We present the synthesis, optoelectronic characterization, and a detailed theoretical study of DMAC-py-TRZ, a novel, efficient TADF emitter. This compound is a structural relative of the well-known TADF compound DMAC-TRZ, substituting the bridging phenylene for a pyridyl group. This marginal change has an enormous impact on the structure and hence on the photophysics as the steric interactions between the DMAC donor and the bridge that force DMAC-TRZ into an orthogonal conformation are attenuated and permit DMAC-py-TRZ to adopt a planar and slightly bent structure in the ground state. The large degree of conjugation in the bent DMAC-py-TRZ structure, demonstrated by the strong intensity of the lowest excitation with CT character, is responsible for a large singlet triplet gap, hence hindering TADF of this bent conformer. The computational analysis predicts that emission occurs, however, from a relaxed orthogonal excited-state geometry, as confirmed by the huge Stokes shift observed in non-polar solvents. In this relaxed orthogonal geometry TADF is indeed observed. Emission from the unrelaxed state is recovered in glassy frozen solvents, where the emission band is largely blue-shifted compared with measurements in liquid solvent, and TADF is quenched. In amorphous matrices, structural disorder leads to the coexistence of both conformers, even if, depending on the emitter concentration, dual fluorescence may disappear due to a fast energy transfer from the bent to the orthogonal conformers. We maintain that this efficient energy transfer is responsible for the good efficiency of DMAC-py-TRZ devices, because of the presence in the matrix of a sizable proportion of compounds that adopt the bent structure, favorable to act as the host for the orthogonal TADF conformer of DMAC-py-TRZ.

10th Anniversary Statement
The Journal of Materials Chemistry C has been one of our favourite journals for OLED materials research. The quality and breadth of the science covered in the journal particularly in the area of emitter development for electroluminescent devices has been excellent. It is always a pleasure to peruse each week's table of contents and to then read exciting and new science in optoelectronic materials. We look forward to the next 10 years and beyond and will continue to support JMCC.

Introduction
In an organic light-emitting diode (OLED), electrons and holes, injected in the device from opposite electrodes, combine to form excitons. According to spin statistics, 25% of the electrically generated excitons are in a singlet state and 75% are in a triplet state. If the excitons form on a fluorescent molecule, emission will only occur from the singlet excitons, effectively limiting the device Internal Quantum Efficiency (IQE). Phosphorescent dyes
harvest both singlet and triplet excitons to emit light from the triplet excited state resulting in an IQE of up to 100%. Most phosphorescent emitters, however, contain noble metals such as platinum or iridium, among the scarcest elements on Earth. Thermally activated delayed fluorescence (TADF) offers a different yet equally appealing strategy to triplet harvesting where 100% IQE is also possible in the device. In TADF emitters, dark triplet excitons are thermally upconverted into emissive singlets via reverse intersystem crossing (RISC). RISC is possible when the energy gap, $\Delta E_{ST}$, between the lowest lying singlet and triplet excited states is of the order of the thermal energy (ca. $0.02 \text{ eV}$), provided that spin–orbit coupling (SOC) between the two states is non-negligible. To minimize $\Delta E_{ST}$, the overlap between the HOMO and LUMO of the molecule must be reduced, localizing the two orbitals in separate electron-donating (for the HOMO) and electron-accepting (for the LUMO) parts of the molecule. This separation is most often obtained by enforcing a large dihedral angle between the electron donor and acceptor moieties. This strategy, however, leads to a reduction of the fluorescence efficiency and, according El Sayed rule, to a reduction of the spin–orbit coupling between the singlet and triplet states as well.

Two of the most common moieties employed as donors and acceptors, respectively, are 9,9-dimethy-9,10-dihydroacridine (DMAC) and 2,4,6-triphenyl-1,3,5-triazine (TRZ), and the combination of the two produces the emitter DMAC-TRZ, first reported by Tsai et al. DMAC-TRZ shows a very high photo-luminescence quantum yield, $\Phi_{PL}$, of 90%, at $\lambda_{PL}$ of 495 nm, as an 8 wt% doped film in mCPCN [9-[3-(9H-carbazol-9-yl)phenyl]-9H-carbazole-3-carbonitrile]. In DMAC-TRZ, the $\Delta E_{ST}$ amounts to a few tens of meV, depending on the host matrix, with a delayed fluorescence lifetime of 1.9 $\mu$s in mCBPBN, in line with an efficient RISC process. The OLED shows a high maximum external quantum yield, $\Phi_{EQE, max}$ of 26.5% at $\lambda_{EL}$ of 500 nm, while devices prepared from neat DMAC-TRZ films show a comparable $\Phi_{EQE, max}$ of 20.0%. The modest reduction of the $\Phi_{EQE, max}$ at high concentration can be understood in terms of the orthogonal conformation of the emitter, which effectively prevents aggregation. Both the doped and non-doped devices show a relatively small efficiency roll-off, with an $\Phi_{EQE, 100}$ of 25.1% and 18.9%, respectively.

