Construction of BaTiO₃–TiO₂ hollow sphere heterojunctions for enhanced microwave dynamic therapy in cancer treatment

Yaodong Chen,^{†*} Fangyu Cai,^{†d} Yadong Liu,^e Wenwen Fan,^a Jingjie Wang,^a Guolin Yin,^a Jiayi Ren,^a Jingwei Cao,^a Yongming Fu^{†*} and Jie Chen^{*b}

Cancer is one of the primary health concerns among humans due to its high incidence rate and lack of effective treatment. Currently, medical techniques to achieve the precise elimination of local cancer lesions with negligible damage to normal tissues are still intensely desired. Herein, we synthesized BaTiO₃–TiO₂ hollow spheres (BTHSs) for use in microwave dynamic therapy (MWDT) for cancer. Under UV irradiation, BTHSs can mediate the production of multiple reactive oxygen species (ROS), mainly ¹O₂, which results in a rapid photocatalytic degradation rate (97%), 1.6-fold that of commercial P25. Importantly, the ROS production process can be triggered by microwaves to effectively execute MWDT for cancer. Under microwave irradiation, BTHSs exhibit a remarkable therapeutic effect and slight cytotoxicity. In terms of mechanism, the enhanced ROS production efficiency of BTHSs can be attributed to their unique hollow structure and the formation of a type-II heterojunction by the incorporation of BaTiO₃. The hollow structure increases the availability of active sites and enhances light scattering, while the BaTiO₃–TiO₂ heterojunction enhances the photocatalytic activity of TiO₂ through charge transfer and electron–hole separation. Overall, this study provides important insights into the design and optimization of sensitizers for MWDT applications.

1. Introduction

Cancer has emerged as a significant barrier to increasing life expectancy due to the rising rates of morbidity and mortality worldwide.^{1–3} Multiple therapeutic theories and technologies have been developed to achieve better treatment efficiency and prognosis.^{4–7} For neoplasms located deep in the viscera, such as hepatocellular carcinoma (HCC), ultrasonic imaging-guided microwave ablation therapy has become a prominent minimally invasive and safe procedure for tumor elimination.^{8–10} However, this procedure often leads to hyperthermia-induced side effects on important organs adjacent to the lesion

undergoing ablation.^{11–13} Therefore, it is necessary to explore and develop novel treatment technologies to address these challenges.

The formation and progression of tumors lead to a reprogramming of malignant cell metabolism, characterized by a shift toward aerobic glycolysis as the dominant energy supply mode. This alteration in metabolism results in an imbalance in redox homeostasis.^{14–16} Consequently, cytotoxic reactive oxygen species (ROS), including singlet oxygen (¹O₂), hydroxyl radicals ([•]OH) and superoxide radicals ([•]O₂[–]), are generated as byproducts of molecular oxygen-based energy metabolism. Interestingly, ROS are preferentially generated and accumulated in tumor cells rather than in normal cells,^{17,18} resulting in a high basal ROS content in cancer cells that is prone to exceed the cytotoxic threshold.^{19–21} Exploiting this disparity, researchers have proposed the induction of additional ROS production as an effective and selective eradication strategy for neoplasms.^{22–24}

Nanostructured TiO₂ is widely recognized as an exceptional photosensitizer for ultraviolet (UV)-mediated photodynamic therapy (PDT) in cancer treatment due to its good biocompatibility and UV absorbance.^{25,26} Upon UV irradiation, electrons and holes are generated inside TiO₂ nanoparticles, are transported to the surface, and react with molecular oxygen and chemisorbed water molecules to generate various cytotoxic

ROS. In particular, the generation of $\bullet\text{OH}$ is an oxygen-independent process, making it highly promising for achieving cytotoxicity in hypoxic tumor microenvironments.^{27,28} However, the limited penetration ability of UV light significantly hinders efforts to broaden the application of PDT based on raw TiO_2 nanomaterials.²⁹

