

Showcasing research from Professor Langelihle Dlamini's laboratory, Department of Chemical Sciences, University of Johannesburg, Johannesburg, South Africa.

Interfacial engineering of a multijunctional  $\text{In}_2\text{O}_3/\text{WO}_3@ \text{Ti}_4\text{N}_3\text{T}_x$  S-scheme photocatalyst with enhanced photoelectrochemical properties

The work entails the fabrication of a ternary composite of two semiconductor materials fused with Titanium Nitride MXene resulting in a multijunctional S-Scheme material, with possible applications in environmental remediation. Therefore, the artwork considered the lattice structure of the materials and their possible charge transfer mechanisms showcasing improved photoelectrochemical properties.

# Interfacial engineering of a multijunctional $\text{In}_2\text{O}_3/\text{WO}_3@\text{Ti}_4\text{N}_3\text{T}_x$ S-scheme photocatalyst with enhanced photoelectrochemical properties†

Antony Okinyi Onjwaya,<sup>a</sup> Majahekupheleni Livileye Malati,<sup>a</sup> Jane Catherine Ngila<sup>a</sup> and Langelihle Nsikayezwe Dlamini <sup>\*a,b</sup>

Achieving high photoelectrochemical conversion efficiency requires the logical layout of a composite photocatalyst with optimal charge separation and transfer with ideal light harvesting capabilities to enhance the photocatalytic performance and the degradation rate towards organic pollutants. Herein, a novel  $\text{In}_2\text{O}_3/\text{WO}_3@\text{Ti}_4\text{N}_3\text{T}_x$  S-scheme heterojunction was successfully synthesized and confirmed through valence band VB-XPS and Mott Schottky combined analysis. The formed MXene-doped  $\text{In}_2\text{O}_3/\text{WO}_3@\text{Ti}_4\text{N}_3\text{T}_x$  S-scheme significantly enhances the charge flow and spatial separation with an improved oxidation and reduction ability. An in-built interfacial electric field at the  $\text{WO}_3\text{--In}_2\text{O}_3$  boundary enhanced the light-harvesting capacity, whereas  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene offers a unique electron trapping effect which effectively lowers high charge carrier recombination rate-related photocatalytic deficit. It preserves the exceptional redox potency of the photocatalyst by providing a directed acceleration and effective separation of the photogenerated charges. A high carrier density ( $N_D = 7.83 \times 10^{21} \text{ cm}^{-3}$ ) with a lower negative flat band ( $V_{\text{FB}} = -0.064 \text{ V}$  vs.  $\text{Ag}/\text{AgCl}$ ) was obtained by Mott–Schottky analysis for 3 wt%  $\text{In}_2\text{O}_3/\text{WO}_3@\text{Ti}_4\text{N}_3\text{T}_x$ , an indicator that a low overpotential is needed to activate photocatalytic reactions. This study, therefore, provides a novel thought for the design and fabrication of an S-scheme heterojunction for photocatalytic reactions for mineralization of organic pollutants in water and clean energy production.

## Introduction

The Earth is rich in natural clean and sustainable solar energy. However, intrinsic intermittence and solar radiation unpredictability limit its *in situ* usage and storage. Its conversion into alternative forms provides a remarkable greener energy solution. Photocatalysis, therefore, provides a cutting-edge solution. It can transform solar energy into storable and transportable chemical fuels.<sup>1</sup> Photocatalysis occurs in three steps: light absorption by a semiconductor, charge separation and transfer, and surface redox reactions which are dependent on the energy bandgap and redox potentials of a semiconductor.<sup>2</sup>

If a strong surface redox reaction is targeted, a photocatalyst should possess a high conduction band (CB) and a deep valence band (VB) position. However, if maximum solar energy

harvesting is desired, a photocatalyst should have a low CB along with a shallow VB. A photocatalyst must have a more negative reduction potential and a much higher positive oxidation potential value.

About 95% of solar radiation is constituted by visible light (400 to 700 nm) and infrared light (above 700 nm).<sup>3</sup> Thus, a photocatalyst that can harness solar radiation within this spectral range is ideal. The minimum energy required to activate a photocatalyst is inversely proportional to the energy bandgap.<sup>4</sup> As a result, a narrow bandgap is appropriate for harvesting maximum light. Single photocatalysts experience rapid electron–hole recombination. In conjunction with their large bandgap energies, they can only maximize a small fraction of the solar spectrum. Strong interparticle forces cause the commonly used commercial  $\text{TiO}_2$  (DP25) photocatalyst, in particular, to exhibit individual particle agglomeration on a tiny specific surface area.<sup>5</sup> This, therefore, limits its efficiency in maximum light harvesting and possession of strong redox potentials.

Heterojunctions formed from stable composite materials can overcome the challenges faced by single photocatalysts.<sup>6</sup> This facilitates maximum light harvesting, fast electron transfer and strong redox potentials. In particular, an S-scheme het-

† Electronic supplementary information (ESI) available. See DOI: <https://doi.org/10.1039/d4dt00135d>

erojunction exhibits interesting features as a preferred heterostructure.<sup>4,7</sup> It is constructed from two n-type semiconductors, an oxidation photocatalyst (OP) with a higher work function and a lower Fermi energy level and a reduction photocatalyst (RP) having a small work function and a high Fermi energy level. At the interface, an electron ( $e^-$ ) from an RP flow to an OP resulting in an electron depletion layer and an electron accumulation layer at the junction between two interfaced semiconductors, respectively. Concomitantly, an in-built internal electric field (IEF) points from the RP to the OP facilitating electron-hole recombination in the CB of the OP and in the VB of the RP, while preserving higher oxidative  $h^+$  in the VB of the OP and more reductive  $e^-$  in the CB of the RP. Similarly, a longer working life, higher transmission efficiency, and higher photocatalytic performance of internal carriers are obtained.

Visible-light photocatalytically active metal oxides like  $\text{In}_2\text{O}_3$  nanoparticles have much low internal resistance and a large specific surface area with a higher reduction potential which make them ideal photocatalysts. But they suffer from limitations of single photocatalysts mentioned previously like fast recombination of separated charge carriers. Therefore, there is a need for coupling them with other photocatalysts which are ideal support carriers for loading other materials with high oxidation activity. In contrast,  $\text{WO}_3$  possesses high oxidation activity with a smaller bandgap suitable for loading onto other semiconductors to construct composite materials. Therefore, fabricating  $\text{In}_2\text{O}_3$  nanoplates together with  $\text{WO}_3$  nanoparticles can yield a stable S-scheme heterojunction photocatalyst with suitable charge separation and strong redox potentials.<sup>5,8,9</sup>

Studies on the physical properties and photocatalytic activity have been reported for the synthesized pristine  $\text{WO}_3$ ,  $\text{In}_2\text{O}_3$  and their binary nanocomposites. Chico-Vecino *et al.* in 2023 fabricated  $\text{WO}_3/\text{In}_2\text{O}_3$  nanocomposites using different concentrations of  $\text{WO}_3$  and found that the composites had higher photocatalytic activity in continuous conversion of  $\text{CO}_2$  in a flow reactor compared to pristine  $\text{WO}_3$  and  $\text{In}_2\text{O}_3$ .<sup>10</sup>

The enhanced photocatalytic properties of the  $\text{WO}_3/\text{In}_2\text{O}_3$  binary composite can be further achieved by introducing a special electron trapping agent. A co-catalyst provides a directional acceleration of the photogenerated electrons with the effective preservation of the excellent redox potency of the individual semiconductor.<sup>11</sup> MXenes have good electron mobility, rich active sites, high porosity, multiple surface functionalities and high hydrophilicity. They provide excellent co-catalyst effects on heterojunctions.<sup>12</sup> Due to their electrical conductivity, they induce a directional, ideal and internal electric field and collect electrons on the surface of a semiconductor, a determiner in fine-tuning the photoactivity of heterojunction materials.<sup>13</sup>

MXenes form a new class of 2D transition metal materials composed of a transition metal (M) layer stacked with layers of carbon or nitrogen and surface terminations  $\text{T}_x$  ( $-\text{O}$ ,  $-\text{OH}$ ,  $-\text{F}$ , and  $-\text{Cl}$ ). They have a general formula of  $\text{M}_{n+1}\text{X}_n\text{T}_x$  where M denotes a transition element, X is either a carbide or nitride

and  $\text{T}_x$  is the surface termination formed in the etching process. They are synthesized from their precursor MAX phases ( $\text{M}_{n+1}\text{AX}_n$ ) by selectively etching A, a group 13 or 14 element and  $n = 1, 2$  or 3 is structurally dependent. Functional groups ( $-\text{O}$ ,  $-\text{OH}$ ,  $-\text{F}$ ,  $-\text{Cl}$ ) form on the surfaces of MXenes as a result of etching and exfoliation, facilitating bond formation with semiconductor surfaces. They form abundant active metal sites at MXene terminals for higher reactivity. MXenes' porosity and super electrical conductivity make them electron sinkers, increasing their charge carrier densities.<sup>14</sup>

Nitride-based MXenes, however, show superior activity over their carbide counterparts. Their increased electron conductivity is due to the increased electron count in N atoms that supersedes the electron withdrawal effect by surface groups. This preserves the metallic character in functionalized nitride based-MXenes.<sup>15</sup> Therefore, the interfacial addition of metallic  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene on a photoactive  $\text{WO}_3/\text{In}_2\text{O}_3$  significantly improves electron-hole separation. No report shows the doping effect of nitride-based MXenes on the  $\text{WO}_3/\text{In}_2\text{O}_3$  intrinsic structure. Motivated by these findings, in this study, therefore, we focused on synthesizing the  $\text{WO}_3/\text{In}_2\text{O}_3@/\text{Ti}_4\text{N}_3\text{T}_x$  S-scheme heterojunction photocatalyst and evaluated its photocatalytic properties.

