Upper storage-capacity limit and multiple occupancy phenomena in H₂-hydroquinone clathrates using Monte Carlo and DFT simulations

B. Parage,^{ab} C. Miqueu,^b M. Pérez-Rodríguez,^{†a} T. Méndez-Morales^c and
M. M. Piñero ^{*a}

The upper hydrogen-storage capacity limit of the β -hydroquinone clathrate has been investigated using hybrid Grand-Canonical Monte Carlo/Molecular Dynamics simulations, for temperatures ranging from 77 K to 300 K. The evolution with pressure of the cage occupancies has been monitored in detail, describing the progressive nature of the uptake process. It is found that the storage capacity of the pure β -HQ + H₂ clathrate could reach 0.6 wt% (weight percentage) only for pressures above 1400 bar, at ambient temperature. The enhancement of the storage capacities by the multiple occupancy phenomenon was accordingly shown to be very limited by the need for extreme conditions. Following this observation, an unmodified version of the van der Waals & Platteeuw theory was applied allowing for the prediction of experimentally accessible formation pressures. Density functional theory calculations were additionally performed to comprehensively characterize the hydrogen diffusion process within the clathrate crystalline structure, considering different occupancy scenarios.

1 Introduction

In the race for the development of renewable energies, hydrogen is now clearly one of the most credible alternatives to fossil fuels. Despite the extensive research carried out in recent years, its widespread use is still hindered by several technical drawbacks, one of them being the lack of a method encompassing both safety and efficiency for storage and transport.^{1,2} The two current main processes, gas compression at 300–700 bar or liquefaction at 20 K have, respectively, high financial and energetic cost weakening the progress towards the so-called *Hydrogen Economy*. For a complete description of the current progress towards the development of hydrogen use as a global energy vector, one can refer for instance to the comprehensive review by Staffell *et al.*,³ and references therein.

The search for possible alternatives is nowadays focused on different targets, with a particular emphasis on inclusion solids, that can store hydrogen either through physical or

chemical entrapment.⁴ Among the wide range of candidates (for instance carbon porous,^{5,6} Mg-based,⁷ solid-state,⁸ and metal organic framework (MOF) materials⁹), clathrate materials stand out for their low cost, operational safety and fully reversible reactions.¹⁰ Clathrates are solid-state molecular complexes consisting in a crystalline lattice able to host small molecules within networks of nano-sized cavities.^{11,12} The encaging species is then termed as host, while the encaged one is referred to as guest.

Among the organic compounds able to form clathrates, the benzene-1,4-diol, or hydroquinone (denoted as HQ), appears today as one interesting track for storing molecular hydrogen. Four polymorphic forms have so far been observed for HQ ($\alpha, \beta, \gamma, \delta$), but only the so-called β -phase actually corresponds to a proper clathrate.^{13–15} The HQ clathrate is usually formed by recrystallization from solution using an adequate solvent (acetone, ethanol, *etc.*), in which are dissolved both the host molecules (HQ) and the guest species.¹⁶ Another way to obtain it is by pressurizing the ambient stable α -phase with the gas species of interest.¹⁷

Three different types of β -hydroquinone structure exist depending on the type of encaged molecule. For CO₂, the structure is said of type I and pertains to the R $\bar{3}$ symmetry group, with unit cell dimensions $a = b = 16.207 \pm 0.006$ Å and $c = 5.780 \pm 0.002$ Å.¹⁶ The crystalline arrangement consists in independent linear channels of interconnected cavities. Each cavity is delimited by two parallel planar hexagonal rings of

H-bonded hydroxyl groups, and retains a roughly spherical form, with a ~ 4 Å radius. The overall stoichiometry corresponds to 1 : 3 cavity to HQ molecules.

Regarding hydrogen, the β -HQ + H_2 clathrate was observed by Strobel *et al.*¹⁷ to form at much lower pressures and presented a better guest retention through heating than simple H_2 hydrates.¹⁸ experimentally highlighted high pressure multiple occupancy of the cavities – *i.e.* the possibility to find more than one guest molecule per cavity – with up to full triple occupancy at ~ 3 GPa. Molecular dynamics simulations performed by Daschbach *et al.*¹⁹ showed that high loadings (3–4 H_2 per cavity) exhibited enhanced stability at low temperatures (20 K), but tended to become globally unfavorable at ambient temperature. Han *et al.*²⁰ filled with hydrogen an empty β -HQ structure, initially formed with CO_2 , reporting so far the fastest uptake and release for hydrogen (2 s), and weight percentages of 0.19 wt% and 0.38 wt% at 10 MPa and 35 MPa, respectively, both at ambient temperature. Recent experimental and simulation investigations showed that these values could be readily improved either by dehydrogenating, doping or confining the HQ framework, reaching uptake rates higher than 6.5 wt% in some cases.^{17,21,22}