The emitters a-DMAC-TRZ and MA-TA are derivatives of DMAC-TRZ where adamantane groups are incorporated into the structure (Fig. 1). In a-DMAC-TRZ, the adamantane-functionalization of the donor moiety leads to a deformed structure that results in an increased optical gap and thus a bluer emission. Dual fluorescence is observed from two different conformers, but overall, the electroluminescence (EL) performance remains similar to the DMAC-TRZ OLED, with an $\Phi_{EQE, max}$ of 28.9%, yet with a $\lambda_{EL}$ of 488 nm. In the report by Wada et al., the replacement of the distal phenyl moieties on the TRZ with adamantyl groups results in a weaker acceptor, leading to a blue-shifted electroluminescence compared to DMAC-TRZ. The adamantyl substitution also reduces the non-radiative decay leading to a $\Phi_{PL}$ of 99%. The blue solution-processed device ($\lambda_{EL}$ of 475 nm) shows an $\Phi_{EQE, max}$ at 22.1%. Conversely, replacement of the distal phenyl rings in TRZ by electron-withdrawing pyrimidines (DMAC-bPmT) results in a red-shifted emission ($\lambda_{EL}$ of 520 nm vs. 500 nm for DMAC-TRZ in toluene). The delayed
emission lifetime of DMAC-bPmT is 3.3 μs in toluene, which is shorter than that of DMAC-TRZ at 8.8 μs in the same medium. The RISC rate constant, $k_{RISC}$, of DMAC-bPmT is $8.8 \times 10^{-3}$ s$^{-1}$, is three times faster than that of DMAC-TRZ (2.9 $\times 10^{-5}$ s$^{-1}$). However, its $\Phi_{PL}$ of 70% in toluene is reduced compared to that of DMAC-TRZ ($\Phi_{PL}$ = 93% in toluene). Rajamalli et al.,$^{13}$ and Dos Santos et al.,$^{13}$ showed that the introduction of a heteroaromatic bridge in sulfone-based D-A TADF emitters can prevent structural relaxation, enhance $\Phi_{PL}$ and improve the color purity due to the narrower emission, and demonstrated an improvement in the efficiency of the devices compared to that with the reference emitter pDTCz-DPS. The materials in the study of Rajamalli et al.,$^{12}$ pDTCz-2DPyS, and pDTCz-3DPyS, both show good $\Phi_{PL}$ of ca. 60%. The blue OLEDs, at $\lambda_{EL}$ of 466 nm and 452 nm for the devices with pDTCz-2DPyS, and pDTCz-3DPyS, respectively, showed EQEmax $\sim$ 12–13%, which are considerably improved over the parent device with pDTCz-DPS (EQEmax of 4.7%). Dos Santos et al.,$^{13}$ showed that the addition of second nitrogen atom within the bridging heterocycle in pDTCz-DPzS, and pDTCz-DPmS contributed to a further enhancement of the EQEmax to 18% and 14%, respectively, at $\lambda_{EL}$ of 522 nm and 461 nm for the devices with pDTCz-DPzS, and pDTCz-DPmS, respectively.

The impact of intramolecular H-bonding on the photophysics of TADF emitters was also investigated by Chen et al. in two phenoxazine-based emitters PXZ-PPO and PXZ-BOO.$^{14}$ PXZ-BOO shows TADF, relevant devices having EQEmax of 19.4% at $\lambda_{EL}$ of 528 nm. In THF solution, PXZ-PPO is present as a mixture of two conformers, a more planar structure with N–H interaction and a twisted structure, where hydrogen bonding is not present. The planar conformation emits in the deep blue at 420 nm but shows no TADF, while the twisted conformer shows green TADF (610 nm) but with a very short lifetime of 170 ns. The planar conformer is dominant in the crystalline phase, while in solution the twisted conformer is largely responsible for the observed photophysics, giving rise to TADF. The PXZ-PPO-based device, with EQEmax of 14.1% at $\lambda_{EL}$ of 528 nm, is slightly inferior to the OLED based on PXZ-BOO, which has an EQEmax of 19.4% at $\lambda_{EL}$ of 528 nm.