## Experimental details

### Materials

Analytical grade chemicals were utilized in this study. Additional purifications were therefore not undertaken. The following reagents were used: sodium tungstate dihydrate ( $\text{Na}_2\text{WO}_4 \cdot 2\text{H}_2\text{O}$ ) powder ( $\geq 99.9\%$ , Sigma-Aldrich), hydrochloric acid (HCl) puriss ( $\geq 36.5\%$ , Sigma-Aldrich), lithium fluoride (LiF) powder ( $< 100 \mu\text{m}$ ,  $\geq 99.98\%$ , Sigma-Aldrich), urea ( $\text{CH}_4\text{N}_2\text{O}$ ) pellets ( $\geq 99.5\%$ , Ace), indium(III) acetate [ $\text{In}(\text{CH}_3\text{O}_2)_3 \cdot 4\text{H}_2\text{O}$ ] powder (anhydrous, 99.99%, Sigma-Aldrich), tetrabutylammonium hydroxide ( $\text{C}_{16}\text{H}_{37}\text{NO}$ ) (TBAOH) aqueous solution (40%, Sisco chemicals), dimethyl sulfoxide ( $\text{C}_2\text{H}_6\text{OS}$ ) anhydrous – DMSO ( $\geq 99.9\%$ , Sigma-Aldrich), titanium (Ti) powder (325 mesh, Alfa Aesar), titanium nitride (TiN) powder ( $< 3 \mu\text{m}$ , Sigma-Aldrich), aluminium nitride (AlN) powder ( $< 10 \mu\text{m}$ , Sigma-Aldrich), isopropanol ( $\text{C}_3\text{H}_8\text{O}$ ) 96% v/v (Sigma-Aldrich), methanol ( $\text{CH}_3\text{OH}$ ) 96% v/v (Sigma-Aldrich), ethanol ( $\text{C}_2\text{H}_6\text{O}$ ) 96% v/v (Sigma-Aldrich), and deionized water (DI).

### Methodology

**Hydrothermal synthesis of  $\text{WO}_3$ .** The schematic procedure for synthesizing pristine materials and their nanocomposites is illustrated in Fig. 1.

Precisely, 7.0 mmol  $\text{Na}_2\text{WO}_4 \cdot 2\text{H}_2\text{O}$  was dissolved in 20 mL of DI  $\text{H}_2\text{O}$ . The pH of the solution was adjusted to 2 by a drop-wise addition of 8 M HCl and continuously stirring for 30 min at room temperature (RT). The dispersed solution was hydrothermally heated at 180 °C in a stainless-steel, Teflon-lined 50 mL autoclave for 4 h and then left to cool to RT. The

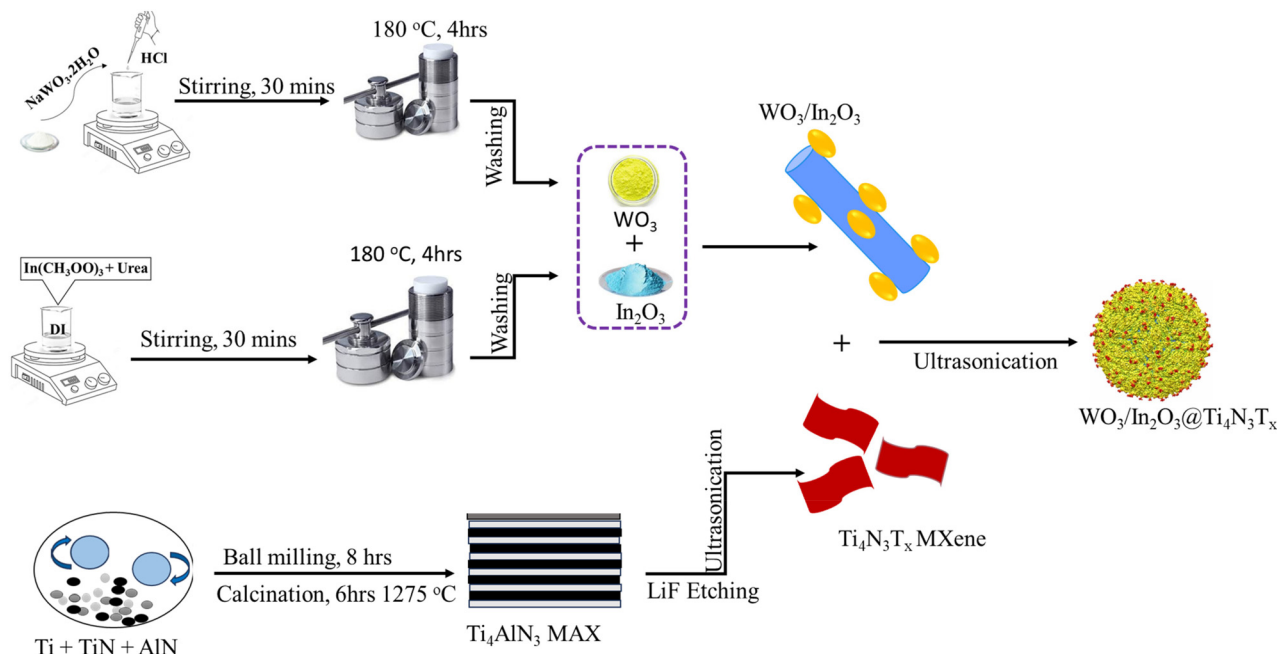

Fig. 1 Schematic of the synthesis of the  $\text{WO}_3/\text{In}_2\text{O}_3@ \text{Ti}_4\text{N}_3\text{T}_x$  composite.

obtained suspension was then washed with DI  $\text{H}_2\text{O}$  and ethanol several times and allowed to dry at RT.

**Hydrothermal synthesis of  $\text{In}_2\text{O}_3$ .** A solution of indium acetate salt was prepared by dissolving 1 g of  $\text{In}(\text{CH}_3\text{OO})_3 \cdot 4\text{H}_2\text{O}$  in 10 mL of DI  $\text{H}_2\text{O}$  and stirred for 30 min. At RT, precisely 2.5 g of urea was added and stirred for 1 h. The mixed solution was then transferred to a 50 mL Teflon-lined autoclave (stainless-steel), heated hydrothermally for 4 h at 180 °C and thereafter cooled to RT. The obtained suspension was washed with DI  $\text{H}_2\text{O}$  by centrifugation and allowed to dry at 60 °C for 6 h. The obtained powder was subjected to calcination at 550 °C for 4 h (Fig. 1).

**Synthesis of the  $\text{WO}_3/\text{In}_2\text{O}_3$  binary nanocomposite.** The  $\text{WO}_3/\text{In}_2\text{O}_3$  (WI) binary nanocomposite synthesis followed a solvothermal procedure reported by Chico-Vecino *et al.*<sup>10</sup> Different quantities of the prepared  $\text{WO}_3$  nanoparticles were dispersed in 20 mL DI  $\text{H}_2\text{O}$  under continuous stirring for 30 min in separate 50 mL clean glass beakers. The desired amount of  $\text{In}_2\text{O}_3$  was then added according to  $\text{WO}_3$  to  $\text{In}_2\text{O}_3$  ratios (5, 15, 30 and 50 wt% of  $\text{WO}_3$ ). The resultant binary composites were labelled (WI: 5, 15, 30 and 50). The suspension was autoclaved (50 mL Teflon-lined), subjected to 180 °C hydrothermal heating for 4 h, and thereafter, left to cool to RT. The resultant dry product was calcined for 4 h at 550 °C, allowed to cool to RT and then labelled WI (5, 15, 30 and 50 wt% of  $\text{WO}_3$ ).