Nonetheless, several issues must be addressed before the hydroquinone clathrate may be envisaged as a widespread hydrogen storage media. Among the lingering questions, the determination of the upper storage capacity limit, along with the pressure and temperature dependence of multiple occupancy, remain unanswered. Also, the lack of detailed experimental or theoretical data concerning the β -HQ + H_2 clathrate equilibrium curve remains crippling for foreseeing experimental manipulations.

The aim of this work is to computationally determine the hydrogen-storage capacity of the pure H_2 -hydroquinone clathrate at several temperatures and pressures, by performing hybrid Grand Canonical Monte Carlo/Molecular Dynamics simulations. Results are discussed in the light of the current clathrate thermodynamic modeling, and used to evaluate the theoretical formation conditions of the β -HQ + H_2 clathrate above 200 K. In addition, the inter-cage transition barriers for various cage occupancies are computed using density functional theory, highlighting the inner dynamics of the uptake process.

2 Methodology

2.1 Hybrid grand canonical Monte Carlo/molecular dynamics simulations

Since we aim to determine the storage capacity of the β -HQ + H_2 clathrate, the thermodynamic variable we are basically interested in is the average number of H_2 molecules in the β -structure at equilibrium with fixed thermodynamic conditions. Such a quantity can be accessed by performing Grand Canonical Monte Carlo (GCMC) simulations. This method was successfully employed by Papadimitriou *et al.*²³ in the case of H_2 hydrates.

When applying this technique, H_2 gas molecules are randomly exchanged from within a β -structure at fixed volume V , and a fictitious gas reservoir imposing both temperature T and chemical potential μ . One H_2 molecule is thus created or removed with equal probability at a random position inside the structure, generating a new micro-state that can either be accepted or rejected on an energy criterion. The acceptance probabilities are those formulated by Metropolis *et al.*,²⁴ and allow to accurately sample the states which contribution to equilibrium is most significant.

In order to capture the H_2 inter-cage diffusion effect, the GCMC algorithm is in this work interspersed with molecular dynamics (MD) steps, as recently performed on the same system by Méndez-Morales *et al.*²⁵ The number of molecules in the system remains consequently briefly fixed while Newton's equations of motion are iteratively solved over few time steps, by means of the selected molecular model for hydrogen and hydroquinone. Thus, the employed method corresponds to hybrid Grand Canonical Monte Carlo/Molecular Dynamics simulations.

Hybrid GCMC/MD simulations were carried out in a rhombohedral box corresponding to a $2 \times 2 \times 8$ replicated β -HQ unit

Fig. 1 (a) Cross section of the β -HQ clathrate structure (GCMC/MD simulation box), viewed along the z -axis. (b) Side view of a β -HQ channel consisting in four empty aligned cages (DFT system, see Section 2.3), viewed along the x -axis. Atoms are represented as spheres (C, purple; O, dark blue; H, red).

cell (Fig. 1a), *i.e.* 288 HQ molecules and 96 cavities. The atomic positions are those of the β -HQ + CO₂ clathrate, experimentally obtained by Torr   *et al.*¹⁶ using X-ray diffraction. This is actually of no importance since the structure was shown to adapt to the type of engaged guest.²⁶

For HQ, the molecular model is parameterized using the classical OPLS-AA force field,²⁷ but using the partial atomic charges recalculated by.²⁶ This combination was shown to describe with accuracy the structure of the β -HQ clathrates for different pure-guest and mixture clathrates. Comesa  a *et al.*²⁶ Regarding hydrogen, the two-sites Cracknell model²⁸ with a 0.7414   bond length is employed.

Simulations were performed using the LAMMPS²⁹ 2020 simulation package. Parameters for energy calculation are those usually applied when simulating the β -HQ structure.^{19,25} Both van der Waals and Coulombic interactions were treated with a real space cutoff of 11  , and a dispersive long range tail correction. The SHAKE³⁰ algorithm was used to constraint bonds and angles to their equilibrium values. Periodic boundary conditions were applied in the three directions of space. Temperature was imposed by means of the Nose-Hoover thermostat with a 10 fs relaxation time. Investigated temperatures are 77 K, 150 K, 200 K, 250 K and 300 K at pressures from 10 bar to 5000 bar.