Recently, microwave dynamic therapy (MWDT), in which microwaves are employed in conjunction with designated nanomaterials to generate ROS, has been proposed for the ablation of neoplasms.³⁰ Compared to PDT, MWDT utilizes minimally invasive electrodes commonly used in clinical microwave ablation to directly reach the interior of tumors and generate microwaves, which penetrate much deeper than light waves.^{31,32} A needle microwave electrode operated at low power can effectively stimulate the generation of plasma from tiny dissolved bubbles in liquids, emitting UV light to trigger ROS production from spherical TiO_2 nanocatalysts.^{33–35} However, TiO_2 -based MWDT still suffers from certain drawbacks, such as the low separation of charge carriers.

Combining hollow structures and heterojunction configurations in TiO_2 nanocomposites is a promising approach to improve the generation and separation of electron-hole pairs. TiO_2 hollow structures (THSSs) possess a large specific surface area and high light harvesting ability to enhance the photo-generation of charge carriers,^{36–38} while heterojunctions facilitate the separation and transfer of electron-hole pairs.^{39–49} Therefore, the development of hollow heterojunction structures has attracted considerable attention due to their synergistic advantages. BaTiO_3 - TiO_2 hollow spheres (BTHSSs) are representative examples of such structures. The bandgap of BaTiO_3 is higher than that of TiO_2 , enabling the transfer of photogenerated electrons from TiO_2 to BaTiO_3 and inhibiting the recombination of photogenerated electron-hole pairs.^{50–52} In addition, the hollow spheres exhibit strong structural stability, excellent photocatalytic activity and biocompatibility, making them ideal candidates for various applications that depend on the generation of additional ROS, including MWDT.

In this study, we successfully synthesized BTHSSs with a heterojunction structure to explore their potential application in MWDT. Photocatalytic experiments clearly demonstrated that these BTHSSs can sufficiently increase the ROS production efficiency under UV irradiation, as determined by electron spin resonance (ESR) and trapping tests. Furthermore, the enhanced ROS production efficiency of BTHSSs under microwave irradiation was also observed, demonstrating the good MWDT performance of these materials for killing cancer cells *in vitro*. The results suggest that BTHSSs are promising nanoscale catalytic materials for MWDT-mediated cancer treatment.

2. Experimental methods

2.1 Synthesis of THSSs

THSSs were prepared by using a polystyrene (PS)-template solvothermal method. Typically, 200 mg of tetrabutyl titanate (TBOT) was dissolved in 15 mL of PS suspension (210 nm in

diameter, 1 wt% in water) under vigorous stirring. Then, 1 mL of hydrochloric acid (38%) was added dropwise. Following stirring for 1 h, a reaction was conducted for 12 h in a Teflon-lined stainless-steel autoclave at 200 °C. Finally, the products were centrifuged, washed with ethanol/deionized water three times, and heated at 500 °C for 2 h.

2.2 Synthesis of BTHSSs

BTHSSs were synthesized from the THSSs by a facile hydrothermal method. Typically, 460 mg of $\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$ was dispersed in 50 mL of ethanol, diethylene glycol, and isopropanol with a volume ratio of 2:2:1 under stirring, while 150 mg of tetrabutylammonium hydroxide was dissolved in 10 mL of deionized water in another beaker and subjected to ultrasonication. After mixing these two solutions, 200 mg of THSSs were dispersed in the mixture under stirring for 30 min, and the mixture was sealed in a 100 mL Teflon-lined stainless-steel autoclave and heated at 170 °C for 4 h. Finally, the product was centrifugally washed with deionized water and ethanol 3 times and dried overnight at 80 °C. To investigate the effect of temperature and time on the synthesis of BTHSSs, other samples were synthesized under the same conditions except for the heating temperature and time.

2.3 Characterization

The morphology and structure of the samples were characterized by scanning electron microscopy (SEM, Hitachi SU-8010) and transmission electron microscopy (TEM, JEOL JEM-2100F). The chemical states were determined by X-ray photoelectron spectroscopy (XPS, Thermo Kalpha). The crystal structure of the samples was analyzed by X-ray powder diffraction (XRD, Ultima IV) with a scan range of 10°–80°.