**Synthesis of  $\text{Ti}_4\text{AlN}_3$  and  $\text{Ti}_4\text{N}_3\text{T}_x$ .** A top-down approach was followed in synthesizing  $\text{Ti}_4\text{N}_3\text{T}_x$  from its synthesized  $\text{Ti}_4\text{AlN}_3$  MAX phase precursor. Pure Ti, TiN and AlN powders (2 : 2 : 1) were mixed *via* ball milling for 8 h, cold pressed into pellets and calcined at 1275 °C for 6 h under argon in a tube furnace

and then crushed into fine powder. Precisely, 0.5 g of MAX was etched by soaking in a 10 mL mild etchant mixture of LiF and 9 M HCl for 12 h. The aluminium fluoride compound was removed by centrifugation at 350 rpm through washing with isopropanol until a pH of 6.5 and the resultant multilayered- $\text{Ti}_4\text{N}_3\text{T}_x$  was obtained. This was followed by delamination in 10 mL TBAOH to obtain few-layered  $\text{Ti}_4\text{N}_3\text{T}_x$ . Excess TBAOH was removed *via* washing with isopropanol under centrifugation (Fig. 1).

**Synthesis of the  $\text{In}_2\text{O}_3/\text{WO}_3@ \text{Ti}_4\text{N}_3\text{T}_x$  composite.** The  $\text{In}_2\text{O}_3/\text{WO}_3@ \text{Ti}_4\text{N}_3\text{T}_x$  (TWI) nanosheet was synthesised by suspending 0.3 g of  $\text{In}_2\text{O}_3/\text{WO}_3$  (WI) in 20 mL of methanol and homogenized at RT for 30 min in a separate 50 mL glass beaker.  $\text{Ti}_4\text{N}_3\text{T}_x$  (1, 3, 5, 7 wt%) was dissolved in 10 mL DMSO in a 50 mL beaker at RT under stirring for 30 min. The mixtures of WI and  $\text{Ti}_4\text{N}_3\text{T}_x$  were transferred into a 100 mL beaker, stirred for 30 min and then ultrasonicated at RT for 12 h. DMSO was removed *via* centrifugation using DI  $\text{H}_2\text{O}$  to obtain a pH of 6.5, followed by calcination at 200 °C in an argon environment for 3 h. The resultant  $\text{In}_2\text{O}_3/\text{WO}_3@ \text{Ti}_4\text{N}_3\text{T}_x$  ternary nanocomposites were formed by the introduction of varied weight percentages of 1, 3, 5 and 7 wt% of  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene into the  $\text{In}_2\text{O}_3$  and  $\text{WO}_3$  heterojunction. The resultant  $\text{In}_2\text{O}_3/\text{WO}_3@ \text{Ti}_4\text{N}_3\text{T}_x$  samples were labelled 1-TWI-30, 3-TWI-30, 5-TWI-30, and 7-TWI-30, respectively, according to the  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene loading (Fig. 1).

**Characterization.** The crystalline structures of the synthesized photocatalysts were captured by X-ray powder diffraction (XRD, Rigaku Ltd, Japan) by exposing the samples to Ni-filtered  $\text{CuK}\alpha$  ( $\alpha = 1.54056 \text{ \AA}$ ) radiation at a working voltage of 40 kV and a current of 40 mA. Examination of the functional

groups with respect to the crystal structure of the synthesized photocatalysts was performed by Raman spectroscopy (Micro 200, PerkinElmer) under working conditions of 532 nm wavelength and an 8.0 mW laser power output. Fourier transform infrared spectroscopy (FTIR) operating on a Bruker Alpha model using KBr as a reference was further used in the identification of the functional groups present on the synthesized nanomaterials. Scanning electron microscopy (SEM) (TESCAN Vega TC) coupled with energy dispersive X-ray spectroscopy (EDS) at a voltage of 20 kV were employed in the examination of the morphology of the nanomaterial. Similarly, Thermo X-ray photoelectron spectroscopy (ESCA lab 250 Xi) combined with an AlK $\alpha$  monochromator of 1486.7 eV was used to examine the chemical and electronic states of the obtained nanomaterials. Utilizing a Shimadzu UV-2550, ultraviolet-visible diffuse reflectance spectroscopy (UV-vis DRS) was performed to assess the optical features of the fabricated photocatalysts. Using photoluminescence spectroscopy (PL) on an LS 45 fluorescence spectrometer, the photoinduced charge carrier recombination rate for the synthesized photocatalyst was assessed (PerkinElmer, precisely, South Africa,  $\lambda_{\text{excitation}} = 350$  nm). The BET surface area, pore size distribution and pore volume were analyzed by nitrogen adsorption-desorption analysis, which was conducted by flowing liquid nitrogen at 77 K (−195 °C) at an equilibrium interval of 10 s with a silica aluminium material as a reference. The operation was undertaken using the Micromeritics ASAP 2020 Physisorption analyzer.

**Photoelectrochemical analysis.** Photoelectrochemical property determination was carried out using an Autolab PGSTAT204 (Netherlands) Potentiostat *via* a three-electrode system.<sup>16</sup> This system is made up of 0.1 M potassium ferrocyanide (K<sub>4</sub>Fe(CN)<sub>6</sub>) solution as the electrolyte, Pt wire as the reference electrode, and a silver/silver chloride (Ag/AgCl) electrode as the counter electrode.<sup>17</sup> The prepared photocatalyst sample coated on a fluorine-doped tin oxide (FTO) glass electrode acted as a working electrode. Polyvinylidene difluoride (PVDF) and the sample were mixed in a 10:1 wt% ratio to form a homogeneous slurry that served as the working electrode. *N*-Methyl pyrrolidone (NMP) was used to dissolve this mixed slurry and form a sticky paste which was then coated onto a FTO glass surface and allowed to dry in air overnight.<sup>18</sup> Visible light was flashed onto the working electrode during the study in a completely dark environment. The data collection was performed using the Gamry instrument (mode reference 1000E) operated at a frequency ranging from 10 kHz to 0.1 Hz with an AC and DC voltage of 10 mV rsm and 0.45 V vs.  $E_{\text{ref}}$ , respectively. 0.8 V was applied at a step size of 2 mV to generate a Mott-Schottky plot at a frequency of 1000 Hz. Using the impedance potentiostat and frequency response analyzer (FRA) software, the charge carrier resistance was evaluated by electrochemical impedance spectroscopy (EIS). This was conducted using an applied voltage of 0.25 V and a current set between 100 mA and 100 nA. With the voltage set at 1.2 V, the photocurrent response was measured using chrono amperometry ( $\Delta t > 1$  mV) to determine the lifespan of the photogenerated charge carriers.

## Results and discussion

### Crystal structure

The obtained WO<sub>3</sub> showed major diffraction peaks located at 23.1°, 23.5°, 23.6°, and 35.1°, which could be identified as the (002), (020), (202), and (222) planes, respectively, as shown in Fig. 2a. The crystalline structure of WO<sub>3</sub> was assigned to the monoclinic form of crystalline WO<sub>3</sub>, in accordance with the ICDD card no: 04-002-3163, the space group *P21/c*. The primary growth direction of the WO<sub>3</sub> crystal lattice was through the (202) facet, indicated by the intense diffraction peak at  $2\theta = 23.5^\circ$ . Sharp and intense diffraction peaks showed an outstanding degree of crystallinity for the obtained WO<sub>3</sub> nanoparticles, which agrees with literature reports.<sup>8</sup> Powdered X-ray diffraction (PXRD) patterns of In<sub>2</sub>O<sub>3</sub> showed major diffraction peaks at 21.5°, 30.6°, 33.1°, 35.4°, 37.7°, 41.8°, 45.6°, 50.9°, and 62.1° which could be identified as the (211), (222), (321), (400), (411), (332), (431), (440), and (631) diffraction planes, respectively (Fig. 2a). ICDD card no: 04-006-0857 ascribed the material to the cubic form of crystalline In<sub>2</sub>O<sub>3</sub>, with the space group *Ia $\bar{3}$*  (*a*, *b*, *c* = 10.1260 Å). The obtained polymorph of In<sub>2</sub>O<sub>3</sub> with a body-centered-cube (bcc) structure has an optimum band-edge position, excellent conductivity and outstanding photoelectrochemical stability, making it suitable for photocatalytic applications (Fig. 2a).<sup>19</sup>

In Fig. 2a, all major diffraction peaks belonging to pristine WO<sub>3</sub> (★) and In<sub>2</sub>O<sub>3</sub> (♣) were observed in binary composites. There was an increased diffraction peak intensity for binary composites compared to pristine materials. Adding WO<sub>3</sub> into In<sub>2</sub>O<sub>3</sub> promoted crystal growth, changing their initial obtained monoclinic and cubic phases into a general hexagonal phase structure.<sup>10,20</sup> The improved crystalline phase regulation optimizes the bandgap and significantly impacts charge carrier recombination inhibition.<sup>21</sup> However, further increase of WO<sub>3</sub> content beyond 30% resulted in the loss of crystallinity. Transformation of the crystalline phase of the binary nanocomposite into the amorphous nature at 50% WO<sub>3</sub> was indicated by the reduction in the sharpness of characteristic peaks (Fig. 2a). This was attributed to the masking effect induced by the phase structure of WO<sub>3</sub> onto the In<sub>2</sub>O<sub>3</sub> crystal structure.<sup>8</sup> Hence, 30% WO<sub>3</sub> (WI-30) content in the composite was therefore used for the fabrication of ternary composites due to its outstanding degree of crystallinity.