Each run consisted in 400 000 MD (time)-steps of 1 fs, interrupted every 10 time-steps by 10 consecutive GCMC insertion-deletion attempts. The starting configuration either corresponds to an empty β -HQ structure or a triply loaded one (*i.e.* 3H₂/cavity). It was preliminary assessed that the final results were independent of the initial loading of the structure by computing complete isotherms starting from both configurations, reaching in both cases the same final equilibrium state. The only difference being the computing time needed to reach equilibrium, the starting configurations were subsequently chosen the closest to the guessed equilibrium state for given *T* and *P* conditions. For every system, a first run was realized to equilibrate the average number of H₂ molecules into the structure. A second identical run was then made starting from the equilibrated box, dumping the atomic coordinates every 20 steps. The average number of H₂ molecules was finally accessed by averaging the 20 000 outputted configurations. The occupancy repartition – *i.e.* the fraction of cavity occupied by 1, 2, *etc.*, H₂ molecules – was analysed with a python code using the MDAnalysis library.³¹

2.2 Fugacity model

The determination of fugacity prior to each molecular simulation calculation deserves a detailed comment at this point. In the simulation, fixing temperature and pressure is equivalent to fixing the temperature and the chemical potential of the fictitious H₂ reservoir. An accurate fugacity model is therefore required in order to simulate real fluid conditions. The Soave-Redlich-Kwong³² equation of state (SRK EoS) is used in this work with hydrogen critical parameters *T*_c = 33.0 K, *P*_c = 12.84 bar and ω = −0.219.³³

Fig. 2 (a) Comparison between the NIST reported values and the SRK calculated values for the compressibility factor of H₂ at 77 K (dashed line, black circles) and 300 K (dashdotted line, black squares). (b) Comparison of the fugacity coefficients at 300 K obtained with different methods: SRK-EOS (black triangles), SRK-EOS with experimental density values (red circles),³⁴ empirical formula (blue circles).

Following the standard procedure for cubic EoS, the fugacity coefficient $\Phi(T, P)$ can be derived in terms of the compressibility factor *Z*:

$$\ln(\Phi) = Z - 1 - \ln(Z - B) - \frac{A}{B} \ln\left(\frac{Z - B}{Z}\right) \quad (1)$$

where $f = \Phi \cdot P$ is the fugacity, and *A* and *B* are both functions of *T*, *P*, and H₂ critical parameters. The accuracy of the SRK fugacity therefore depends on that of the predicted compressibility factors. However, assessing the accuracy of the obtained values is a complex task, given the usual absence of experimental values for fugacity coefficients. In order to evaluate the limits of validity of this model, and thus the accuracy domain of the performed simulations, the calculated values of the compressibility factor were therefore compared with NIST reference values.³⁵ The computed fugacity coefficients at 300 K were also compared to an empirical formula derived by Shawn and Wones,³⁴ and also to values obtained by replacing the experimental *Z* values in eqn (1). This latter approach may be akin to a perfect volume-translation model. Compressibility factors at 77 K and 300 K, and fugacity coefficients at 300 K, are shown on Fig. 2a and b, respectively.

Whatever the temperature, it is not surprising to find that the SRK EoS overestimates the compressibility factor, roughly from 500 bar and 1000 bar at 77 K and 300 K, respectively, with deviations increasing for denser phases. At 300 K, a very good agreement between the different fugacity coefficients is observed up to 3000 bar, although the deviations on Z reach $\sim 15\%$. It can thus be reasonably assumed that Φ may be trusted slightly beyond the PVT accuracy of the EoS used. Fixing an approximate and arbitrary limit of 10% error on the compressibility factor, we consider that the calculated fugacity coefficients can be reasonably trusted up to 1500 bar at 77 K, 2000 bar at 150 K, 200 K and 250 K, and 3000 bar at 300 K. Above these thresholds, they are more likely highly underestimated, as observed for the last two points on the right side of Fig. 2b.

2.3 Density functional theory calculations

Density Functional Theory (DFT) is based on the fact that finding the ground energy of a many-body system can be achieved by minimizing a so-called energy functional, with respect to the electronic density. The aim of this part is to use DFT to calculate the transition energy barriers of an H_2 molecule going from a filled cage to an empty adjacent one. Similar calculations have already been performed to study guest transitions in hydrates,^{36,37} and even in some case for the β -HQ + H_2 clathrate.³⁸ This methodology will be shown to provide an interesting complementary approach to the study of the average clathrate cage occupancies.

