Recombination resistance identification through current–voltage curve reconstruction in perovskite solar cells†

Pablo F. Betancur, [ID] [a] Omar E. Solis, [ID] [a] Rafael Abargues, [ID] [a] Teresa S. Ripolles [ID] [a] and Pablo P. Boix [ID] *[b]

Perovskite solar cells (PSCs) have demonstrated remarkable advancements in efficiency and stability, yet fully understanding the dynamic processes governing their performance remains a challenge. Impedance spectroscopy (IS) offers a powerful means to characterize PSCs over a wide range of time scales, revealing insights into the internal electronic and ionic processes. However, critical factors like recombination, charge extraction, and transport resistance are often coupled in the same spectra response, affecting their accurate identification. This study explores the use of the j–V curve reconstruction as a tool to identify when recombination governs the impedance response. Our findings show that recombination resistance can be accurately identified, regardless of the underlying recombination mechanism, in the solar cells with unhindered charge extraction. Conversely, in devices with hindered charge extraction, the IS fitting struggles to decouple the transport, extraction and recombination processes, resulting in inaccurate j–V reconstructions. These findings emphasize the importance of accurately identifying the physical processes influencing IS spectra to improve diagnostics and device performance in PSC technologies.

Introduction

Perovskite solar cells (PSCs) have experienced a remarkable rise in efficiency, followed by an improvement in stability over the last decade. As this technology moves closer to commercialization, gaining a deeper understanding of the dynamic processes occurring under operating conditions that influence cell performance and lifetime becomes essential. Current density–voltage (j–V) measurement is one of the basic and more established characterization protocols for photovoltaic devices, enabling the determination of their performance in terms of power conversion efficiencies (PCEs) through parameters such as short-circuit current (j_{sc}), open-circuit voltage (V_{oc}), and fill factor (FF), whose maximum achievable values are well established in the literature.[1–3] However, the j–V curve alone is insufficient to fully capture the complexity of the device behavior, offering only a static representation of its performance under specific conditions. This limitation is especially relevant for PSCs, as the j–V curve does not provide sufficient information about the

electronic and ionic processes which ultimately govern the device operation, thus masking the limiting factors that directly impact their performance.

Impedance spectroscopy (IS) provides a non-destructive approach to address these limitations. It is a powerful technique that enables the electrical characterization of devices at any steady state (fixing the illumination and DC voltage conditions) of the j–V curve across a wide range of time scales, shedding light on the internal processes of the PSCs.[4,5] In a typical impedance measurement, a small frequency-modulated (AC) signal is applied around a fixed (DC) voltage bias. The subsequent AC current response is then measured, allowing the extraction of frequency-dependent data in the complex plane. This provides an insight into the internal mechanisms of the device across different temporal ranges. Due to this capability, IS could be used to decouple different processes that occur with designable kinetics, such as rapid electronic movement or slower ion migration and electrochemical reactions within the bulk material or at interfaces.[6] IS has been widely used in other systems like batteries, organic and dye-sensitized solar cells.[7–11] However, the IS data interpretation for the case of PSCs remains as topic of discussion in the scientific community. The clear identification of different features in the Nyquist plot with specific device processes can be ambiguous, hindering the use of the technique as a pragmatical analysis tool. The vast majority of IS spectra from PSC consist of distinct high frequency (HF) and low frequency (LF) features well

separated in the form of two arches,[6] bringing a common baseline to examine the data.

The implementation of equivalent circuit models (ECMs) is one of the most common approaches to analyze IS data. ECMs simplify complex systems into manageable models composed of basic electrical components. Although it is not strictly necessary to work with an ECM for the physical analysis, successfully fitting the data to an appropriate ECM ensures that it complies with the linear response criterion and contributes to confirm its validity as an IS spectra. From a qualitative point of view, different ECMs can reproduce the same spectra, highlighting the importance of working with accurate simplified models whose parameters correspond to the physical processes that determine the experimental IS response. Avoiding overparameterization is crucial, as it can lead to unreliable data interpretations. Detailed reviews of different ECMs implemented for PSCs[6,12,13] analyze the common elements between them, and the various approaches when more complex features appear in the response. Among these, an ECM based on a parallel coupling of the ionic and electronic phenomena,[14] derived from a phenomenological approach, can model the particularities of PSCs. This ECM consists of a series resistance (R_s) associated with the electrodes and wiring resistance, the geometrical capacitance (C_g) showcased at the high frequency regime related to the dielectric properties of the perovskite, a resistor (R_{rec+tr}) that couples both the recombination and transport/injection resistances, in parallel with a low frequency branch formed by a pair of resistance (R_{ion}) and capacitance (C_{ion}) related to the ionic nature of the perovskite and charge accumulation at the interfaces. This model has been widely employed to analyze different PSC systems,[15–19] as it simplifies the interpretation of the impedance spectral features and provides a unified framework for comparing the data reported in the literature.