The XRD patterns of Ti<sub>4</sub>AlN<sub>3</sub> MAX and Ti<sub>4</sub>N<sub>3</sub>T<sub>x</sub> MXene are displayed in Fig. 2b and the extract of the patterns (5–20° ( $2\theta$ )) is shown in the ESI (Fig. S1†). The synthesized Ti<sub>4</sub>AlN<sub>3</sub> MAX phase showed peaks at approximately 5.8°, 13°, 18°, 36°, 44° and 62° which corresponded to the (002), (004), (103), (101), (104), and (110) hexagonal phases of Ti<sub>4</sub>AlN<sub>3</sub>, respectively (Fig. 2b and S1†). These peaks matched the reference Ti<sub>4</sub>AlN<sub>3</sub> phases reported in the literature.<sup>22</sup> The aluminium layer was etched out following an *in situ* prepared HF from LiF and HCl treatment. The (103) peak disintegrated into reflection peaks (◆) in Ti<sub>4</sub>N<sub>3</sub>T<sub>x</sub>, as shown in Fig. S1.† Consequently, the (002) peak broadened and shifted from 5.8° to 5.4°, indicating the change in the lattice parameter (*c*-LP) of the cell. This is

Fig. 2 XRD patterns for (a) pristine  $\text{WO}_3$ ,  $\text{In}_2\text{O}_3$ , and binary nanocomposites; (b)  $\text{Ti}_4\text{AlN}_3$  MAX,  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene and ternary nanocomposites.

evident by the shift in  $d$ -spacings from 6.73 Å in  $\text{Ti}_4\text{AlN}_3$  MAX to 7.47 Å. Similarly, lattice parameter changes in the unit cell of  $\text{Ti}_4\text{N}_3\text{T}_x$  were due to the introduction of functional groups ( $-\text{O}$ ,  $-\text{OH}$ ,  $-\text{F}$ ) and  $\text{Li}^+$  intercalation between the interspaces. In ternary nanocomposites, PXRD patterns for 1, 3, 5, and 7 wt% showed a  $\text{Ti}_4\text{N}_3\text{T}_x$  (110) peak ( $\blacktriangle$ ) along with other peaks belonging to  $\text{WO}_3$  ( $\star$ ) and  $\text{In}_2\text{O}_3$  ( $\clubsuit$ ), further confirming a successful fabrication of the TWI-30 ternary heterojunction (Fig. 2b). However, 3-TWI-30 showed the best crystallinity.

Herein, the PXRD results ascertained the successful synthesis of all nanomaterials. Using the Scherrer equation, grain sizes ( $\text{WO}_3$ ,  $\text{In}_2\text{O}_3$ , WI-30, and 3-TWI-30) in the nanostructure were calculated using their diffraction peak broadening in accordance with eqn (1):<sup>23</sup>

$$D = \frac{0.9\lambda}{\beta \cos \theta} \quad (1)$$

where  $\lambda$  corresponds to the monochromatic X-ray wavelength,  $\beta$  represents the peak width at half maximum height and  $\theta$  is the diffraction angle. Pristine  $\text{WO}_3$  ( $23^\circ$ ),  $\text{In}_2\text{O}_3$  ( $30^\circ$ ), WI-30 ( $24^\circ$ ) and 3-TWI-30 ( $30^\circ$ ) exhibited crystalline sizes of 57, 48, 33 and 38 nm, respectively. In the nanocomposites, a decrease in crystal size with an increase in  $\text{WO}_3$  content into  $\text{In}_2\text{O}_3$  was observed. A reduction in crystal size indicates increased crystallinity, a contributing factor in suppressing the  $e^-/h^+$  recombination rate. The suppression of crystal growth is attributed to the heterojunction formation.<sup>19</sup>

Raman findings shown in Fig. S2a and b† ascertain vibrational modes in the as-synthesised material. The phonon bands of  $\text{WO}_3$  confirmed PXRD findings which showed sharp

well-defined peaks at 806, 717, 326, 269 and  $135\text{ cm}^{-1}$  corresponding to the monoclinic phase of  $\text{WO}_3$  (Fig. S2a†). The band peaks at 717 and  $806\text{ cm}^{-1}$  were assigned to O–W–O stretching modes while 326, 269 and  $135\text{ cm}^{-1}$  to O–W–O bending vibrations.<sup>24</sup> The cubic  $\text{In}_2\text{O}_3$  structure belongs to the space groups  $I_a^3$  and  $T_h^7$ . Two types of cations are present in the structure: 24 (point groups)  $\text{In}^{3+}$  with the point symmetry  $C_2$  and 8 (side groups)  $\text{In}^{3+}$  with the side symmetry  $S_6$ .<sup>25</sup> In a body-centered cell, the existing 48 oxygen atoms retain the  $C_1$  site symmetry and are arranged in general places (e). Such a structure is described by the following vibration modes as given in eqn (2):<sup>25</sup>

$$4A_g + 4E_g + 14T_g + 5A_u + 5E_u + 16T_u \quad (2)$$

While the  $T_u$  vibrations are both infrared active and Raman inactive, the  $A_g$ ,  $E_g$ , and  $T_g$  symmetry vibrations are both Raman active and infrared inert. However,  $A_u$  and  $E_u$  vibrations are both infrared and Raman inactive. Unambiguous Raman spectra signatures of the cubic  $\text{In}_2\text{O}_3$  structure with phonon modes at 305, 363, and  $495\text{ cm}^{-1}$  were also observed for our synthesized sample and indexed to  $E_{2g}$ ,  $A_g$ , and  $E_g$  with reference to a literature report (Fig. S2a†).<sup>26</sup> The nanocomposite structures comprised of individual pristine  $\text{WO}_3$  ( $\star$ ) and  $\text{In}_2\text{O}_3$  ( $\clubsuit$ ) phonon modes (Fig. S2a†). The binary peaks slightly broadened, became less intense and slightly shifted to higher wave-numbers. These slight shifts were related to the increase in the length of the In–O bond induced by substitution of  $\text{In}^{3+}$  by  $\text{W}^{6+}$ . Additionally, the observed small line width in each spectrum contributed to the nanocrystalline structure with good crystallinity as observed in the XRD patterns.

Raman spectra for MAX and MXene were labelled after Gaussian and Lorentzian function fitting (Fig. S2b†). The peaks were indexed as  $\omega_2$  ( $134.6\text{ cm}^{-1}$ ) and  $\omega_9$  ( $558.6\text{ cm}^{-1}$ ) which belong to  $E_{1g}$  group vibrations. They contained in-plane modes of Ti and N atoms. Similarly,  $\omega_4$  ( $212.5\text{ cm}^{-1}$ ),  $\omega_6$  ( $251.2\text{ cm}^{-1}$ ),  $\omega_7$  ( $378.1\text{ cm}^{-1}$ ), and  $\omega_8$  ( $548.5\text{ cm}^{-1}$ ) modes corresponded to  $A_{1g}$  symmetry out-of-plane vibrations of Ti and N atoms. These peaks were present in the  $\text{Ti}_4\text{AlN}_3$  MAX phase while  $\omega_4$ ,  $\omega_6$ ,  $\omega_7$ , and  $\omega_8$  ( $548.5\text{ cm}^{-1}$ ) modes were observed in the  $\text{Ti}_4\text{N}_3\text{T}_x$  spectrum. After etching Al, a reduction in peak intensity was observed. The peaks shifted to lower energy. The induced structural surface moieties during etching and delamination processes resulted in peak broadening with an increased interlayer  $d$ -spacing.<sup>27</sup> Addition of  $\text{Ti}_4\text{N}_3\text{T}_x$  into the binary nanocomposite further resulted in increased peak intensities. The observed optical phonon modes of  $\text{WO}_3$ ,  $\text{In}_2\text{O}_3$  and  $\text{Ti}_4\text{N}_3\text{T}_x$  in the nanocomposite suggested the effective development of 3-TWI-30 which indicated a clear fabrication of a ternary nanocomposite (Fig. S2a†).