Calculations were carried out with the GAUSSIAN 16 package.³⁹ The Perdew, Burke and Ernzerhof (PBE) exchange–correlation functional⁴⁰ was used for its accuracy in the modeling of H-bonded structures,⁴¹ along with the Grimme correction for dispersive interactions. In order to reduce calculation time, the 3-21G Pople-type basis set is employed.

The system consists in four empty aligned cages (338 atoms, Fig. 1b), constructed and preoptimized by Pérez-Rodríguez *et al.*³⁸ Three initial configurations were built by placing from one to three H_2 molecules in one of the central cages. Atom coordinates were those reported by Daschbach *et al.*¹⁹ using MD simulations. Structures were first optimized, constraining

Fig. 3 Filled β -HQ cages with from one to three H_2 molecules used in DFT calculations. Same atom color code as in Fig. 1a and b. H_2 guest molecules in white.

only the positions of the outer oxygens in order to allow the cell to adapt to the loading.³⁸ The relevant H_2 molecule was then displaced following a path parallel to the channel axis, from its initially optimized position to the center of the adjacent cage, by creating 10 intermediate configurations. The energy barrier was computed by making an optimization/single-point energy calculation on each one of the equi-spaced path positions, this time also constraining the position of the moving H_2 molecule. The three optimized initial configurations used for computing the transitions barriers are shown on Fig. 3. The highlighted atoms on Fig. 4 correspond to the fixed outer oxygens mentioned above.

2.4 Clathrate classical thermodynamic modelling

The main approach concerning the macroscopic thermodynamic modelling of clathrates corresponds to the theory initially developed by van der Waals and Platteuw (vdW&P),⁴² 1958. Based on statistical mechanics, this model allows for the prediction of the formation conditions and phase equilibria of clathrates with a wide range of guests. Concerning gas-hydroquinone clathrates, the equilibrium curve is derived by solving the equality between the chemical potentials of the α -phase and the β -phase at given temperature and pressure conditions. In practice the chemical potentials are replaced by their differences with those of the empty metastable β -phase, facilitating calculations. The original version of the theory was recently revised by Conde *et al.*⁴³ in order to account for the possible solubility of guest molecules in the α -phase, as it was experimentally observed for hydrogen with HQ.⁴⁴ The equilibrium condition accordingly writes:⁴³

$$\Delta\mu^\beta = \Delta\mu^\alpha + \Delta\mu^{\alpha-\text{sol}} \quad (2)$$

where $\Delta\mu^\alpha$ is derived from classical thermodynamics,⁴² and corresponds to an integral from a reference state chosen at the quadruple point of the HQ phase-diagram.⁴³ Terms $\Delta\mu^\beta$ and $\Delta\mu^{\alpha-\text{sol}}$ can be gathered, yielding the following expression:

$$\Delta\mu^\beta - \Delta\mu^{\alpha-\text{sol}} = RT(\nu^\alpha - \nu^\beta)\ln(1 - \theta) \quad (3)$$

where ν^α and ν^β are the number of cavities per HQ molecules in both phases (1/18 & 1/3 respectively) and θ corresponds to the total occupancy ratio – i.e. the number of occupied cavities over the total number of cavities – of the β structure. In the case where the considered guest species is known to show multiple occupancy, θ hence corresponds to the sum of each type of occupancy ratio θ_i ($i = 1, 1 \text{ H}_2/\text{cavity}$; $i = 2, 2 \text{ H}_2/\text{cavity}$; etc.). The most commonly used expressions for θ_i are Langmuir-type functions derived from classical adsorption equilibria. Considering that a cavity (C) filled with i guest(s) (G) necessarily results from one filled with $i - 1$, we get:

$$\forall i \geq 1, CG_{i-1} \xrightleftharpoons{C^{(i)}} + GC^{(i)} CG_i \quad (4)$$

and then,

$$\theta_i(T, P) = \frac{f^i \cdot \prod_{k=1}^i C^{(k)}}{1 + \sum_{j=1}^{\max \text{ occ.}} f^j \prod_{k=1}^j C^{(k)}} \quad (5)$$