The presence of two conformers of a TADF emitter has also been documented by Shi et al. in the TRZ derivative compounds TP2P-PXZ and TP5P-PXZ.$^{15}$ Phenoxazine and a central terpyridine bridge were used to promote the formation of an intramolecular hydrogen bond in TP2P-PXZ, while in the control compound TP5P-PXZ this interaction is absent. The presence of quasi-equatorial (QE) and quasi-axial (QA) conformations of TP2P-PXZ led to a self-doped system, where the QA conformer effectively acts as the host material. This led to an efficient OLED with an EQEmax of 25.4% at $\lambda_{EL}$ of 548 nm while the performance of the device with TP5P-PXZ was somewhat attenuated with an EQEmax of 14.6% at a slightly red-shifted $\lambda_{EL}$ of 560 nm. Similarly, two conformers have been found coexisting in the crystalline phase for the compounds Trz-Py-NCS and Trz-Py-SAC.$^{16}$

These examples show that modification of the nature of the aromatic bridge in a TADF emitter can lead to significant changes in the molecular geometry, with the co-existence of different conformers that show distinctive photophysics. In this work, we introduce the emitter DMAC-py-TRZ, where the phenylene bridge in DMAC-TRZ$^7$ is replaced by a 2-pyridyl bridge. DMAC-py-TRZ emits at $\lambda_{PL}$ of 539 nm and has a $\Phi_{PL}$ of 58% in toluene solution while as a 10 wt% doped mCP film the $\Phi_{PL}$ is 496 nm and the $\Phi_{PL}$ is 57%. Its crystal structure (Fig. 2) documents a small dihedral angle between the DMAC and pyridyl bridge of 19.7(2)$^1$ and a V-shaped or bent structure of the DMAC donor, with an associated bending angle (deviation from a planar conformation) of 45°. This behaviour is in line with that observed by Shi et al.$^{15}$ We present an in-depth computational study and an extensive optoelectronic and photophysical characterization that showcases the impact that conformational changes in the excited state and not just in the ground state have on the photophysics of the compound.

**Results and discussion**

**Computational analysis**

The ground-state geometries of DMAC-TRZ and DMAC-py-TRZ were optimized in the gas phase using density functional theory (DFT) at the M062X/6-31G(d) level of theory.$^{17–19}$ The excited-state energies were calculated using time-dependent density functional theory (TD-DFT) within the Tamm–Dancoff approximation.$^{20}$ at the same level of theory (TDA-DFT). We employ the term “orthogonal” to describe the structure with a dihedral angle between the DMAC and the bridge that is close to 90° and we dub as “bent” the structure with the small dihedral angle and V-shaped geometry of the DMAC.

In a recent publication,$^{21}$ an extensive computational analysis of DMAC-TRZ set the basis for a few-state model that was carefully validated against spectroscopic properties in solution. Then the same model was exploited to calculate ISC and RISC rate constants, also accounting for environmental effects including dielectric and conformational disorder.$^{22,23}$ In the ground-state equilibrium geometry of DMAC-TRZ, the DMAC and TRZ moieties are mutually orthogonal (Fig. 2), in line with the crystal structure.$^{21}$ In this orthogonal geometry, the $S_1$ and $T_1$ states each have a pure charge transfer (CT) character. In other terms, the HOMO and LUMO have negligible overlap so that the singlet–triplet gap is almost closed, with $\Delta E_{ST} = 0.01$ eV. The close similarity between the orbitals involved in $S_1$ and $T_1$ states
implies a vanishing SOC, according to El Sayed’s rule, as to hinder direct RISC from T1 to S1.

As for the excited states of DMAC-TRZ, S1 (with a strong 1CT character) retains an orthogonal geometry, while T1 (3CT) undergoes a large conformational deformation where the dihedral becomes ~60°. At this angle, ΔE_ST increases as does SOC. A rigid scan of the dihedral angle of DMAC-TRZ (Fig. S9c, ESI‡) is informative. Specifically, starting from the optimized ground-state geometry, we calculated the ground and excited state energies upon gradual rotation of the DMAC unit about the phenylene bridge without allowing for any additional molecular relaxation (the dihedral angle for the scan is defined in Fig. S9a, ESI‡). The resulting S0, S1, T2 and T3 potential energy surfaces (PES) all show a flat minimum for the orthogonal geometry, while T1 shows a double minimum around (90 ± 30)° angle.19 The molecular orbitals (MOs) and natural transition orbitals (NTOs) shown in Fig. S11 and S12 (ESI‡) reveal that in the orthogonal structure, the HOMO is localized on DMAC and the LUMO is on the TRZ.