### Functional groups

Functional groups of the pristine and nanocomposites were further ascertained from the FTIR spectrum in Fig. S2c†. Stretching and bending modes which correspond to the W-O vibrations of the material were seen in the FTIR spectrum of pure  $\text{WO}_3$  as reported in the literature.<sup>28</sup> The peak observed at  $3429\text{ cm}^{-1}$  was due to the stretching vibration of the surface O-H group. The minor peak at  $1624\text{ cm}^{-1}$  was the W-OH vibration and the strong peak at  $766\text{ cm}^{-1}$  was ascribed to the W-O-W bridging mode.<sup>29</sup> Similarly, peaks at  $440$  and  $557\text{ cm}^{-1}$  were attributed to In-O stretching vibrations in cubic  $\text{In}_2\text{O}_3$ . The bands at  $602$  and  $827\text{ cm}^{-1}$  were characteristic of In-O bending vibrations in  $\text{In}_2\text{O}_3$ .<sup>28</sup> Broad characteristic peaks at  $557\text{ cm}^{-1}$  and  $827\text{ cm}^{-1}$  present in  $\text{In}_2\text{O}_3$  corresponded to the  $\beta$ - $\text{In}_2\text{O}_3$  phase. Additionally observed peaks at  $3424$  and  $1646\text{ cm}^{-1}$  belonged to the stretching and bending vibrations of O-H bands.<sup>30</sup>

The  $\text{Ti}_4\text{AlN}_3$  MAX phase exhibited a broad peak at  $\sim 675\text{ cm}^{-1}$ , which was ascribed to a Ti-Al-N vibration as per literature reports.<sup>31</sup> After etching and delamination to  $\text{Ti}_4\text{N}_3\text{T}_x$ , disappearance of this broad spectral feature and formation of a new peak at  $537\text{ cm}^{-1}$  were observed. This was attributed to the successful removal of the Al layer and formation of a new Ti-N vibration. Notably, in the exfoliated  $\text{Ti}_4\text{N}_3\text{T}_x$  spectrum, a much broader peak centered at  $\sim 3424\text{ cm}^{-1}$  was observed to be a characteristic O-H/N-H stretch. Similarly, formation of a new peak at  $537\text{ cm}^{-1}$  was observed which could be ascribed to the Ti-F stretching. This was related to the hydrophilic nature of  $\text{Ti}_4\text{N}_3\text{T}_x$  due to terminal functional groups (O-F, Ti-F, OH, and NH).

Furthermore, FTIR spectra for binary nanocomposites comprised of prominent peaks of  $\text{WO}_3$  and  $\text{In}_2\text{O}_3$  (Fig. S2c†).<sup>9</sup> The vibrational peak intensity of  $\text{Ti}_4\text{N}_3\text{T}_x$  belonging to Ti-N, Ti-F was observed in the case of the ternary nanocomposite. Concomitantly, a broad band and sharp intense peak at  $3424$  and  $1637\text{ cm}^{-1}$  were assigned to the  $\nu(\text{O-H})$  stretching modes as a result of  $\delta(\text{H-O-H})$  bending vibration modes, respectively. This O-H stretching showed a much broader peak in the ternary nanocomposite due to the contribution of the O-H functional group from  $\text{Ti}_4\text{N}_3\text{T}_x$ . All surface functional groups belonging to  $\text{Ti}_4\text{N}_3\text{T}_x$  (O-F, Ti-F, OH, and NH) were observed in the ternary nanocomposite, indicating the successful addition of  $\text{Ti}_4\text{N}_3\text{T}_x$  to the binary nanocomposite.

### Morphology

The shape and microstructure of the as-synthesized materials were investigated using SEM and TEM as shown in Fig. S3† and Fig. 3. In Fig. S3a,† 2D  $\text{WO}_3$  nanoparticles exhibit a rod-like morphology and their composition was confirmed by EDS to be W and O. The SEM image of pristine  $\text{In}_2\text{O}_3$  nanoparticles in Fig. S3b† shows a cube-like morphology, which agglomerated to exhibit a flower-like comb.<sup>32</sup> Their EDS spectrum confirmed the presence of In and O. In Fig. S3c,† the 2D  $\text{WO}_3$  nanoparticles were finely disseminated over  $\text{In}_2\text{O}_3$  nanosheets

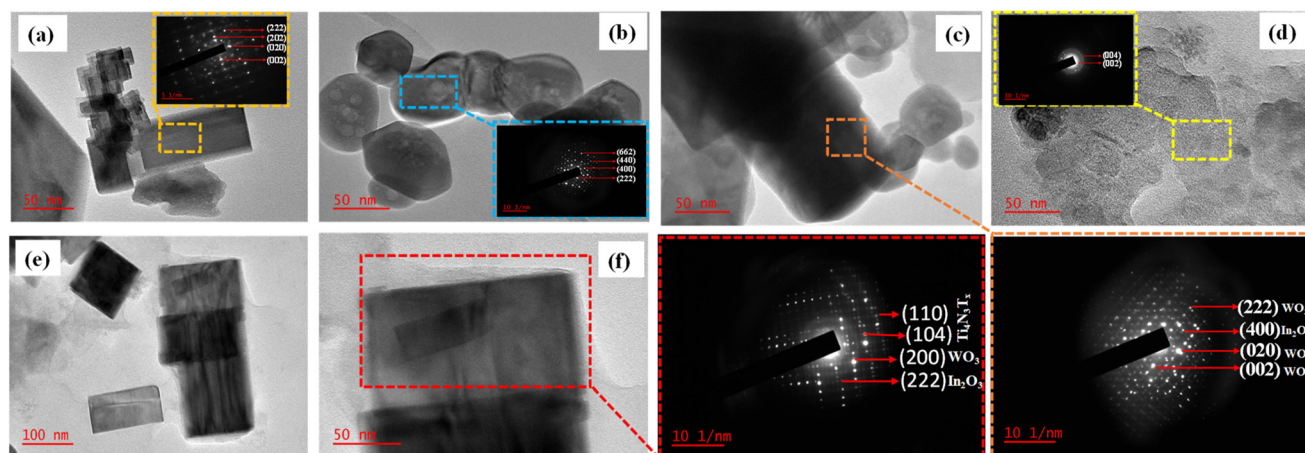

Fig. 3 TEM images for (a)  $\text{WO}_3$ , (b)  $\text{In}_2\text{O}_3$ , (c) WI-30, (d)  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene, (e) 3-TWI-30 ternary and (f) HRTEM 3-TWI-30 ternary heterostructures.

resulting in the formation of the  $\text{WO}_3/\text{In}_2\text{O}_3$  binary nanocomposite. This was further confirmed by the EDS spectrum indicating the elemental composition to be W, In and O. Fig. S3d and e† show the SEM images of  $\text{Ti}_4\text{AlN}_3$  and  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene, respectively. The SEM images of  $\text{Ti}_4\text{AlN}_3$  MAX (Fig. S3d†) and  $\text{Ti}_4\text{N}_3\text{T}_x$  in Fig. S3e† display a morphological change before and after etching.<sup>33</sup> Their EDS analysis was consistent with previous literature reports, which showed the presence of Ti, N, Al and O in the MAX phase.<sup>34</sup> The removal of Al in MXene was confirmed by the disappearance of the Al peak in the EDS spectrum (Fig. S3e†). In Fig. S3f,† there was an over-layer of the  $\text{Ti}_4\text{N}_3\text{T}_x$  structure on the binary nanocomposite as evidenced by the appearance of a disintegrated layer. The elemental composition was confirmed by EDS analysis to be In, W, N, F, and O. The elemental mapping for the 3-TWI-30 ternary composite is indicated in Fig. S4† to include Ti, W, In, N, O and F.