where f is the gas phase fugacity and $C^{(k)}$ is the so-called Langmuir constant, describing the affinity between the k engaged guest(s) and the cavity. A spherical potential is usually assumed to describe host–guest interactions, with a radius of $R = 3.95 \text{ \AA}$ in the case of a β -HQ cavity. For simple occupancy ($k = 1$) the constant reads:⁴²

$$C^{(1)} = 4\pi\beta \cdot \int_0^R e^{-\beta\phi(r)} \cdot r^2 \cdot dr \quad (6)$$

where β is the Boltzmann factor, r is the distance of the guest molecule from the cage center, and $\phi(r)$ is the spherical potential describing the interaction of the guest with the host-lattice. This latter can be derived following the Lennard-Jones-Devonshire (LJD) method,^{42,45} in which $\phi(r)$ is obtained by averaging the interactions over Z molecules distributed across the surface of the sphere. Using a standard Lennard-Jones (LJ) potential for individual host–guest interactions, the spherical potential then writes:

$$\phi(r) = Z\varepsilon \cdot \left(\frac{\sigma^{12}}{5R \cdot r^{11}} \cdot \delta_{10}(r) - \frac{\sigma^6}{2R \cdot r^5} \cdot \delta_4(r) \right) \quad (7)$$

where $Z = 24$ for HQ clathrates, σ and ε are the collision diameter and the depth of the LJ potential, respectively, and $\delta_n(r)$ is given by:

$$\delta_n(r) = \left(1 - \frac{r}{R}\right)^{-n} - \left(1 + \frac{r}{R}\right)^{-n} \quad (8)$$

In the forthcoming calculations (see Section 3.3), the classical Lorentz–Berthelot mixing rules are used to estimate the H_2 -HQ pair potential parameters, with HQ parameters ($\sigma = 2.90 \text{ \AA}$, $\varepsilon/k_B = 150.06 \text{ K}$),⁴² and H_2 parameters ($\sigma = 2.93 \text{ \AA}$, $\varepsilon/k_B = 37.00 \text{ K}$).⁴⁶

For more than one guest into a cavity ($k \geq 2$), guest–guest interactions have to be accounted for in the calculation of $C^{(k)}$, making the generalisation of eqn (6) a nested multidimensional integral.⁴⁷ This latter problem has so far rendered cumbersome the inclusion of multiple occupancy phenomena

in the modelling of clathrates, even though approximate methods have been proposed.⁴⁸

3 Results and discussion

3.1 Storage capacities at cryogenic temperature (77 K)

The set of simulations performed at 77 K was done for pressures between 10 and 1250 bar. Initial configurations correspond to a triply loaded clathrate, since it was found to reach faster equilibrium than the empty one.

On Fig. 5, the H_2 uptake in the clathrate as a function of pressure is shown. The content varies from $\sim 0.73 \text{ wt\%}$ to $\sim 1.20 \text{ wt\%}$, with at first a strong dependence on pressure, below 500 bar. This trend is followed by a clearly marked stabilisation in the range 500–1250 bar. This is undoubtedly related to the evolution of the average cavity occupancy ratios shown on Fig. 6. Within the examined pressure range, the

Fig. 5 Hydrogen weight percentage as a function of pressure for the β -HQ clathrate at 77 K (red squares).

Fig. 6 Occupancy ratio of the cavities as a function of pressure for the β -HQ clathrate at 77 K: simple occupancy, blue squares; double occupancy, orange squares; triple occupancy, grey squares; total occupancy, red squares.

structure already appears to be fully occupied, with 80% of singly occupied cavities and 20% of doubly occupied cavities, at 10 bar. A quite fast inversion of this order is then observed with the increase of pressure, corresponding to the strong dependence cited above. The plateau observed on Fig. 5 matches the saturation of the structure with two H₂ per cavity, double occupancy becoming exclusive at 1000 bar. An apparent discrepancy with the experimental value reported by Woo *et al.*²¹ of ~ 1.63 wt% at 80 bar and 77 K is to be noted. This experimental result corresponds to 2–3 H₂ per cavity, which contradicts the non-occurrence of triple occupancy in our GCMC simulations. The accuracy of the employed classical description for the host-guest interactions might be arguable at such a low temperature, as it would lead to a wrong sampling of the phase-space in the case it is inadequate.

3.2 Storage capacities at higher temperatures (200–300 K)

For higher temperatures, the starting configuration for the simulations corresponds to the empty β -HQ structure, for identical reasons as in 3.1. The H₂ uptake in the clathrate as a function of pressure is shown on Fig. 7 and 8.