Nevertheless, even with an adequate ECM, obtaining relevant parameters that reproduce the IS response of PSCs can be challenging. The dominance of the low geometric capacitance and high ion-related capacitance result in the coupling of charge transport, extraction, and recombination phenomena and their associated resistances.[11] These competing processes that ultimately govern the overall performance of PSCs are coupled in the spectral response, and subsequently in the parameter R_{rec+tr} of the previously discussed model. In highly efficient PSCs, this coupling does not represent a problem because the charge transport and extraction processes can be negligible for the cell behavior. However, as these processes get hampered, their coupling with the recombination resistance becomes an issue. Thus, it is crucial to find strategies to corroborate the physical meaning behind the resistances in the ECM and their relationship with the j–V characteristic of the devices. There are several techniques such as external quantum efficiency,[20] bias-dependent photoluminescence imaging,[21] and transient photovoltage techniques[22–24] which indirectly allow the reconstruction or prediction of the j–V curve in photovoltaic devices. This is especially helpful in tandem solar cells systems, where the j–V characteristic of the individual subcells is typically not directly measurable. Beyond the academic interest of reconstructing the j–V curve from various experimental

data, this method serves as a useful tool for interpreting complex measurements with challenging data interpretation.

Here, we present a simple method to determine if the recombination resistance (R_{rec}) is the dominant component of the R_{rec+tr} parameter extracted from the ECM analysis of the IS response. We evaluate four different PSCs cases (optimal, highly recombinative buried interface, low interfacial recombination with hindered extraction, and high interfacial recombination with hindered extraction) to assess when the calculated R_{rec+tr} allows to reconstruct the j–V curve, and therefore depicts the real R_{rec}. In the cases of unhampered charge extraction, the resistive parameter of the IS can be used to fully reproduce the j–V characteristics under different illuminations. This confirms the recombinative nature of the R_{rec+tr} parameter in these cases.

Results and discussion

To analyze the behavior of the IS response and identify the parameter that represents the PSCs recombination in an optimized system, we choose a perovskite composition based on a combination of cations that has shown results improving the performance and stability of the devices. Specifically, the triple-cation perovskite CsMAFA (as Cs^+: cesium cation, MA^+: methyl-ammonium cation, and FA^+: formamidinium cation) takes advantage of combining MA^+ and FA^+ cations, which reduces the defect density and improves the overall cell performance,[25] and the addition of small amount of Cs^+ enhances thermal and moisture stability, addressing one of the significant limitations of purely organic-based perovskite.[26] This perovskite composition, $Cs_{0.05}(FA_{0.85}MA_{0.15})_{0.95}Pb(I_{0.85}Br_{0.15})_3$, will be used as a reference for all the devices discussed in this study. We focus on various combinations of hole transport materials (HTMs) such as PEDOT:PSS (poly(3,4-ethylenedioxythiophene) polystyrene sulfonate) and MeO-2PACz ([2-(3,6-dimethoxy-9H-carbazol-9-yl)ethyl]phosphonic acid), and electron transport materials (ETMs), such as C_{60} and ICBA (Indene-C_{60} Bisadduct). These combinations aim to achieve devices with distinguishable recombination and charge extraction effects, ultimately affecting the overall cell performance. All the photovoltaic parameters for the devices under study are represented in Table 1. We selected cells with an average performance for each condition, the devices statistics and schematics are shown in Fig. S1 (ESI†). Based on the employed selective contacts, the devices were separated into the following cases:

(i) MeO-2PACz/CsMAFA/C_{60}: optimized device with 17% PCEs and V_{oc} of 1.1 V. The implementation of self-assembled monolayers such as MeO-2PACz have been reported to promote

Table 1 Photovoltaic parameters for the devices under study with different selective contacts (HTM/ETM) at 1 sun illumination conditions