2.4 Detection of UV-induced ROS

The total ROS generation induced by UV photocatalysis was evaluated by measuring the effectiveness of the generated ROS in the decomposition of methyl orange (MO) using photochemical reaction apparatus (PL-03, Changzhou Hongming Co., Ltd.). Specifically, 10 mg of BTHSSs were dispersed in 50 mL of MO aqueous solution (10 mg L⁻¹). The suspension was vigorously stirred in the dark for 2 h to establish an adsorption/desorption equilibrium between the dye and the nanoparticles. Then, the suspension was irradiated with a 300 W mercury lamp, and 0.5 mL of the solution was removed at 5 min intervals. The concentration of MO was determined at 464 nm using a UV-Vis spectrophotometer (MAPADA M4). The degradation efficiency was calculated by C/C_0 , where C and C_0 represent the MO concentration at the beginning and during the reaction, respectively. To investigate the main active species involved in photocatalytic reactions, excess *p*-benzoquinone (BQ), isopropanol (IPA), and triethylene diamine (DABCO) were separately added as scavengers for $\bullet\text{O}_2^-$, $\bullet\text{OH}$ and $^1\text{O}_2$, respectively. The photocatalytic degradation efficiencies of the THSSs and BTHSSs were compared after adding free radical scavengers to determine the involved active species.

2.5 Detection of MWDT-induced ROS

1,3-Diphenylisobenzofuran (DPBF, 400 μL , 1 mg mL^{-1}) or methylene blue (MB, 1 mL , 0.1 mg mL^{-1}) was added to the nanoparticles suspended in deionized water (50 mL , 1 mg mL^{-1}). The suspension was vigorously stirred in the dark for 2 h to establish an adsorption/desorption equilibrium between the dye and the nanoparticles. Then, 0.5 mL of the above mixture was added to an EP tube with a maximum capacity of 1.5 mL . Subsequently, the samples were irradiated using a needle microwave probe for 30 min under 10 W power using microwave emission equipment at 2450 MHz (WB-3100AI, Baoxing Medical, China) on ice. After centrifugation, the concentrations of DPBF and MB were determined as described above for MO except that the detection wavelengths were 410 nm and 665 nm, respectively.

2.6 Cell culture

The representative cancer cell line HepG2 (HCC cells) was supplied by the Cell Bank of Type Culture Collection of the Chinese Academy of Sciences (Shanghai, China). The culture medium for HepG2 cells was prepared by supplementing DMEM with fetal bovine serum and penicillin–streptomycin

reagent in a sterile environment. A humidified incubator containing 5% CO_2 was set to 37 $^\circ\text{C}$.

2.7 MTT assay

HepG2 cells were incubated with different doses of THSs or BTHSs for 24 h in a 96-well plate. To detect cell viability, a standard MTT assay was performed. Briefly, the tested cells were sequentially subjected to 4 h of incubation with MTT, dissolution with DMSO, and measurement of the absorbance at 490 nm. For the MWDT experiments, the HepG2 cells were incubated with THSs or BTHSs for 24 h, followed by microwave irradiation, 3 h of incubation and MTT detection.

2.8 ROS detection in cancer cells

HepG2 cells were incubated with THSs or BTHSs for 24 h in a 48-well plate. Subsequently, the cells were washed twice with PBS and incubated with a DCFH-DA probe (300 μL , 10 $\mu\text{mol L}^{-1}$) for 20 min. Then, microwave irradiation was conducted on ice, and the visualized fluorescence intensity reflecting intracellular ROS production was imaged by means of a fluorescence microscope (BX53, Olympus) after washing with PBS.

2.9 Calcein AM/PI staining

HepG2 cells were incubated with THSs or BTHSs for 24 h in a 48-well plate. Subsequently, the cells were irradiated with microwaves on ice after washing twice with PBS. After 3 h, the cells were incubated with 300 μ L calcein AM/PI reagent for 30 min in the dark. The survival status of the cells was visually determined by means of a fluorescence microscope after washing with PBS.