The H₂ content obtained in simulation at 300 K and up to 350 bar is shown on Fig. 7, alongside the experimental values reported by Han *et al.*²⁰ A remarkably accurate correspondence is observed in this comparison, supporting the soundness of the method employed, at least in a range of temperatures where the classical description remains accurate enough. Results for higher pressures are reported in Fig. 8. Again, a really good correlation is obtained with the experimental weight percentage reported by Strobel *et al.*¹⁷ of ~ 0.64 wt% at 2000 bar and 296 K. A clearly marked linear dependence of the H₂ uptake with pressure is observed for all three temperatures. The slope coefficients are $\sim 18.5 \times 10^{-5}$ wt% bar⁻¹ at 200 K and $\sim 14.0 \times 10^{-5}$ wt% bar⁻¹ at both 250 K and 300 K, which turn out to be 50 times greater than values reported for H₂ hydrates at similar conditions.²³ In any case, it is worth recalling that the highest pressure points of each curve are likely to be underestimated,

Fig. 8 Hydrogen weight percentage as a function of pressure for the β -HQ clathrate at 200 K (circles), 250 K (triangles) and 300 K (squares), with linear fits.

as the SRK fugacity becomes inaccurate for H₂ at such high pressures, as discussed in Section 2.2.

In this range of temperatures, it is rather difficult to fill the structure, as it requires for instance almost 1400 bar to reach the stoichiometric threshold of one H₂ per cavity (or 0.6 wt%) at 300 K. Lowering the temperature allows a faster uptake with pressure but still too slow-paced to reach interesting values under conditions relevant to practical industrial applications. As it can be seen on Fig. 9, the filling is primarily done with the structure nearly fully accommodating one H₂ per cavity. At 250 K, pressures greater than 2800 bar are required for doubly occupied cavities to become dominant, while triple occupancy remains nearly negligible below 5000 bar. Similar trends are observed at 200 K and 300 K but shifted toward a lower and higher pressure range, respectively. As temperature rises, the multiple H₂ guest occupation modes for HQ clathrates are shifted to remarkably higher pressure ranges. These observations are consistent, although differing by roughly one order of magnitude, with the experimental estimation of the β -HQ + H₂ occupancy done by¹⁸ from volume considerations of the pure

Fig. 7 Hydrogen weight percentage as a function of pressure for the β -HQ clathrate at 300 K (red squares) compared to²⁰ results (black circles).

Fig. 9 Occupancy ratio of the cavities as a function of pressure for the β -HQ clathrate at 250 K. Same color code as in Fig. 6.

components. At 343 K, they estimate the thresholds of two and three H₂ per cavity to be reached around ~ 1.5 GPa and ~ 3 GPa, respectively. Also, our results match previous observations reporting a greater stability of lower loading at ambient conditions.¹⁹

3.3 Theory-simulation comparative analysis

The determination of the cage occupancy's pressure dependence brings useful insights for the theoretical thermodynamic modelling of this system. The theory elements used in the following are those presented and discussed in Section 2.4.

On the one hand, the presented results show that the enhancement of the β -HQ clathrate storage capacities by the H₂ multiple occupancy phenomena is in practice very limited by the need for extremely high pressures. For temperatures above 200 K, it is reasonable to assume that the clathrate equilibrium curve is located within a pressure range where single occupancy remains practically exclusive. This latter assumption allows to predict the formation conditions of the β -HQ + H₂ clathrate with no need to account for multiple occupancy in the thermodynamic modelling. Using a Fortran 90 code, eqn (2) was solved, yielding theoretical formation pressures of 30.7 bar at 200 K, 78.4 bar at 250 K and 151.2 bar at 300 K. These values are compatible with the experimentally reported formation occurrence of the clathrate from the α -phase at 700 bar and 296 K.¹⁷ Formation conditions at 77 K and 150 K predicted with this method should nevertheless not be trusted, since doubly occupied cages become not negligible even at low pressures.

On the other hand, the observed trends on Fig. 6 and 9 demonstrate the progressive nature of the filling process. The structure will first nearly fully accommodate one H₂ per cavity before doubly occupied cavities can occur. It is obvious here that doubly occupied cavities almost exclusively result from the filling of singly occupied ones, which is not necessarily the case with H₂ hydrates.²³ This behavior is a remarkable validation for the Langmuir-type functions introduced in eqn (5), which are widely used to model such isotherms. The conclusions drawn from the GCMC simulations can thus be exploited to access useful theoretical parameters.