Device	V_{oc} (V)	J_{sc} (mA cm^{-2})	FF (%)	PCE (%)
MeO-2PACz/C_{60}	1.09	20.66	76.86	17.42
PEDOT:PSS/C_{60}	0.80	20.63	83.57	13.87
MeO-2PACz/ICBA	1.06	11.40	21.00	2.65
PEDOT:PSS/ICBA	0.83	1.91	19.78	0.32

a fast hole extraction, reducing non-radiative recombination at the hole-selective interface.[27] This configuration is used to evaluate parameters for highly efficient devices. The conduction band energy of C_{60} (~ -4.2 eV[28,29]) is a well fit to the CsMAFA, which value has been reported around -4.0 eV.[30]

(ii) PEDOT:PSS/CsMAFA/C_{60}: this configuration was chosen to promote a scenario with high recombination. The highly doped nature of the PEDOT:PSS leads to a strong interfacial recombination between the HTM and the absorber, as reported in the literature.[31,32] In the devices studied, this is reflected by a reduction of the PCE to 13% and V_{oc} to 0.8 V.

(iii) MeO-2PACz/CsMAFA/ICBA, and (iv) PEDOT:PSS/CsMAFA/ICBA: the implementation of ICBA as ETM aims to induce a hindered charge extraction in a system with low (case iii) and high (case iv) surface recombination. The conduction band of the ICBA (-3.7 eV[33,34]) presents higher energy compared to the CsMAFA (~ -4.0 eV). This mismatch in the band energy alignment explains the lack of rectification in the j–V curve (Fig. 1(a)) and the overall charge extraction problem of this devices with PCEs under 3%.

The j–V curves measured before and after the IS are shown in Fig. S2 (ESI†). In the first two cases (i) and (ii), the devices do not exhibit significant degradation after measurement, except for an increase in hysteresis with the use of PEDOT:PSS. With the addition of ICBA as ETM (iii) and (iv), differences are observed between the pre-IS and post-IS j–V curves. However, for all cases, the current values during IS remain stable and closely match the reverse j–V curve measured post-IS. This confirms that the devices are analyzed near steady-state condition, minimizing the impact of degradation or system instability. Fig. 1(b) and (c) show the Nyquist plots resulting from the IS measurements at V_{oc} and J_{sc} conditions, which consistently display a qualitatively similar pattern. They reproduce the characteristic shape of the PSCs IS spectra, which consists of one arch at the HF regime and one at the LF regime, and both are well distinguished in all cases regardless of the performance of the device. This showcases that even when charge extraction is hampered, the absorber remains the main contributor to the Nyquist shape in our cases. Thus, the correct identification of the specific physical phenomenon behind these features becomes critical. The IS measurements for the ICBA-based devices result in spectra with relatively large values of Z' at low frequencies. Note that, while this is classically interpreted as an improved recombination resistance, the V_{oc} values of the PEDOT:PSS/ICBA devices do not support this claim. Additionally, these large Z' spectra for the ICBA samples display relatively lower bias dependance, as can be seen in Fig. S3 (ESI†). This unusual behavior is in accordance with the inefficient charge extraction of these devices. The corresponding Bode plots for all cases are depicted in Fig. S4 (ESI†).

The ECM described in the introduction section can be employed as a tool to fit the data and analyze the impedance patterns. The extracted values of each parameter are plotted in Fig. 2, with a schematic representation of the ECM shown in the inset of Fig. 2(a). Among these parameters is the geometrical capacitance (C_g) which dominates the HF regime. C_g primarily

depends on the nature and thickness of the absorber material and represents a typical and expected behavior for PSC. Accordingly, it presents a constant value around 10^{-8} F cm^{-2} through the different voltages for all samples, as expected for the unaltered thicknesses of all the device stacks. Using C_g and the measured perovskite thickness (500 nm) to estimate the dielectric permittivity of the material, we obtain an average value of 30, which aligns with other values reported for mixed perovskites.[35–38]

A prominent influence of the ionic nature is typically observed in the LF regime response of PSCs, reflected in the C_{ion} and R_{ion} parameters of the employed ECM. The behavior of these parameters strongly depends on the primary recombination mechanism,[13] as suggested by drift-diffusion simulation models. However, it cannot not directly quantify the recombination process. The presence of negative hooks or negative capacitances in the Nyquist plots are a well-documented phenomena in PSC.[39–42] Inductive loops, whether positive or negative, may arise due to the kinetic delay in ionic charge buildup at the interface, which can be explained by a surface polarization model.[43]

In systems dominated by bulk recombination, low ion vacancy density combined with low electronic diffusion coefficient can produce negative R_{ion} values, which also translate into negative hooks on the Nyquist plot.