In contrast with DMAC-TRZ, the ground-state optimized geometry of DMAC-py-TRZ has a bent structure (Fig. 2f), as also observed in the crystal structure (Fig. 2b). To better understand the structural differences between DMAC-TRZ and DMAC-py-TRZ, a rigid dihedral angle scan of DMAC-py-TRZ starting from an analogous orthogonal conformation to that of DMAC-TRZ has been performed. The rigid scan leads to a qualitatively similar picture for the two compounds (Fig. S9, ESI‡), with relevant MOs and NTOs in Fig. S11 and S12 (ESI‡), showing the HOMO and LUMO localized on the donor and acceptor moieties, respectively. The presence of the nitrogen atom in the pyridine bridge effectively increases the electron-withdrawing strength of the acceptor, resulting in a stabilized LUMO and a smaller HOMO–LUMO gap in DMAC-py-TRZ (HOMO–LUMO = 4.78 eV for the orthogonal structure) vs. DMAC-TRZ (HOMO–LUMO = 4.99 eV for the orthogonal structure). Accordingly, the S1 and T1 excitations occur at lower energy in DMAC-py-TRZ than in DMAC-TRZ and both the S1 and T1 states are stabilized compared to those of DMAC-TRZ (Fig. S9c and d, ESI‡). The rigid energy scan, however, points to a large increase of the ground-state energy when the dihedral angle deviates significantly from orthogonality, so that non-orthogonal conformations are hardly accessible. To address the bent conformer, we performed a relaxed scan of the dihedral angle, relevant results being shown in Fig. 3 (see also ESI‡ Fig. S18).

The relaxed scans show that for each of the emitters, two minima are present, corresponding to the orthogonal and bent structures. For DMAC-TRZ, the energy difference between the two conformers amounts to 0.04 eV, slightly larger than thermal energy at room temperature. The energy barrier for the interconversion between the two conformers, 0.22 eV (21.2 kcal mol–1), is, however, much larger than thermal energy so that only the orthogonal geometry is expected to be significantly populated at room temperature. The situation is very different for DMAC-py-TRZ where the bent conformer (dihedral angle ~10°) is lower in energy than the orthogonal conformer by 0.20 eV and the energy barrier for the interconversion between the bent and orthogonal conformers is 0.20 eV (19.3 kcal mol–1). Thus, at room temperature only the bent conformer is populated. The MOs and NTOs calculated for the bent structure (Fig. S11 and S12, ESI‡) show that in both molecules there is a partial delocalization of the HOMO onto the acceptor moiety and, for DMAC-py-TRZ, also a partial delocalization of the LUMO onto the donor moiety.

Divergent results are obtained for the excited state energies at the geometries relevant to the rigid/relaxed scans of the dihedral angle (Fig. 3c and d) of the two compounds. For DMAC-TRZ, the rigid (Fig. S9c, ESI‡) and the relaxed scans (Fig. 3c) lead to the same picture: the S1 state maintains the same orthogonal conformation as the ground state, while the T1 state is stabilized and adopts a twisted structure (dihedral angle: ~60°). Full optimisations of S1 and T1 confirm this result.21 In the orthogonal geometry, the S1 state is an almost pure CT state and, hence, has a negligibly small oscillator strength. The scenario is much more interesting for DMAC-py-TRZ. In the bent geometry (the energy minimum, Fig. 3b), the vertical excitation energy to S1 amounts to 4.034 eV and the ΔEST is 0.786 eV, which is far too large for TADF to be operational at ambient temperature. Moreover, the oscillator strength for the S0 → S1 is large (1.27, Fig. S12c, ESI‡) in this geometry due to the significant overlap of the orbitals involved in the transition (Fig. 4a). However, the bent geometry is not the equilibrium geometry for S1 (Fig. 4d) and a huge structural deformation is predicted in the S1 state from the bent to the orthogonal structure. In other terms, in DMAC-py-TRZ the absorption occurs from the bent geometry and the lowest energy transition is both high in energy and has a large oscillator strength. By contrast, fluorescence occurs from the orthogonal structure at a much lower energy (3.17 eV) and with negligible oscillator strength (as per the non-overlapping orbitals, in Fig. 4b). In this orthogonal geometry the ΔEST reduces to only 8.2 meV, making TADF possible. To better appreciate the
differing photophysics of the two different conformers in either DMAC-TRZ or DMAC-py-TRZ, Fig. S19 (ESI†) compares relevant calculated spectra and Table S29 (ESI†) summarizes the calculated $\Delta E_{ST}$.