Taking advantage of the shape of the Langmuir isotherms, the double occupancy Langmuir constant $C^{(2)}$ was easily evaluated by linear regression of the GCMC data. The following relation, derived from eqn (5):

$$\frac{\theta_2}{\theta_1} = C^{(2)} \cdot f \quad (9)$$

was found verified at every investigated temperature, with correlation coefficients $R^2 > 0.99$ in any case. Subsequently, a temperature-dependent expression was obtained by fitting the $C^{(2)}$ values (Fig. 10):

$$C^{(2)} = \left(\frac{6.89 \times 10^{-4}}{T} \right) \cdot \exp\left(\frac{-555.64}{T} \right) \quad (10)$$

where T is in Kelvin and $C^{(2)}$ in bar^{-1} . The choice of this fitting function is motivated by the general shape of $C^{(k)}$,^{47,48} and was

Fig. 10 Double occupancy Langmuir constant $C^{(2)}$ with temperature obtained from the GCMC data (red squares) and its fit function $a/T \cdot \exp(-b/T)$ (red line), with $a = 6.89 \times 10^{-4}$ and $b = -555.64$. Point at 77 K is not shown but correspond to value $C^{(2)} \approx 10^{-6} \text{ bar}^{-1}$.

already employed for similar purposes for H₂ hydrates.²³ Such a compact expression provides a helpful comparison tool when testing different methods to theoretically estimate this intricate type of constant. However, it should be used prudently as its accuracy is very likely to depend on that of the simulation force-field. Although a relation similar to eqn (9) does exist for $C^{(3)}$, no satisfying expression could be obtained, as triple occupancy remains practically null on the investigated range of pressures.

Due to the absence of a straightforward expression like eqn (9), the $C^{(1)}$ Langmuir constant was obtained by directly fitting the GCMC occupancy data with the θ_1 -isotherm, keeping the maximum occupancy fixed at three H₂ molecules within a cavity.

The selection of the θ_1 -isotherm, as opposed to θ_2 , is most appropriate for determining $C^{(1)}$, given that contributions of $C^{(2)}$ and $C^{(3)}$ remain of second order in this isotherm. The

Fig. 11 Simple occupancy Langmuir constant $C^{(1)}$ with temperature obtained from the GCMC data (red squares) and calculated using vdW&P theory (black triangles). Points at 77 K are not shown but correspond to values $\sim 0.45 \text{ bar}^{-1}$ and $\sim 145.83 \text{ bar}^{-1}$ for GCMC and vdW&P, respectively.

obtained values for $C^{(1)}$ from 150 K are shown on Fig. 11, alongside the theoretical ones calculated from eqn (6). A quite satisfying match is observed for the three last temperatures (above 200 K). This correlation further underscores the quality of our results in this temperature range, as the theoretical and simulation approaches utilize very different tools, be it only in the treatment of host-guest interactions or phase-space sampling. Both GCMC points at 77 K and 150 K are quite far from those calculated theoretically, being over and underestimated, respectively. The classical treatment of inter-molecular interaction being likely to be disputable at these temperatures, neither method should be unequivocally considered more reliable. It is worth mentioning that values obtained with this method for the $C^{(2)}$ constant converged to the same of that using eqn (9), whereas again no stable values could be obtained for $C^{(3)}$.

3.4 Inter-cage transition barriers

The inter-cage transition barriers for initially up to three H_2 in a cavity are reported on Fig. 12. The x -axis and y -axis correspond respectively to the fractional inter-cage centers distance, and to the total energy difference with respect to the H_2 initial position.

The transition barrier peaks are estimated at 0.41 eV for the 0100 \rightarrow 0010 transition, 0.29 eV for the 0200 \rightarrow 0110 transition and 0.20 eV for the 0300 \rightarrow 0210 transition. For comparison, the same calculations performed on hydrates between two large cages yielded barriers of 0.23 eV, 0.30 eV and 0.25 eV at similar loadings.⁴⁹ The proximity of these values – especially for initial double and triple occupancies – reflects the structural similarities between the hydroxyl rings in the β -HQ clathrate and the water hexamers delimiting hydrate cages. Also, the obtained value for the 0100 \rightarrow 0010 transition perfectly matches the linear dependence of the barrier peak with the atomic radii of the guest found by Rodríguez-García *et al.*⁵⁰ using MD umbrella

sampling, with an error below 5% on their predicted value of 0.39 eV at 310 K and 10 bar.