2.10 Statistical analysis

One-way ANOVA was implemented using SPSS 23.0 software, which is designed for the statistical analysis of data collected from multiple groups (>2). In addition, the recognized statistically significant threshold was set as $P < 0.05$.

3. Results and discussion

The EDS spectra show that the THS sample consisted of only Ti and O, and Ba was successfully incorporated without the introduction of other impurities in the BTHS sample (Fig. 1a). The XRD pattern of the BTHSs shows the coexistence of BaTiO₃ and anatase TiO₂ phases (Fig. 1b). The diffraction peaks at 25.18°, 38.02°, 47.96°, 54.60°, 62.72°, 70.39°, 74.98°, and 82.74° correspond to the (101), (004), (200), (105), (204), (220), (215), and (224) planes of anatase TiO₂ (PDF card No. 98-001-0081), while the diffraction peaks at 22.27°, 32.02°, and 44.87° correspond to the (100), (110), and (200) planes of BaTiO₃ (PDF card No. 01-075-1606), respectively. These results indicate that a portion of TiO₂ crystals was calcified to form BaTiO₃-TiO₂ nanocomposites.

Fig. 1c shows the SEM image of THSs, indicating that the hollow spheres exhibited a uniform size distribution with an average diameter of approximately 240 nm. After forming BaTiO₃, the average diameter did not significantly increase, but the surface became rougher (Fig. 1d). The TEM image of the BTHSs further confirmed the hollow structure of the spheres with a wall thickness of ~ 30 nm (Fig. 1e). In the high-resolution TEM image, lattice spacings of 0.23 nm and 0.32 nm corresponding to the (111) plane of BaTiO₃ and (110) plane of TiO₂, respectively, were observed (Fig. 1f). The selected electron diffraction (SAED) pattern indicated that the BTHSs were polycrystalline (inset of Fig. 1f). As seen from the elemental mapping profiles in Fig. 1g-i, Ti, Ba, and O were uniformly distributed in the 30-nm-thick shell of a BTHS.

The chemical compositions of the THSs and BTHSs were analyzed by XPS. The survey spectrum shows the presence of Ba, Ti, O and C in the BTHSs, with C originating from environmental sources (Fig. 2a). The high-resolution Ti 2p, O 1s and Ba 3d spectra are presented in Fig. 2b-d, respectively. In Fig. 2b, the Ti 2p spectrum of the BTHSs shows two peaks at 458.6 and 464.0 eV, corresponding to Ti 2p_{3/2} and Ti 2p_{1/2}, respectively. In comparison to the those of the TiO₂ sample, the peak positions of Ti 2p states experience a slight shift toward lower energy, indicating the coexistence of TiO₂ and BaTiO₃.⁵³ In Fig. 2c, the O 1s spectrum of TiO₂ exhibits two peaks at 529.7 and 531.9 eV,

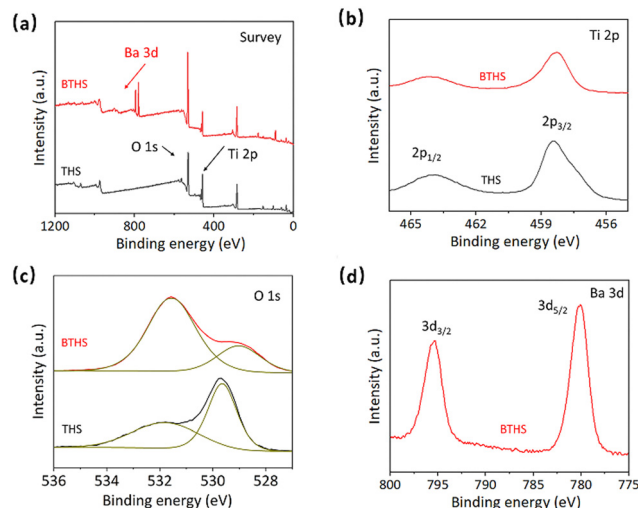

Fig. 2 XPS spectra of THSs and BTHSs. (a) Survey spectrum. (b) Ti 2p. (c) O 1s. (d) Ba 3d.