In our study, this model aligns well with the experimental observations captured on the spectra, particularly close to open circuit conditions. For instance, PEDOT:PSS-based devices are strongly affected by surface recombination and do not exhibit negative hooks, unlike MeO-2PACz-based devices (Fig. S3, ESI†). These hooks can be a signal of higher influence of bulk recombination processes for the latter, related to an improved HTM/perovskite interface, regardless of the analyzed electron transport material. In this line, self-assembled monolayers such as MeO-2PACz have been reported to promote a fast hole extraction, reducing non-radiative recombination at the interface,[27] which supports the dominance of bulk recombination in these cases. Additionally, following the drift diffusion studies, the parameters determined by ionic effects should not change significantly for the cases ruled by surface recombination. However, the PEDOT:PSS/ICBA device shows a reduction in C_{ion} and an increase in R_{ion}. Similarly, in the case of MeO-2PAC device, with better charge extraction and less surface recombination than PEDOT:PSS, the use of ICBA contact increases the ionic density, as indicated by the reduction of R_{ion}. This is the first indication that in our case, with the incorporation of ICBA (cases iii and iv), recombination is not the dominant phenomenon determining the performance of the solar cell.

As mentioned before, the ECM used in this work couples both recombination and transport/injection resistances in a unique parameter named R_{rec+tr}. In a conventional cell with suitable charge extraction, such as those with C$_{60}$ (cases i and ii), this parameter is dominated by the recombination. Thus, the typical evolution of the R_{rec+tr} parameter dominated by recombination as a function of the voltage achieves a minimum value close to V_{oc}, with an exponential increase towards lower voltages, followed by a voltage-independent region as we approach short circuit conditions (Fig. 2(b)). This approach enables a quantitative comparison of recombination

based on R_{rec+tr}, with PEDOT:PSS/C$_{60}$ devices showing lower recombination resistance, consistent with their lower V_{oc} and higher surface recombination compared to MeO-2PACz/C$_{60}$.[31]

To understand the behavior of this parameter when charge extraction is hindered by a mismatch on the energy level alignment between the absorber and ETM, we characterize the PEDOT:PSS/ICBA device, a case with extremely hindered electron extraction and high surface recombination resistance at the hole contact. For these devices, R_{rec+tr} parameter remains almost constant independently of the voltage applied. It is worth to remark that both PEDOT:PSS/ICBA and PEDOT:PSS/C$_{60}$ devices display similar V_{oc}, yet the R_{rec+tr} parameter for PEDOT:PSS/ICBA devices is larger than for MeO-2PACz/ICBA ones, in contrast to what it is expected from their V_{oc} values. Therefore, it can be inferred that when charge extraction and transport are suboptimal, the resistance associated with these processes masks the system recombination resistance, as predicted by the ECM.

To address this limitation of IS caused by the mixed nature of R_{rec+tr}, it is essential to understand the coupling between extraction, recombination, and transport resistances. Specifically, it is necessary to determine when recombination is the factor dominating the device performance. In PSCs, the current density at the outer contacts of the solar cell, $j(V)$, can be described as the sum of two components: the current density from photogenerated charge carriers, j_{ph}, which corresponds to the short-circuit current, j_{sc}, if negligible recombination at zero bias is considered, and the current density from internal recombination within the perovskite layer and at the interfaces, $j_{rec}(V)$. Assuming that photogeneration is a voltage-independent process, as expected from the low exciton binding energy of I-based halide perovskites:

$$j(V) = j_{ph} - j_{rec}(V) \qquad (1)$$

Under open-circuit conditions, j_{ph} is completely offset by recombination current $j_{rec}(V_{oc})$, this means that the solar device operates under a kinetic balance of generation and recombination currents. Considering that the recombination resistance (R_{rec}) could be expressed as the inverse of j_{rec}, it is possible to express j_{ph} as:

