscript. All authors have approved the final version of the manuscript.

Conflicts of interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

Acknowledgements

The authors acknowledge the support from the Central Analytical Research Facility (CARF) and Centre for Materials Science at Queensland University of Technology (QUT). The PhD scholarship (QUTPRA) from Queensland University of Technology, Brisbane, Australia, and the financial support from an ARC Discovery Project (DP180102003) are highly appreciated.