representing Ti-O bonds and oxygen vacancies, respectively. For the BTHSs, the peak assigned to lattice oxygen shifts considerably to 529.0 eV, which is attributed to Ba-O bonds. The Ba 3d spectrum in Fig. 2d exhibits two prominent peaks at 780.2 and 796.2 eV, corresponding to Ba 3d_{5/2} and Ba 3d_{3/2}, respectively. These results confirm the successful formation of the BaTiO₃-TiO₂ heterojunction.

The PL spectra of THSs and BTHSs are shown in Fig. 3a. The strong peak at 400 nm corresponds to the intrinsic emission of TiO₂, while the broad peak in the range of 500–700 nm corresponds to defect-related emissions. Upon heterojunction formation with BaTiO₃, the intensity of the intrinsic emission significantly decreases, which can be attributed to the spatial separation of hole-electron pairs enhanced by the effective charge transfer between TiO₂ and BaTiO₃. Fig. 3b presents the transient photocurrent curves. It can be observed that the photocurrent of BTHSs is three times higher than that of THSs under the same conditions, indicating superior charge separation efficiency in BTHSs.

The photocatalytic ROS production of THSs and BTHSs was compared by evaluating the photocatalytic degradation efficiency of MO (Fig. 4a). Upon exposure to UV illumination, MO was barely degraded without any catalysts. When commercial P25 was used as a photocatalyst, the MO concentration decreased to $\sim 57\%$ of its initial value after 30 min, confirming

Fig. 3 Photoelectric properties of THSs and BTHSs. (a) PL spectra. (b) Photocurrent behaviors.

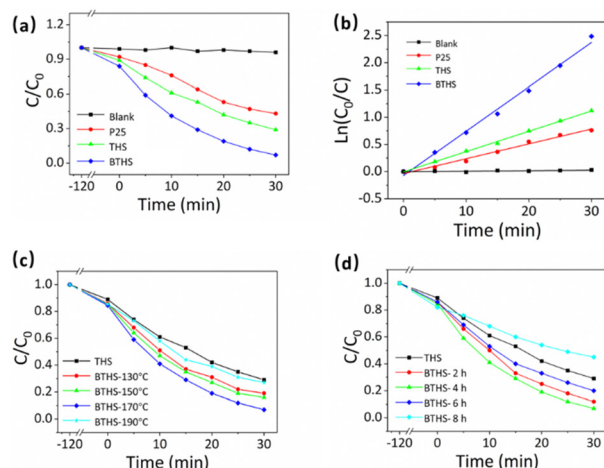

Fig. 4 (a) Photocatalytic degradation processes of different catalysts. (b) The corresponding reaction kinetic curves. (c) Photocatalytic degradation processes of BTHSs synthesized at different temperatures for 4 h. (d) Photocatalytic degradation processes of BTHSs synthesized at 170 °C for different times.

the efficient catalytic activity of TiO_2 . The synthesized THSs achieved an even lower MO concentration, reaching $\sim 21\%$. The BTHSs exhibited the highest efficiency for degrading MO, with a degradation rate of $\sim 93\%$. The photocatalytic degradation kinetics of the samples followed a quasi-first-order reaction equation, as shown in Fig. 4b. Notably, the reaction rate constant of the BTHSs was more than twice that of the THSs. The photocatalytic degradation performance of the samples synthesized under different heating temperatures and times is presented in Fig. 4c and d, respectively, displaying that the optimal synthesis conditions were heating at 170 °C for 4 h.