In DMAC-py-TRZ, the T1 state is predicted to exist as a twisted geometry in both the rigid (Fig. S9d, ESI†) and relaxed scans (Fig. 3d). The full optimization of the excited state geometry, however, yields conflicting results. For S1, the situation is clear: taking either the bent or the orthogonal geometry as starting points for the excited state optimization, the S1 geometry (Fig. 3d) always converges to the orthogonal conformation, supporting the results from the relaxed scan analysis. For T1, instead, two different structures are reached depending on the starting geometry (Fig. S10, ESI†), with slightly different $\Delta E_{S1-T1}$ values (0.93 eV where the dihedral angle is 30° and 0.41 eV where the dihedral angle is 60°). The energy of the two triplet conformations is similar ($\Delta E_{T1 \_60-\_30} = 0.07$ eV), so that a firm conclusion about the equilibrium geometry for T1 cannot be reached.

Optoelectronic properties

Cyclic Voltammetry (CV) and Differential Pulse Voltammetry (DPV) of DMAC-py-TRZ and DMAC-TRZ were measured in degassed DCM with tetra-n-butylammonium hexafluorophosphate as the electrolyte and Fe/Fc⁺ as the internal reference. The voltammograms in Fig. 5a are reported versus a Saturated Calomel Electrode (SCE). Both materials show pseudo-reversible reduction and oxidation waves. Both oxidation and reduction waves for DMAC-py-TRZ ($E_{onset}/E_{red} = 1.11/-1.64$ V) are anodically shifted compared to those of DMAC-TRZ (0.97/-1.72 V). The corresponding HOMO and LUMO energies are $-5.31/-2.62$ eV and $-5.45/-2.70$ eV for DMAC-TRZ and DMAC-py-TRZ, respectively. Comparing electrochemical redox gaps measured in solution with gas-phase DFT results is tricky.$^{25,26}$ Experimentally, the HOMO–LUMO gap of DMAC-py-TRZ, $\sim 2.75$ eV, is larger than the HOMO–LUMO gap of DMAC-TRZ $\sim 2.69$ eV. Considering an orthogonal geometry for both dyes, DFT results for the HOMO–LUMO gaps are 4.78 eV and 4.99 eV for DMAC-py-TRZ and DMAC-TRZ, respectively, showing the opposite trend vs. experiment. The same is true if the bent geometry is considered for both dyes, with calculated HOMO–LUMO gaps of 5.73 eV and 5.77 eV for DMAC-py-TRZ and DMAC-TRZ, respectively. However, if we properly consider an orthogonal structure for DMAC-TRZ ($E_{HOMO-LUMO} = 4.99$ eV for orthogonal geometry) and a bent structure for DMAC-py-TRZ ($E_{HOMO-LUMO} = 5.73$ eV for bent geometry), calculated HOMO–LUMO gaps reflect the trend observed experimentally. A better estimate of the ionization potential (IP) and electron affinity (EA) of both dyes is obtained by comparing the energy of the radical cation and radical anion molecules in their relaxed geometry with the energy of the neutral dye: IP = $E_{radical \_cation} - E_{neutral}$ and EA = $E_{radical \_anion} - E_{neutral}$. In this case, the IP-EA gap (to be compared with the experimental data) are 7.39 eV and 7.24 eV for DMAC-py-TRZ and DMAC-TRZ, respectively, for the orthogonal geometries. For the bent geometries, the gaps are 7.63 eV and 7.25 eV for DMAC-py-TRZ and DMAC-TRZ, respectively. Also in this case, if we consider the orthogonal conformer for DMAC-TRZ and a bent conformer for DMAC-py-TRZ the calculated gaps reflect the trend observed experimentally. A perfect agreement between DFT estimates and experimental data is, however, not expected since our gas-phase calculations do not account for solvation effects.$^{25,26}$ In any case, the HOMO stabilization in DMAC-py-TRZ vs. DMAC-TRZ is ascribed to the presence of the electron-withdrawing pyridyl...
bridge, which reduces the electron density on the donor. Similarly, the electron density of the acceptor is reduced, resulting in a more stabilized LUMO level.