$$j_{ph} = j_{rec}(V_{oc}) = \frac{k_B T}{\beta q R_{rec}(V_{oc})} \qquad (2)$$

Where $k_B T$ represents the thermal energy, q the elementary charge and β a parameter related with the recombination of the system. β can be used to calculate the "electronic ideality factor", $m = 1/\beta$, and depends on the dominant recombination mechanism of the device. The calculation of ideality factors from resistance in quasi-open-circuit conditions is a well-established method in PSCs and has been widely reported in the literature.[44–47] The electronic ideality factor (m) can be obtained from the slope of the recombination resistance, R_{rec}, as function of the bias at the high voltage range (Fig. S6a, ESI†) using eqn (3):

$$R_{rec} = R_0 \, \exp\left(-\frac{q V_F}{m k_B T}\right) \qquad (3)$$

This journal is © the Owner Societies 2024

Phys. Chem. Chem. Phys., 2024, **26**, 29904–29912 | **29907**

We observe that the electronic ideality factor shows strong sensitivity to the light intensity with the implementation of MeO-2PAC (Fig. S6b, ESI†). In this case, reducing surface recombination enhances the contribution of bimolecular recombination, which has been reported to be more sensitive to increases in light intensity due decreased defect-associated charge trapping.[48–50] Additionally, drift-diffusion modeling has shown that devices dominated by surface recombination show lower apparent ideality factor values due to a reduction in ionic vacancies within the perovskite active layer,[51] consistent with our experimental data. While typical values for m range between 1 and 2 depending on the nature of the recombination process, values outside this range have been reported in PSCs.[44,45,47,52–54] To our knowledge, these outliers lack a well-defined physical interpretation.

The shape of the j–V curve is influenced by the variation of the recombination flux with applied voltage, which is modeled through m and the series resistance voltage loss.[24] Consequently, the current at any specific voltage (V_F), in the j–V curve can be expressed as:

$$j(V_F) = \frac{mk_BT}{qR_{rec}(V_F)} - j_{sc} \qquad (4)$$

Eqn (4) presents a method to recalculate the final current at each voltage of the j–V curve using the parameters obtained by the ECM of the impedance data. Specifically, from R_{rec+tr} when this parameter is dominated by the recombination (and thus, it is possible to write $R_{rec+tr} = R_{rec}$), and the ideality factor. In those cases, for cells with optimal charge extraction, the ideality factor could be obtained from two approaches: directly from the impedance fitting using R_{rec+tr} $vs.$ V (Fig. S6a, ESI†) or corelating the j_{sc} with $R_{rec+tr}(V_{oc})$ (eqn (2)). The parameters used for the current recalculation are presented in the Table S1 (ESI†). Fig. 3 shows a remarkable correlation between experimental j–V curves and the j–V reconstruction, regardless of the method used to calculate m. The reconstructed j–V is compared to the average current measured at each DC vias during the IS. This so called "experimental curve" exhibits values comparable to the reverse j–V scan post-IS (Fig. S2, ESI†), indicating that the analysis is conducted under near steady-state conditions for each device, where factors like hysteresis or degradation are not interfering with the curve interpretation.

The successful reconstruction of the j–V curve for cases i and ii indicates a reliable estimation of the device recombination resistance from the R_{rec+tr} parameter. Furthermore, it corroborates that the photogenerated current is independent of the voltage applied and the shape of the j–V curve depends solely on the recombination processes. The calculated $R_{rec+tr} = R_{rec}$ encompasses accurately the different recombination mechanisms, including bulk recombination in devices with less recombinative HTMs, such as MeO-2PACz (case i, Fig. 3(a)), and high surface recombination in devices with PEDOT:PSS (case II, Fig. 3(b)).

For the cases with hindered charge extraction (iii and iv) the R_{rec+tr} $vs.$ V_{app} plot (Fig. 2(b)) presents an atypical response, maintaining independent to the change in voltage. Thus, as previously discussed, in these devices it is not possible to extract m from the plot slope, leading to try to calculate the ideality factor using only eqn (2). Interestingly, no $R_{rec+tr}(V_F)$