Fig. 3a shows TEM images of pristine  $\text{WO}_3$  with a 2D rectangular shape-like structure.<sup>35</sup>  $\text{In}_2\text{O}_3$ , in Fig. 3b, shows a body-centered cubic morphology. Fig. 3c confirms the formation of a binary composite with  $\text{In}_2\text{O}_3$  cubes decorated onto the rectangular-shaped structure of  $\text{WO}_3$ .  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene in Fig. 3d shows a nanosheet-like morphology.<sup>36</sup> The formed ternary composite in Fig. 3e was confirmed by the layering of  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene nanosheets onto the rectangular  $\text{WO}_3$ . The cubic  $\text{In}_2\text{O}_3$  is not clearly shown. This is due to the masking effect of  $\text{WO}_3$ . The SAED patterns for all the materials were indexed by calculating the  $d$ -spacings for the individual material using the ImageJ software. The SAED patterns for  $\text{WO}_3$  observed were (222), (202), (020) and (002) (Fig. 3a inset). This is in agreement with the XRD pattern analysis.<sup>35</sup> Similarly, the  $\text{In}_2\text{O}_3$  cubic structure indicated the SAED sets of (622), (440), (400) and (222) as shown in Fig. 3c inset. These were further confirmed in the binary composite with those belonging to  $\text{WO}_3$  dominating as indicated in Fig. 3c.  $\text{Ti}_4\text{N}_3\text{T}_x$  exhibits two distinct crystal planes belonging to (002) and (004) (Fig. 3d inset).

Furthermore, the presence of  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene nanosheets on  $\text{WO}_3/\text{In}_2\text{O}_3$  confirms the role of  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene as the electron sinks = in separating electrons from the CB of  $\text{WO}_3$ . The formation of the ternary nanocomposite was further confirmed by the SAED sets of (110), (104), (200), and (222) to be a combination of the three as shown in Fig. 3e and HRTEM in Fig. 3f.

### Elemental composition and chemical states

The chemical composition, oxidation states and the electron migration route of the heterostructure were ascertained by analysing the change in binding energy using X-ray photoelectron spectroscopy (XPS) (Fig. S5† and Fig. 4).

The survey spectra of the  $\text{Ti}_4\text{AlN}_3$  MAX phase,  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene,  $\text{WO}_3$ ,  $\text{In}_2\text{O}_3$  nanoparticles, WI-30, and 3-TWI-30 heterostructures are displayed in Fig. S5† (and its extract) presenting Ti, N, W, O, In, and Al elements.

The F element observed on the  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene results from etching with LiF salt and HCl. The W 4f spectrum shown in Fig. 4a has two evident peaks at 35.3 and 37.4 eV, ascribed to

W 4f<sub>7/2</sub> and W 4f<sub>5/2</sub> of  $\text{WO}_3$ , respectively. In the WI-30 and 3-TWI-30 heterostructures, these W 4f peaks slightly shifted toward lower binding energy in comparison to pristine  $\text{WO}_3$  nanoparticles implying electron depletion on  $\text{WO}_3$ . The In 3d spectrum in Fig. 4b consists of a doublet at binding energies of 452.2 eV for In 3d<sub>3/2</sub>, and 444.6 eV for In 3d<sub>5/2</sub> which shifted to higher binding energy in WI-30 due to electron accumulation.<sup>37</sup> Fig. 4c shows a high-resolution O 1s spectrum for pristine  $\text{WO}_3$ ,  $\text{In}_2\text{O}_3$ , and their composites,  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene and  $\text{Ti}_4\text{AlN}_3$  MAX with two peaks at 530.3 and 532.1 eV. The intense peak at 530.3 eV is attributed to the lattice oxygen in  $\text{WO}_3$  and  $\text{In}_2\text{O}_3$  species characteristic of metal oxides, and the weak peak at 532.1 eV could be due to the adsorbed oxygen.<sup>38</sup> The 530 eV peak is more intense and broader in indium oxide than in the  $\text{WO}_3$  photocatalyst indicating more oxygen vacancies in  $\text{In}_2\text{O}_3$ .<sup>10</sup> O 1s for  $\text{Ti}_4\text{AlN}_3$  MAX and  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene was fitted, and three sub-peaks observed were related to Ti–O (528 eV), Ti–OH (532 eV) and adsorbed moisture (533 eV). Fig. 4d indicates the observed Ti 2p peaks for both  $\text{Ti}_4\text{AlN}_3$  and  $\text{Ti}_4\text{N}_3\text{T}_x$  nanocomposites. A more informative understanding of the prevailing chemical state present in MAX and MXene can be obtained from the Ti 2p spectra. Two transition splits are produced by the Ti 2p spin–orbit splitting within the range of 453–460 eV forming Ti 2p<sub>3/2</sub> and the peaks from 460 to 466 eV are due to the Ti 2p<sub>1/2</sub>. A similar peak of Ti<sup>2+</sup> at 455.0 eV, and at 456.9 eV (Ti<sup>3+</sup>) and 458.6 eV (Ti<sup>4+</sup>) in TiN are also observed in the  $\text{Ti}_4\text{AlN}_3$  MAX. After Al<sup>3+</sup> exfoliation, there is a disappearance of the original Ti<sup>2+</sup> feature in  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene. The observed peaks at 457.0 and 458.5 eV are ascribed to Ti<sup>3+</sup> and Ti<sup>4+</sup>. Additionally, the Ti<sup>3+</sup> peak at 457.0 eV in the  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene spectrum broadened compared to the MAX phase (Fig. 4d). The similarity in electronegativities exhibited by both Ti and Al (1.54 for Ti; cf. 1.61 for Al) indicates the likelihood of a shared Ti–Al bonding structure in the  $\text{Ti}_4\text{AlN}_3$  MAX phase to include Ti<sup>2+</sup>, Ti<sup>3+</sup>, and Ti<sup>4+</sup> as well as Al<sup>3+</sup>, as observed in its XPS spectrum.<sup>31</sup> However, the two terminal Ti layers in the 7-atom layer  $\text{Ti}_4\text{N}_3\text{T}_x$  sheets exhibit a Ti<sup>4+</sup> oxidation state in Fig. 4d. The Ti<sup>4+</sup> peak is observed in the Ti 2p spectrum at 459 eV with a slightly lower energy Ti<sup>4+</sup> peak in the  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene due to the Ti<sup>4+</sup> environment consisting of both Ti–O and Ti–N characters. Similar to the Raman and FTIR spectroscopic data, these XPS Ti 2p data also indicate the formation of surface oxide (T<sub>x</sub> = O and/or OH). Two inner Ti layers in the 7-atom layer  $\text{Ti}_4\text{N}_3\text{T}_x$  sheet formally are in a Ti<sup>3+</sup> oxidation state and are bound only *via* Ti–N interactions in both the  $\text{Ti}_4\text{AlN}_3$  MAX and  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene phases. The shift to a higher binding energy observed in Ti 2p in 3-TWI-30 is due to an increased electron density flowing from the CB of  $\text{WO}_3$  in WI-30.<sup>37,39</sup> Fig. 4e and f illustrate the distinct variations in the spectrum areas for Al 2p and N 1s for the  $\text{Ti}_4\text{AlN}_3$  MAX and  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene phases, respectively. The Al peak position (about 75 eV) in Fig. 4e is in line with an Al<sup>3+</sup> environment in the  $\text{Ti}_4\text{AlN}_3$  MAX phase. This peak decreases in intensity and shifts to lower binding energy after etching. This is due to distortion of the Ti–Al–N bond and formation of new Ti–N weak van der Waal bonds in the  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene. The N 1s spectrum for the

Fig. 4 XPS spectra of the as-prepared materials (a) W 4f, (b) In 3d (c) O 1s; (d) Ti 2p and the intensity for (e) Al 2p and (f) N 1s.

Ti<sub>4</sub>AlN<sub>3</sub> MAX phase in Fig. 4f exhibits an intense peak at 397.3 eV which is consistent with the peaks present from a metal nitride bond. After Al removal, an increase in peak intensity was observed with a subsequent shift to a lower binding energy in Ti<sub>4</sub>N<sub>3</sub>T<sub>x</sub> MXene. However, after addition of the Ti<sub>4</sub>N<sub>3</sub>T<sub>x</sub> MXene, the peaks shifted to higher binding energy. The N 1s in Ti<sub>4</sub>N<sub>3</sub>T<sub>x</sub> MXene shifted to lower binding energy and broadened. This is relatable to the weakened bond due to the Al removal.<sup>37</sup> However, in 3-TWI-30, the N 1s peak becomes more broader and uniformly distributed. This is due to the effect of accepted electrons from WI-30.<sup>40</sup>

### Optical properties

UV-vis spectroscopy was used to examine optical band edge absorption, bandgap and emission band peaks of the synthesized materials. Pristine WO<sub>3</sub> and In<sub>2</sub>O<sub>3</sub> (Fig. 5a) dis-

played relatively lower absorption intensities in the visible light region with absorption edges at 520 and 420 nm, respectively.

Introduction of WO<sub>3</sub> nanoparticles into the In<sub>2</sub>O<sub>3</sub> photocatalyst improved the photon absorption of the photocatalyst. A red shift was observed upon increasing the WO<sub>3</sub> content in the binary composite from 5 to 30% with a maximum absorption at 470 nm (WI-30).