To assess the stability of BTHSs, the photocatalytic process is repeated, as shown in Fig. 5a. After four cycles of catalytic degradation of MO, the degradation rate of photocatalysts remained at 85%. Afterwards, the BTHSs are subjected to centrifugation and drying processes and analyzed by XRD, as shown in Fig. 5b. Compared to the XRD pattern of initial BTHSs, no discernible changes can be observed, exhibiting a favorable level of stability of BTHSs.

To investigate the role of reactive radicals in the photocatalytic activity of THSs and BTHSs, the photoinduced generation of three representative ROS ($^1\text{O}_2$, $\cdot\text{OH}$ and $\cdot\text{O}_2^-$) was tested by electron spin resonance (ESR) (Fig. 6a–c). The BTHSs generated significantly more radicals than the THSs. To study the

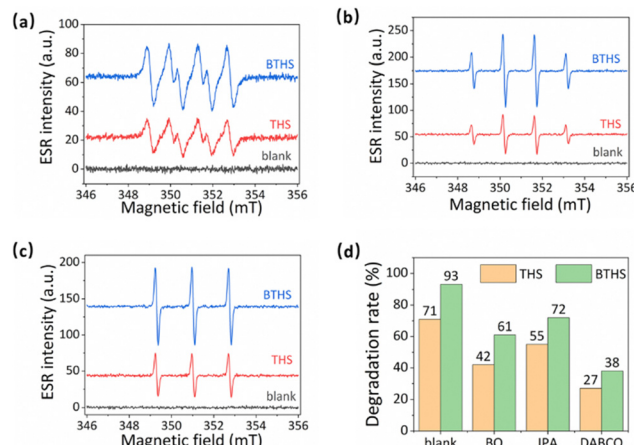

Fig. 6 (a)–(c) ESR signals of (a) superoxide radicals, (b) hydroxyl radicals, and (c) singlet oxygen catalyzed by THSs and BTHSs. (d) The radical scavenger tests.

contribution of each ROS, the ROS were selectively quenched using their corresponding scavengers (Fig. 6d). The addition of each type of ROS scavenger led to a decrease in photocatalytic activity to varying degrees for both THSs and BTHSs. The most severe inhibition of the catalytic activity was observed when a singlet oxygen scavenger was added. The dominant inhibitory effect of the singlet oxygen scavenger on both THS and BTHS photocatalysts suggests that the generation of singlet oxygen is the key factor in the degradation of MO. This work provides an improved understanding of the mechanism of BTHS-mediated photocatalytic ROS production.

To reveal the detailed photocatalytic mechanism, the band alignment structure of the $\text{TiO}_2/\text{BaTiO}_3$ heterojunction is determined, as shown in Fig. 7. Fig. 7a shows the DRS spectra of $\text{TiO}_2/\text{BaTiO}_3$, revealing their absorption ranges in the ultraviolet region. Fig. 7b presents the corresponding Tauc plots, where the band gaps (E_g) of TiO_2 and BaTiO_3 are determined to be 3.11 and 2.95 eV, respectively. The measured band gap values are slightly smaller compared to standard crystals, which can be attributed to the presence of abundant defects during the hydrothermal synthesis process. Fig. 7c displays the VB-XPS spectra, confirming that the valence band (VB) values of TiO_2 and BaTiO_3 are 2.88 and 2.56 eV, respectively, indicating that the VB of TiO_2 is more positive than BaTiO_3 . Mott–Schottky curves of TiO_2 and BaTiO_3 under different frequencies are shown in Fig. 7d and e, respectively. The positive slope of the curves indicates that both TiO_2 and BaTiO_3 are n-type semiconductors. By the intersection of the tangent line of the M–S curves and the x-axis, the flat band potentials of TiO_2 and BaTiO_3 are determined to be -0.11 and -0.23 V, respectively, indicating a more negative conduction band (CB) position of BaTiO_3 compared to TiO_2 . Based on these results, TiO_2 and BaTiO_3 can form type-II heterojunction, as shown in Fig. 7f. The excellent UV photocatalytic performance of BTHSs was attributed to the synergistic effect of their hollow structure and heterojunction. The unique energy band structure of the heterojunction plays a crucial role in enhancing the photocatalytic

Fig. 5 Stability of BTHSs. (a) Repeat test. (b) XRD pattern of BTHSs after the reaction.