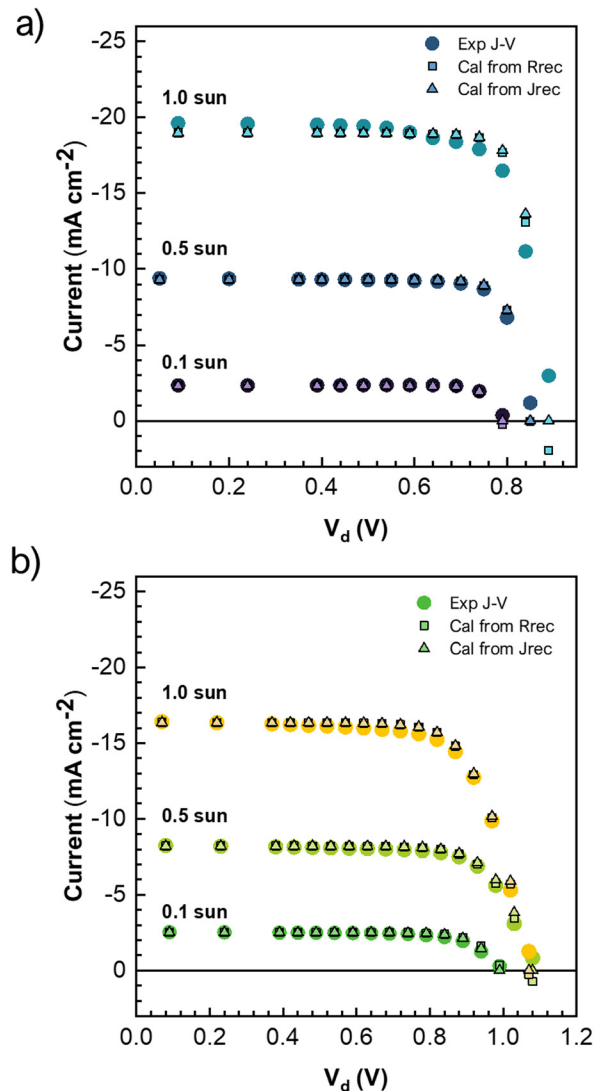

Fig. 3 Experimental j–V curve (dots) and its reconstruction (eqn (4)) by using m-values obtained either the slope of R_{rec} $vs.$ V_{app} (squares) or from J_{rec} (eqn (2), triangles) at different illumination intensities for (a) PEDOT:PSS/C$_{60}$ and (b) MeO-2PACz/C$_{60}$ devices. The voltage applied is optimized by the series resistance contribution as $V_d = V_{app} - jR_s$.

(where V_F represents bias values close to open circuit conditions) leads to a m value that can successfully reconstruct the experimental j–V curve (Fig. S7, ESI†). This strongly indicates that charge extraction and transport resistance are dominating the device performance, masking the recombination resistance into the R_{rec+tr} parameter. Thus, using the j–V reconstruction is possible to determine when recombination resistance or transport/extraction resistance is dominating in R_{rec+tr}.

To generalize this method, we implemented one of the most basic equivalent circuit models (ECMs) used in IS analysis (Fig. S8, ESI†). In this circuit, the high frequency (HF) and low frequency (LF) response are modeled by pairs of resistive and capacitive elements in series. Consequently, the recombination and transport processes are also interpreted in series, which hinders the accurate reconstruction of the j–V curve (Fig. S9, ESI†).

Conclusions

In this work we demonstrate that charge transport, extraction and recombination resistances are coupled in the IS spectra response, as predicted by the implemented ECM. In devices with optimized charge extraction, including all those with high efficiency, the accurate j–V curve reconstruction indicates that recombination resistance is the dominant phenomenon within the R_{rec+tr} parameter. As the photogenerated current does not present voltage dependence, the recombination governs the j–V behavior in these cases. The successful j–V reconstruction is achieved in devices using both PEDOT:PSS and MeO-2PACz as HTMs, suggesting that the ECM R_{rec+tr} accurately reflects the overall recombination resistance regardless of the dominant recombination mechanism. In contrast, for devices with hindered charge extraction (ICBA-based devices), we demonstrate that the j–V curve reconstruction does not match the experimental data. In such cases, the contribution of charge extraction and transport resistance becomes noticeable and masks the true recombination resistance. These findings highlight the importance of individually identifying and separating the physical processes that influence the IS spectra, offering a pathway for more precise interpretation of IS data and improved diagnostics in perovskite solar cell technologies.