A further increase in WO<sub>3</sub> content showed a blue shift in absorption.

This could be attributed to the masking effect of WO<sub>3</sub> on In<sub>2</sub>O<sub>3</sub>. Ti<sub>4</sub>N<sub>3</sub>T<sub>x</sub> showed no absorption edge across the 200–800 nm, which was related to its metallic structure (Fig. 5b). The observed absorption edge range for ternary nanocomposites was 480 nm to 430 nm with 3-TWI-30 absorbing within the visible range (463 nm) (Fig. 5c).

Fig. 5 (a and b) UV-vis absorption spectra and (c and d) Tauc plots of the as-prepared materials.

$E_g$  for the as-synthesized photocatalysts was examined using the Kubelka–Munk eqn (3):

$$(\alpha h\nu) = A(h\nu - E_g)^{1/n} \quad (3)$$

where  $\alpha$  represents the optical absorption coefficient,  $h\nu$  is the photon energy, and  $n$  determines the type of optical transition where  $n = 2$  or  $3$  for an indirect allowed and indirect forbidden transition, respectively and  $n = 1/2$  or  $3/2$  for a direct allowed and direct forbidden transition, respectively. Both  $\text{WO}_3$  and  $\text{In}_2\text{O}_3$  have a direct allowed transition,  $n = 1/2$ ,  $E_g$  is the bandgap energy and  $A$  is a material dependent constant.<sup>41</sup> From Tauc plots of different photocatalysts,  $E_g$  values of pure  $\text{WO}_3$  and  $\text{In}_2\text{O}_3$  were 2.13 eV and 2.62 eV, respectively, while those of WI-5, WI-15, WI-30 and WI-50 were 2.39 eV, 2.43 eV, 1.90 eV and 2.44 eV, respectively (Fig. 5c).

The introduction of  $\text{WO}_3$  nanoparticles onto the  $\text{In}_2\text{O}_3$  photocatalyst narrowed the  $E_g$  of nanocomposites, hence promoting visible light absorption, a first requirement step in a photocatalytic reaction.<sup>42</sup> Therefore, the constructed WI-30 binary heterojunction composite vastly improved the utiliz-

ation of broad light absorption in comparison to pristine materials. Upon fabrication of the ternary nanocomposite, there was a visible change in  $E_g$  with 1, 3, 5 and 7 wt% (TWI-30) having an  $E_g$  of 2.36 eV, 2.33 eV, 2.56 eV and 2.55 eV, respectively (Fig. 5d). A ternary nanocomposite, made up of 3 wt% MXene, showed the lowest  $E_g$  of 2.33 eV, suggesting superior absorption capabilities to the other MXene loading wt%.

XPS valence band (VB) analysis further deduced the changes in the position of the energy band edges due to the bandgap position shift. The XPS VB spectrum for  $\text{WO}_3$  in Fig. 6a derives its VB potential ( $E_{\text{VB}}$ , vs. vacuum) to be 2.98 eV (vs. vacuum), while that for  $\text{In}_2\text{O}_3$  was 2.03 eV (vs. vacuum) (Fig. 6b).<sup>43</sup> Based on their respective  $E_g$  values, the conduction band potentials  $E_{\text{CB}}$  (vs. vacuum) were estimated to be 0.85 and 2.03 eV, respectively. The extrapolated XPS  $E_{\text{VB}}$  average in WI-30 and 3-TWI-30 was 2.21 and 2.12 eV (vs. vacuum), respectively as shown in Fig. 6c and d. These confirm the successful effect of heterostructure formation on influencing band potentials and band edge deduction as summarized in Table 1 and Fig. 7, respectively.

Fig. 6 XPS VB spectra for (a)  $\text{WO}_3$ , (b)  $\text{In}_2\text{O}_3$ , (c) WI-30 and (d) 3-TWI-30.

**Table 1** Optoelectronic parameters of the photocatalysts: optical absorption edge (Abs. edge), energy bandgap ( $E_g$ ), XPS valence band (XPS<sub>VB</sub>) and XPS conduction band (XPS<sub>CB</sub>)

Sample	Absorption edge (nm)	Bandgap (eV)	XPS <sub>VB</sub> (eV)	XPS <sub>CB</sub> (eV)
$\text{WO}_3$	416	2.13	2.98	0.85
$\text{In}_2\text{O}_3$	455	2.62	2.03	−0.32
WI-30	470	1.90	2.21	0.31
3-TWI-30	463	2.33	2.12	−0.21

### Photoelectrochemical studies

The photoluminescence intensities for pure  $\text{WO}_3$  and  $\text{In}_2\text{O}_3$  photocatalysts exhibited the strongest PL peaks in the range of 340 nm–360 nm at an excitation wavelength of 350 nm, indicating the highest recombination rate of photoinduced carriers (Fig. 8a and b).

After loading  $\text{WO}_3$  nanoparticles onto  $\text{In}_2\text{O}_3$ , a reduction in the PL intensities was observed for binary nanocomposites in comparison to pristine  $\text{WO}_3$  with WI-30 recording the least peak intensity.

A decrease in PL intensity signified that there was a reduction in photoinduced charge carrier recombination

rate.<sup>44</sup> The formation of the heterojunction contributed to the change in the charge carrier transfer route. Similarly, reduction in  $e^-/h^+$  recombination could be as well attributed to improved crystallinity of composites. The smaller the crystal size, the shorter the diffusion pathways of charge carriers as well as improved spatial separation of  $e^-/h^+$ .<sup>45</sup> Consequently, increased content of  $\text{WO}_3$  results in masking of  $\text{In}_2\text{O}_3$  which caused an increase in the recombination rate of nanocomposites. A consequential reason for the observed increase in PL intensity is the increase in  $\text{WO}_3$  content to 50%.

MXenes are metallic compounds with high conductivity properties, therefore exhibiting efficient charge transfer mobility.<sup>46</sup> Hence, upon fabrication with  $\text{Ti}_4\text{N}_3\text{T}_x$ , a much lower PL intensity was recorded, with 3-TWI-30 reporting the lowest PL intensity (Fig. 8b). The reduced PL intensity suggests the successful formation of a Schottky barrier between the WI-30 heterostructure and MXene.<sup>46</sup> The Schottky barrier, therefore, acted as a shuttle for  $e^-$  from WI-30 to  $\text{Ti}_4\text{N}_3\text{T}_x$ . In addition to the metallic nature of the MXene, a reduction in PL intensity might be related to the porous nature of  $\text{Ti}_4\text{N}_3\text{T}_x$  which acted as electron traps further separating and stabilizing photoseparated electrons from active holes. However, MXenes can behave as recombination centres at high  $\text{Ti}_4\text{N}_3\text{T}_x$  loading,

Fig. 7 Band edge position diagrams of the synthesized semiconductors based on the XPS data.

Fig. 8 (a and b) PL spectra, (c and d) EIS Nyquist plot of the as-prepared materials, inset: Randles-Ershler equivalent circuit. ( $C_{dl}$  = double layer capacitance,  $R_{CT}$  = charge transfer resistance, and  $R_s$  = solution resistance) and (e and f) photocurrent response of the pristine and nanocomposites.

evidenced by increased recombination rates as observed in 5-TWI-30 and 7-TWI-30 composites.

Considering the diameters of the semicircles, the Nyquist plots reveal the generated charge carrier resistance (Fig. 8c and d). The Nyquist plot has the imaginary impedance value ( $Z''$ ) and the real impedance value ( $Z'$ ), which show the charge transfer resistance ( $R_{CT}$ ) fitted by the Randles–Ershler equivalent circuit (Fig. 8c and d; inset). A smaller arc radius shows an efficient charge transfer and a more effective separation of photoinduced charge carriers.<sup>47</sup>

As shown in Fig. 8c, pristine  $\text{WO}_3$  and  $\text{In}_2\text{O}_3$  photocatalysts exhibited largest curves, an indication of a high charge transfer resistance, 41.2 and 42.3  $\Omega$ , respectively, attributed to the lower interfacial charge transfer and increased charge carrier recombination rate.

Upon binary fabrication, an increase in curves and later reduction with WI-30 reporting the smallest curve with a resistance of 33.0  $\Omega$  was observed. WI-5, WI-15, and WI-50 exhibited 38.5, 70.5 and 71.5  $\Omega$ , respectively. There was a significant reduction in charge-transfer resistance upon incorporating the appropriate amount of  $\text{WO}_3$  into the intrinsic structure of  $\text{In}_2\text{O}_3$ . The induced interfacial reaction mechanism within 30%  $\text{WO}_3$  and  $\text{In}_2\text{O}_3$  contact leads to faster and more efficient charge separation and transfer.