Fig. 5b compares the absorption spectra of DMAC-TRZ and DMAC-py-TRZ in toluene. The CT band of DMAC-py-TRZ at 370 nm is slightly blue-shifted with respect to DMAC-TRZ at 382 nm. The most striking difference is recognized, however, in the much larger intensity of the band measured for DMAC-py-TRZ \((\varepsilon = 43,800 \text{ M}^{-1} \text{ cm}^{-1})\) vs. DMAC-TRZ \((\varepsilon = 2,100 \text{ M}^{-1} \text{ cm}^{-1})\). This is a direct consequence of the different conformations adopted by the two compounds in the ground state: the orthogonal conformation of DMAC-TRZ (observed in the crystal structure and predicted by DFT) hinders an effective conjugation and suppresses the intensity of the low-energy CT transition. On the other hand, the bent conformation of DMAC-py-TRZ (observed in the crystal structure and predicted by DFT) promotes an efficient conjugation of the two moieties, perfectly in line with the oscillator strength calculated with TD-DFT (oscillator strengths are reported in Fig. S12 (ESI\(^\dagger\)), together with NTOs).

Neither the absorption spectra of DMAC-TRZ and DMAC-py-TRZ (Table S27, ESI\(^\dagger\)) show solvatochromism, in line with a very small permanent dipole moment of the molecule in the ground state. Photoluminescence (PL) spectra or DMAC-py-TRZ in Fig. 5c (Table S27, ESI\(^\dagger\)) show a strong positive solvatochromism akin to that observed for DMAC-TRZ (Fig. S13 and ref. 20, ESI\(^\dagger\)). The large positive PL solvatochromism observed for both compounds suggests that the emissive excited state has a large permanent dipole moment, thus confirming the CT character of this state in both compounds.\(^{27,28}\) The progressive broadening of the emission band in the solvatochromism study is a result of polarity-induced inhomogeneous broadening.\(^{28,29}\) The well-resolved vibronic structure of the emission band in non-polar solvents is often considered an indication of a local nature of the relevant excitation. Therefore, to prove the CT nature of the lowest transition in DMAC-py-TRZ in all solvent, including non-polar ones, Fig. S14 (ESI\(^\dagger\)) shows spectra collected for the two molecular fragments, DMAC and py-TRZ. For py-TRZ, only absorption spectra are shown since the species is not emissive. The spectroscopic features of both molecular fragments are located at higher energies than the lowest energy feature seen in DMAC-py-TRZ, confirming that this specific feature is related to a CT state. An important and unusual result is recognized in the large Stokes shift observed for DMAC-py-TRZ in non-polar solvents (Table S27, ESI\(^\dagger\)): in methycyclohexane, the absorption band is located at 370 nm, while the emission is seen at 472 nm, amounting to a Stokes shift of \(\sim 0.7 \text{ eV}\). This large Stokes shift can only be explained in terms of a very large molecular relaxation upon photoexcitation, well in line with the TD-DFT results that predict the relaxation of the \(S_1\) state from the bent to the orthogonal geometry.

In degassed toluene, DMAC-TRZ and DMAC-py-TRZ have similar \(\Phi_{PL}\) of 67% and 58%, respectively, in line with emission originating in both compounds from a similar orthogonal geometry. The \(\Phi_{PL}\) decrease in air (\(\Phi_{PL} = 22\%\) and 17%, respectively), indicating the presence of accessible triplet excited states. The prompt and delayed lifetimes, \(\tau_p\) and \(\tau_d\), for DMAC-TRZ in degassed toluene are of 20.8 ns (1.1%) and 5.2 \(\mu\)s (98.9%), in line with those previously reported,\(^7\) while the \(\tau_p\) and \(\tau_d\) for DMAC-py-TRZ are 44.0 ns (8.1%) and 1.5 \(\mu\)s (91.9%), respectively (Fig. S15, ESI\(^\dagger\)).

To summarize, theoretical and spectroscopic studies agree with the picture where DMAC-TRZ maintains the same orthogonal conformation in both the ground and the \(S_1\) states. However, DMAC-py-TRZ undergoes a significant geometric reorganization from the bent geometry in the ground state to the orthogonal geometry in the excited state.