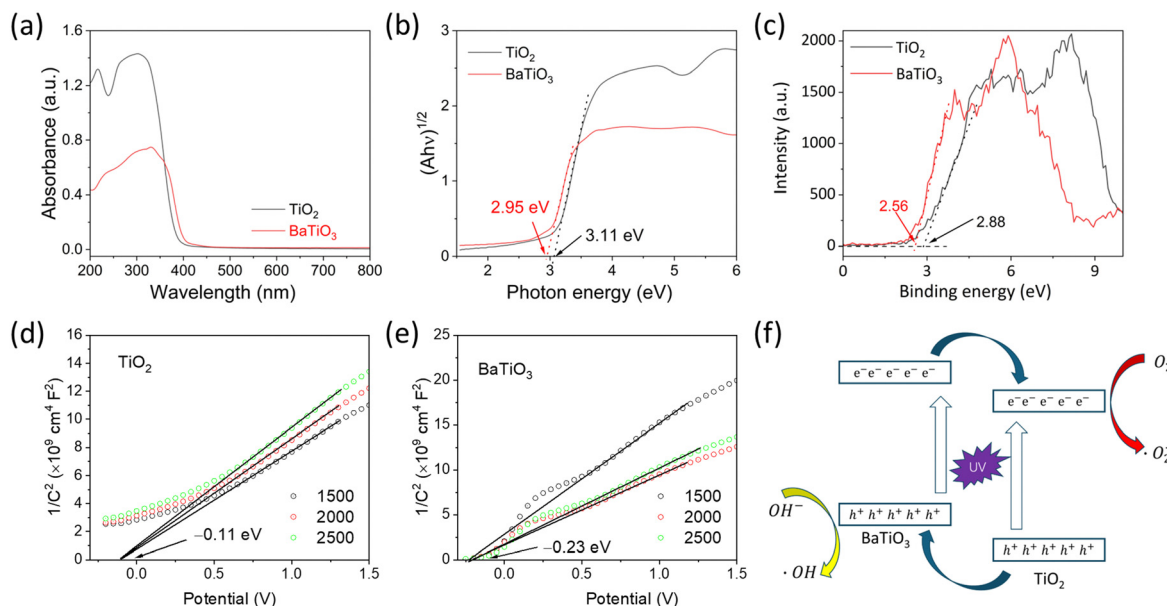

Fig. 7 The photocatalytic mechanism of BTHSs. (a) DRS spectra. (b) Tauc plots. (c) VB-XPS spectra. (d) Mott–Schottky curves of TiO_2 . (e) Mott–Schottky curves of BaTiO_3 . (f) Detailed band alignment structure of the $\text{TiO}_2/\text{BaTiO}_3$ heterojunction.

activity by promoting the generation of free radicals. Specifically, the $\text{BaTiO}_3/\text{TiO}_2$ heterojunction possesses a bandgap structure that enables efficient photoinduced charge separation.⁵⁴ The VB value of TiO_2 is positioned higher than that of BaTiO_3 , allowing the extraction of electrons from the CB of BaTiO_3 .⁵⁵ This leads to the accumulation of holes on the CB of BaTiO_3 . Consequently, the recombination rate of photogenerated electron–hole pairs is effectively suppressed. Furthermore, an interface junction is formed at the interface between BaTiO_3 and TiO_2 , facilitating the transfer of holes from the CB of BaTiO_3 to TiO_2 . This process contributes to the enhanced generation of free radicals.⁵⁶ Additionally, the hollow internal structure of BTHSs enhances light absorption, and the thin shell reduces the electron migration distance, which promotes efficient carrier separation and transfer.⁵⁷ Therefore, by utilizing the unique energy band structure and hollow structure of BTHSs, the photocatalytic activity can be significantly improved, and the generation of free radicals can be effectively increased.