Materials and methods

Materials

N,N-Dimethylformamide (DMF, $\geq$99.8%, anhydrous), dimethyl sulfoxide (DMSO, 99.9%, anhydrous), chlorobenzene (CB, 99.8%, anhydrous) and cesium iodide (CsI, 99.9%) were purchased from Sigma Aldrich. Formamidinium iodide (FAI, $HC(NH_2)_2I$, 99.99%) and methylammonium bromide (MABr, CH_3NH_3Br, 99.99%) were purchased from Greatcell Solar Materials. Lead iodide (PbI_2, 99.99%), lead bromide ($PbBr_2$, 99.99%) and [2-(3,6-dimethoxy-9H-carbazol-9-yl)ethyl]phosphonic acid (MeO-2PACz, 98%) were purchased from TCI Chemicals. Fullerene (C_{60}), di[1,4]methanonaphthaleno[1,2:2′,3′;56,60:2″,3″][5,6]fullerene-C_{60}-Ih, 1′,1″,4′,4″-tetrahydro-(ICBA) and bathocuproine (BCP) were purchased from 1-Materials. PEDOT:PSS AI 4083 aqueous dispersion was purchased from Heraeus. All the purchased chemicals were used as received without further purification.

$Cs_{0.05}(FA_{0.85}MA_{0.15})_{0.95}Pb(I_{0.85}Br_{0.15})_3$ perovskite precursor solution

The 1.24 M perovskite precursor solution with 10% mol of PbX_2 as an excess was prepared by dissolving 1.15 mmol of PbI_2 (532.3 mg), 1.05 mmol of FAI (180.5 mg), 0.19 mmol of MABr (20.7 mg), 0.21 mmol of $PbBr_2$ (74.8 mg) and 0.06 mmol of CsI (16.8 mg) in 1 mL of a mixed solvents of DMF : DMSO (4 : 1 in volume), the solution was stirring overnight at room temperature.

Device fabrication

Patterned ITO substrates (2.0 × 1.5 cm², 6–8 ohm sq⁻¹, BIOTAIN CRYSTAL CO., LIMITED) were washed in an ultrasonic bath for 15 min per process. First, the substrates were washed in water with soap and rinsed with distilled water.

Then, the substrates were washed with ethanol, acetone, and isopropanol, sequentially. After drying under nitrogen flow, the substrates were treated for 30 min with UV-O₃. The HTM PEDOT:PSS was filtered with 0.45 μm PVDF filter and spin coated on top of the ITO substrate at 5000 rpm for 30 s and annealed at 130 °C for 20 min in ambient conditions, after PEDOT:PSS deposition, the substrates were transferred into a N₂-filled glovebox for the perovskite deposition. MeO-2PACz was deposited from the precursor solution (1 mg mL⁻¹ in absolute ethanol) at 3000 rpm for 30 s and annealed at 100 °C for 10 min, this procedure was carried out into a N₂-filled glovebox.

The perovskite solutions were filtered with 0.22 μm PTFE filter. The films were deposited using 30 μL of the precursor solution and spin coated with two steps, firstly, 1000 rpm for 12 s and, secondly, 5000 rpm for 27 s. After 22 s of having started the second step, 200 μL of CB was deposited like antisolvent and the annealing treatment was carried out at 100 °C for 30 min. The ETM C_{60} was thermal evaporated 30 nm under a pressure less than 10^{-6} mbar. ICBA solution (20 mg mL⁻¹ dissolved in CB) was deposited by spin coating on top of the perovskite film at 1200 rpm for 30 s and annealing at 100 °C for 10 min. Finally, the samples were transferred into a vacuum chamber, BCP (6 nm) and Ag (100 nm) were sequentially deposited by thermal evaporation under a pressure less than 10^{-6} mbar.

Device characterization

j–V curves measurements of the fresh devices were taken with a Ossila solar simulator class AAA and automated j–V measurement system (T2003B3-G2009A1). Impedance spectroscopy was carried out using a Gamry 1010E potentiostat/galvanostat on complete solar cells at room conditions and different light intensities, such as 100, 50 and 10 mW cm⁻². The measurements were performed at different offset voltages spaced 50 mV from open circuit to 0 V, with a 10 mV AC perturbation ranging between 1 MHz to 0.01 Hz. Z-view software was employed to analyze the results and fit the data to the equivalent circuit. The solar cells were characterized in ambient conditions ($T \sim 30$ °C and RH $\geq$ 60%) without any encapsulation, with an active area of 0.084 cm² defined by a mask.