In our case, increasing the occupancy visibly decreases the barrier peak, by as much as 30% for two H_2 in a cavity and 50% for three H_2 in a cavity, relative to when the transported H_2 is alone in the cage. Moreover, barrier peaks significantly increase when looking at the reverse paths, soaring respectively to 0.42 eV and 0.58 eV for the 0110 \rightarrow 0200 and 0210 \rightarrow 0300 transitions. These findings support the previous observations made on the filling process of the system. It is now clear that the structure will firstly accommodate one H_2 per cavity, since multiply occupied cages will be easily scattered in the neighboring ones. The reverse process is even relatively less likely as the barriers significantly increase for the hop back. This is fully consistent with previous observations reporting enhanced intercage diffusion for doubly and triply occupied cavities,¹⁹ further corroborating our understanding of the system's behavior.

Even though these results allow for a convenient way to interpret the GCMC data, it should be remembered that DFT calculations amount to a temperature of 0 K. Concomitant dynamical effects of both the H_2 molecules and the HQ lattice should be considered in order to establish a more accurate picture of the inter-cage diffusion phenomena at ambient temperatures.

4 Conclusions

The aim of this work was to investigate the hydrogen-storage capacity of the pure H_2 -hydroquinone clathrate through molecular simulations in order to evaluate its feasibility as a storage media for molecular hydrogen. The presented results allow to gather and complete the so far scarce and scattered data on this system, but also to unfold further experimental and theoretical research perspectives.

The determination of the H_2 uptake with pressure was achieved by performing Hybrid Grand-Canonical Monte Carlo/Molecular Dynamics simulations at various thermodynamic conditions. Results demonstrate a low uptake of hydrogen at ambient conditions, even for pressures that can be regarded as extreme for practical applications (0.6 wt% at 1400 bar and 300 K), confirming the available experimental data.^{17,20} It was shown that working at cryogenic temperature would allow a faster uptake but still requiring at least 500 bar to reach the double stoichiometric threshold of two H_2 per cavity. The multiple occupancy phenomena was accordingly found not to allow for a significant improvement of the storage capacities, as every occupancy degree was found to result from the previous one. One explanation for these findings could be that the stabilization of the host lattice, resulting from the inclusion of H_2 molecules, is too small compared to the corresponding entropy decrease, thus hindering the reduction of the total free-energy. These results therefore highly question the potential use of the pure hydroquinone clathrate for hydrogen storage exclusively, as the determined uptakes really fall short of the

Fig. 12 Energy profiles in eV of one H_2 passing through the hexagonal ring of H-bonded hydroxyl groups for initial cage occupancy going from 1 to 3 H_2 (0100 \rightarrow 0010, red; 0200 \rightarrow 0110, blue; 0300 \rightarrow 0210, green). Data points are interpolated by spline functions for a better representation.

ultimate 6.5 wt% target fixed by the *Department of Energy* of the United States.¹⁰

The transition barriers for various cage occupancies were computed in parallel using density functional theory. The obtained values show a decrease of the barrier peak when increasing the cage loading, providing further confirmation of the already reported easy hydrogen diffusion along the channels of the β -structure.¹⁹ Also, it is now clear that the main advantage of the hydroquinone clathrate with H₂ lies in its fast capture and release of the gas, which constitutes a major advantage for industrial applications.⁴

Beyond giving information on the filling process, the detailed analysis of the occupancy ratios provided guiding insights for the thermodynamic modeling of the β -HQ + H₂ clathrate. A version of the theory only accounting for singly occupied cavities was theoretically found to be sufficient for predicting, we hope, accurate formation pressures at temperatures above 200 K. The determined conditions are much more moderate than those for H₂ hydrates, and now await for experimental validation.

Further simulation investigations on the β -HQ + H₂ clathrate should now focus on ways to improve its storage capacity. Among the most interesting tracks, doping the framework with fullerene (C₆₀) was recently demonstrated to allow a great enhancement of the hydrogen uptake.²¹ The effect of more standard promoters in the gas phase, such as tetrahydrofuran or carbon dioxide, has not been investigated yet. It is reasonable to think that the distortion of the lattice resulting of the inclusion of bigger molecules may lead to an increase of the maximum cage occupancy. Ultimately, the study of the hydroquinone clathrate's stability in nanoporous matrices was recently mentioned as necessary in order to assess the potential of the confining method at the theoretical level.²²