Based on the preminent performance of BTHSs and THSs in UV-induced ROS generation, we investigated whether this procedure can be activated by microwave irradiation to produce ROS with significant cytotoxicity, such as $^1\text{O}_2$ and $\cdot\text{OH}$. Therefore, the capability of BTHSs and THSs to catalyze ROS production under microwave irradiation was detected using DPBF and MB degradation efficiency. DPBF is widely believed to be mainly degraded by $^1\text{O}_2$, while MB mainly undergoes degradation reactions with $\cdot\text{OH}$.^{58–60} The results indicate that microwave irradiation alone was unable to cause significant degradation of DPBF or MB. Under microwave irradiation, THSs and BTHSs catalyzed the remarkable degradation of DPBF and MB, while the catalytic degradation effect of P25 was weaker (Fig. 8a and b). This phenomenon could be attributed to the benefits of the hollow cavity, which increased the

Fig. 8 The degradation performances of (a) DPBF and (b) MB under MWDT.

utilization rate of UV by enhancing the UV harvest through its high specific surface area and multiple reflections within the interior cavity. In addition, BTHSs exhibited better catalytic performance with regard to microwave-induced ROS production than THSs. This disparity could be illustrated by the presence of the $\text{BaTiO}_3\text{--TiO}_2$ heterojunction, which facilitates the separation and transfer of generated charge carriers. Overall, the existence of hollow structures and heterojunctions markedly improves the catalytic capacity of TiO_2 nanoparticles, making BTHSs an excellent candidate nanomaterial for MWDT.

Then, we further investigated whether these two nanoparticles could produce ROS in cancer cells and exert MWDT effects. First, we demonstrated that BTHSs or THSs alone had no notable cytotoxicity in HepG2 cells (Fig. 9a). After combined intervention with microwave irradiation and BTHS/THS incubation, enormous ROS production was detected in HepG2 cells, and ROS levels were higher in the BTHS + MW group than in the THS + MW group. However, no obvious ROS generation was detected in the other groups (Fig. 9b). Subsequently, calcein AM/PI staining was employed to observe the survival or death of

Fig. 9 (a) Cytotoxicity assays of THSs and BTHSs in cancer cells. (b) Intracellular ROS detection after THS- or BTHS-mediated MWDT. (c) The therapeutic effect of THS or BTHS-mediated MWDT in cancer cells detected by calcein AM/PI staining and (d) MTT assays. MW: microwave irradiation. ** $P < 0.01$.

HepG2 cells. The results showed that the mortality rate of HepG2 cells was positively correlated with the ROS level, and the largest amount of cell death was observed in the BTHS + MW group (Fig. 9c). Next, MTT assays quantitatively validated this result (Fig. 9d). It should be noted that although BaTiO₃ nanomaterials exhibit excellent biocompatibility and non-toxicity in biological therapeutic applications,^{61–63} the degradation and discharge of nanomaterials remain important challenges for the application of inorganic nanomaterials in tumors. Typically, surface modification with targeting moieties is employed to enhance the accumulation of nanomaterials at tumor sites and facilitate their excretion through urine or feces, thereby reducing the adverse effects on normal tissues.^{64,65} In future studies, we will further improve the design of nanomaterials to make them more suitable for clinical applications.

4. Conclusions

In summary, hollow-structured BaTiO₃-TiO₂ heterojunctions are successfully synthesized for MWDT. Under UV irradiation, BTHSs can effectively generate multiple ROS, mainly composed of ¹O₂, which can be triggered by microwaves to implement effective MWDT for cancer. The enhanced catalytic ROS production performance of BTHSs can be attributed to their unique hollow structure and BaTiO₃-TiO₂ heterojunction, which increased the utilization rate of UV as well as facilitated the separation and transfer of generated charge carriers, making BTHSs an excellent nanomaterial for mediating MWDT.

Although the mechanism of MWDT still needs further investigation, this study provides important insights into the design and optimization of catalytic materials for MWDT studies.