Spectra collected in a glassy 2-MeTHF matrix at 77 K (Fig. 5d) shed further light on the geometrical relaxation of DMAC-py-TRZ upon photoexcitation. In the frozen matrix, the emission peaks at 404 nm, blue-shifted compared to that in liquid 2-MeTHF at ambient conditions (\(\lambda_{PL} = 596 \text{ nm}\), Table 1 and Fig. S16, ESI\(^\dagger\)). Apparently, in the frozen matrix the excited compound cannot relax, so that emission occurs from the bent structure and hence peaks at much higher energy than in the (non-polar) liquid solvent. The gated signal collected in the glassy matrix (red line in Fig. 5d) is ascribed to phosphorescence, suggesting a large \(\Delta E_{ST}\) for this conformer under these conditions, again in line with that calculated for the bent structure.

The PL behavior of DMAC-py-TRZ was also characterized in polyTHF, a viscous solvent where conformational relaxation is hindered. Interestingly, two emission bands are observed in this viscous medium (Fig. S17, ESI\(^\dagger\)). The first emission band at

\(^a\) Measured at room temperature. \(^b\) \(\lambda_{exc} = 340 \text{ nm}\). \(^c\) Obtained \(via\) the optically dilute method\(^23\) (see ESI), quinine sulfate \((0.5 \text{ M})\) in \(\text{H}_2\text{SO}_4\) (aq) was used as the reference, \(\Phi_{PL} = 54.6\%\), \(\lambda_{exc} = 360 \text{ nm}\).\(^3,11\) \(^d\) Obtained using an integrating sphere. \(^e\) \(\tau_p\) (prompt lifetime) and \(\tau_d\) (delayed lifetime) were obtained from the transient PL decay of degassed solution/doped film, \(\lambda_{exc} = 378 \text{ nm}\). \(^f\) \(S_0\) was obtained from the onset of the prompt fluorescence measured at 77 K, obtained in the 1–100 ns time range. \(^g\) \(S_0\) was obtained from the onset of the phosphorescence spectrum measured at 77 K, obtained in the 1–8.3 ms time range. \(^h\) \(\Delta E_{ST} = S_1 - T_1\).
410 nm is similar to the one observed in the glassy matrix at 77 K while the second emission at 600 nm is similar to the emission observed in DMSO at room temperature. At ambient temperature, the excited state relaxation, fully hindered in glassy matrices at low temperature, is partially hindered in the viscous polyTHF. Accordingly, the presence of the two emission bands is evidence of the simultaneous presence of the unrelaxed (bent) emissive species (as in the glassy matrix) as well as of relaxed (orthogonal) species (as in the liquid solvent).

Having observed that the $S_1$ relaxation of DMAC-py-TRZ in frozen glassy matrices at low temperature is fully hindered while it is only partially hindered in viscous solvents at ambient condition, we next transitioned to an investigation of the behavior of this compound in amorphous matrices where large geometric reorganization is also likely to be hindered (Fig. 6). Spin-coated thin films of DMAC-py-TRZ doped into PMMA at 10 wt% were first prepared (Fig. 6a). Emission at $\lambda_{em}$ of 316 nm was observed with a $\Phi_p$ of 63.8% under a N$_2$ atmosphere, which decreased to 58.0% upon exposure to oxygen. Biexponential decay kinetics were observed in the time-resolved PL measurements, with $\tau_p$ of 26.0 ns and an average $\tau_d$ of 4.7 $\mu$s [$\tau_1 = 1.0 \mu$s (32.6%), $\tau_2 = 7.4 \mu$s (67.4%)], respectively. The presence of a delayed fluorescence suggests that at least some emitter molecules adopt an orthogonal conformation, as to allow for TADF. Compared to the data obtained in toluene ($\tau_p$ of 44.0 ns and $\tau_d$ of 1.5 $\mu$s), DMAC-py-TRZ possesses a shorter-lived prompt component and a slightly longer-lived delayed component. We then investigated the photophysics in mCP (1,3-bis(N-carbazoyl)benzene) as the host matrix, a suitable high triplet energy host for both compounds that would be relevant for OLEDs. Fig. 6d shows results at a 10 wt% doping concentration. The emission in mCP is blue-shifted at $\tau_p$ of 496 nm, compared to that of the doped PMMA film. The $\Phi_p$ of the doped film in mCP is 57.4% under N$_2$, which decreased to 53.5% in air. The $\tau_p$ is 24.9 ns and the average $\tau_d$ is 5.3 $\mu$s [$\tau_1 = 1.4 \mu$s (46.8%), $\tau_2 = 7.7 \mu$s (53.2%)]. In both PMMA and mCP matrices at 10% doping the delayed emission is thermally activated (Fig. 7). However, extracting detailed information from such highly doped matrices is dangerous because of spurious phenomena, including homo energy-transfer and inner filter effects (self-absorption). Specifically, the $\Delta E_{ST}$ could be largely underestimated in films at 10% dye concentration due to self-absorption that moves the apparent onset of the absorption peak to the red. However, extracting the $\Delta E_{ST}$ from rates is similarly dangerous in view of the large error bars associated with rates.$^{29}$

To minimize spurious concentration effects, low-concentration (down to 1 wt%) films were fabricated, relevant spectra being shown in Fig. 7. In these films both the high frequency emission originating from the bent structure, and the low-frequency emission from the orthogonal structure, are present, suggesting that both conformers are present in all films. The high frequency emission decays much more rapidly (Fig. 7b), again confirming that it originates from the bent conformer. Upon increasing concentration, the high frequency emission progressively weakens and disappears for doping concentrations above 3 wt%.

Two phenomena may exist to explain this observation, both related to the large transition dipole moment (large oscillator strength) of the $S_0 \rightarrow S_1$ transition in the bent geometry: (1) self-absorption; and (2) energy transfer from the bent to the orthogonal structure. Both phenomena are expected to become more efficient upon increasing the concentration of the emitter in the host matrix.

**Conclusions**

The synthesis of a new TADF emitter, DMAC-py-TRZ, is presented, together with an extensive computational analysis and experimental characterization. The chemical structure of DMAC-py-TRZ only marginally differs from that of the parent DMAC-TRZ compound. However, this minor change of the bridging moiety between the donor and acceptor has an
enormous impact on the conformation and hence on the photo-
physics of the compound. Specifically, while DMAC-TRZ main-
tains the same orthogonal geometry in both the ground and the
first excited singlet states, DMAC-py-TRZ assumes a bent geometry
in the ground state, as highlighted by the large oscillator strength
measured in solution for this dye. However, upon excitation to the
S1 state, the system undergoes a large geometrical rearrangement
to the orthogonal structure. This large relaxation is confirmed by
the very large Stokes shift measured in non-polar solvents. In frozen
2-MeTHF glass at very dilute conditions, the relaxation is hindered and only a blue-shifted emission is seen from the
unrelaxed bent conformer, without any hint of emission from the
orthogonal structure. In mCP films a distribution of conformers
exists and at low concentrations dual emission is observed,
originating both from both the bent and orthogonal structures.
However, upon increasing the doping concentration, the emission
from the orthogonal conformer dominates. While self-absorption
can be partly responsible for the phenomenon, we conclude that
an efficient energy transfer from one conformer to the other also
contributes to the spectral change. Indeed, TADF is not expected
nor observed in the bent structure, due to a too large ΔEST. The
good TADF efficiency of DMAC-py-TRZ in solution, similar as for
DMAC-TRZ, is in line with the very fast molecular relaxation from
the bent (TADF-silent) to the orthogonal geometry (TADF-active)
in solution. The situation is more delicate in matrices where the host
rigidity hinders a large molecular rearrangement. The observed
good efficiency of TADF in matrices then suggests efficient energy
transfer of excitons created on the bent (and TADF silent) struc-
tures towards molecules in the orthogonal (and TADF-active)
structure as to retrieve all photogenerated singlet states for TADF
activity. Most probably, efficient triplet-to-triplet energy transfer is
also required to explain the good efficiency of DMAC-py-TRZ
OLEDs, but this will be subject of a subsequent study.

Note added after first publication

This article replaces the version published on 5 April 2023, in
which Table 1 included values of S1 and T1 (as well as their
difference, ΔEST) for the environments mCP 10 wt% and PMMA
10 wt%, for each of the materials DMAC-TRZ and DMAC-py-TRZ.
These values have been removed in the current version because
the authors no longer believe they can accurately measure them
due to self-absorption, as is explained in the article. For com-
pleteness, the removed values of S1 and T1 have instead been
included in the ESI ‡ where they can be found in Table S28.