Further addition of  $\text{Ti}_4\text{N}_3\text{T}_x$  to the WI-30 binary nanocomposite reduced the charge resistance, with 3-TWI-30 reporting the least 31.9  $\Omega$  resistance, while 1-TWI-30, 5-TWI-30 and 7-TWI-30 exhibited 41.9, 49.6 and 49.0  $\Omega$  resistance, respectively. This was related to the metallic nature and charge transfer capacity of MXenes which offer stable landing sites for photogenerated electrons. Similarly, in 2015, Yan *et al.* reported that oxygen vacancies of  $\text{In}_2\text{O}_3$  in the ternary composite facilitate the formation of inter-bandgap states below the CB minimum responsible for the extra charge carriers facilitating an increased  $e^-$  lifetime. They bind electrons to states of shallow defects.<sup>48</sup> An extended lifetime would provide photo-generated holes in the VB a longer time to migrate toward the electrode/electrolyte contact and participate in the oxidation process.

Photocurrent response was recorded to explore interfacial electron–hole separation and transfer (Fig. 8e and f).<sup>49</sup> Five cycles of on and off of visible light irradiation were performed to record the transient photocurrent responses of pure  $\text{WO}_3$ ,  $\text{In}_2\text{O}_3$ , and nanocomposites with  $\text{WO}_3$  exhibiting the lowest photocurrent response. Photocurrent intensities of WI-30 photocatalysts were most improved and gradually reduced upon increasing the  $\text{WO}_3$  content (Fig. 8e). Transient photocurrent of the WI composite catalyst was distinctly enhanced compared to that of pure  $\text{WO}_3$  or  $\text{In}_2\text{O}_3$ . Introduction of  $\text{WO}_3$  nanoparticles enhanced the separation efficiency of  $e^-/h^+$  in WI up to a given limit, after which, it masked  $\text{In}_2\text{O}_3$  resulting in the reduction of photocurrent response.

Similarly, in 2021, Banerjee *et al.* reported that 8.5 wt% of NiO could cover  $\text{InTaO}_4$  and offset its light absorption.<sup>50</sup> In 2023, Chico-Vecino *et al.* also prepared the  $\text{WO}_3/\text{In}_2\text{O}_3$  composite and observed the same effect.<sup>10</sup> Upon MXene introduction,

an increase in photocurrent density was observed with 3-TWI-30 exhibiting the highest photocurrent density (Fig. 8f). This was due to the increased light absorption ability of the ternary nanocomposite and a tighter connection between WI-30 and  $\text{Ti}_4\text{N}_3\text{T}_x$  leading to more efficient separation and flow of  $e^-/h^+$ .<sup>51</sup> High photocurrent response minimizes photo-corrosion of  $e^-/h^+$ . In turn, their recombination rate is minimized.

A Mott–Schottky study was conducted to deduce band edge potentials and explore the charge transfer pathways in Fig. S6a.† The deduced flat band potential from the Mott–Schottky plot was employed in the determination of the band edge structure and pathways opted by  $e^-/h^+$  in semiconductor materials. The X axis intersections in the Mott–Schottky plots yielded values of the flat-band potentials. Notably, a shift in the flat band potentials was observed in the composites with the WI-30 binary nanocomposite exhibiting higher values compared to pristine materials (Fig. S6c and d†). This indicated an excellent interfacial  $e^-$  migration. The individual oxides demonstrated positive slopes on their Mott–Schottky curves suggesting n-type semiconductors (Fig. S6a and b†).

Accordingly, the Fermi level for n-type semiconductors is estimated to be 0.1 V to 0.3 below the CB.<sup>52</sup> Based on this assumption, flat band potential ( $E_{FB}$ ) values were used in calculating the CB potential for each material. Using the Nernst equation, the obtained  $E_{FB}$  values against the Ag/AgCl scale were changed to the NHE scale, as shown in eqn (4).

$$E_{NE} = E_{Ag/AgCl} + E_{Ag/AgCl}^{\circ} + 0.059 (\text{pH}) \quad (4)$$

where  $E_{Ag/AgCl}$  measures the potential *via* the Ag/AgCl reference electrode and  $E_{Ag/AgCl}^{\circ} = 0.197$  at 25 °C. Electrolyte solution was kept at a pH of 6.5. Their individual valence band (VB) values were calculated from their respective bandgaps extrapolated from UV-vis DRS Tauc spectra using eqn (5):

$$E_{VB} = E_g + E_{CB} \quad (5)$$

Through the determined bandgap and VB position, the CB and energy levels of  $\text{WO}_3$  and  $\text{In}_2\text{O}_3$  were deduced to be  $-0.246$  and  $-1.204$  V while their VBs were 1.884 and 1.416 V, respectively, as further indicated in Table S2.† Additionally, MS plots were utilized to evaluate the carrier concentration ( $N_D$ , donor carriers for an n-type semiconductor) for the synthesized photocatalysts, according to eqn (6):

$$N_D = \frac{2}{e\epsilon\epsilon_0 \times \text{MS}_{\text{slope}}} \quad (6)$$

where  $e$ ,  $\epsilon$ , and  $\epsilon_0$  stand for the  $e$ -charge, vacuum permittivity, and dielectric constant, respectively.

The dielectric constants for  $\text{WO}_3$  and  $\text{In}_2\text{O}_3$  were obtained from the literature as 5.03 and 8.9, respectively.<sup>53,54</sup> The calculated  $N_D$  from the individual MS slope in Table S2 provided in the ESI† was  $11.05 \times 10^{21}$ ,  $6.25 \times 10^{21}$ ,  $2.70 \times 10^{21}$  and  $7.83 \times 10^{21} \text{ cm}^{-3}$  for  $\text{WO}_3$ ,  $\text{In}_2\text{O}_3$ , WI, and TWI, respectively. The lowest MS slope in  $\text{WO}_3$  results in the highest  $N_D$ , while 3-TWI-30 showed a better  $N_D$ . Moreover, the  $N_D$  value

increased as the  $\text{Ti}_4\text{N}_3\text{T}_x$  loading increased, an indication of increased induction in charge carrier mobility.

To identify the formed reactive species accountable for the breakdown of organic pollutants in wastewater, the CB and VB potentials for the synthesized materials were compared with  $\text{O}_2/\text{O}_2^-$  and  $\text{OH}^-/\text{OH}$  generation potentials. This was based on the energy band edge diagram deduced from Mott-Schottky analysis (Fig. S6†). The CB of  $\text{In}_2\text{O}_3$  had a redox potential capable of producing superoxide radicals ( $E_{\text{CB}} = -1.66 \text{ V}$ ;  $E(\text{O}_2/\text{O}_2^-) = -0.33 \text{ V vs. NHE}$ ). Similarly,  $\text{WO}_3$  has a VB potential capable of producing hydroxyl radicals ( $E_{\text{VB}} = 1.88 \text{ V}$ ;  $E(\text{OH}^-/\text{OH}) = 0.96 \text{ V}$ ) as indicated in Fig. 9.

The work function plays a key role in determining the charge transfer mechanism at the interface of the 3-TWI-30 S-scheme structure.

Fig. 10 shows the obtained work function of  $\text{WO}_3$  (a),  $\text{In}_2\text{O}_3$  (b),  $\text{Ti}_4\text{N}_3\text{T}_x$  (c), WI-30 (d) and 3-TWI-30 (e) obtained *via* XPS and the sketches of the internal electric field and charge transfer (Fig. 11f–h). In the XPS measurement, the energy transformation is given by a relationship of the solid sample:  $h\nu = E_k + E_b + \Phi$  ( $h\nu$  is the incident photon energy,  $E_k$  is the photoelectron kinetic energy,  $E_b$  represents the electron binding energy, and  $\Phi$  gives the sample's work function).<sup>55</sup> The difference in the work function gives a different contact potential energy ( $\Delta V = \Phi - \varphi$  ( $\varphi$  is the work function of the instrument and the value is 5.05 eV). These have a net effect on the kinetic energy of the free electrons with a concomitant change in the electron binding energy. XPS detects the changes in the binding energy while the distance between the inflection points (IP) allows for the determination of  $\Delta V$  (Fig. 10(a–e)).  $\Phi$  could then be calculated. The work functions of  $\text{WO}_3$ ,  $\text{In}_2\text{O}_3$ ,

$\text{Ti}_4\text{N}_3\text{T}_x$ , WI-30 and 3-TWI-30 were determined to be 7.311, 5.75, 7.980, 6.13, and 5.919 eV, respectively.

An S-scheme structure was constructed based on the obtained band edges (VB, CB), work functions and Fermi levels.  $\text{In}_2\text{O}_3$  forms a reduction photocatalyst (RP) with higher CB and VB positions relative to  $\text{WO}_3$  as an oxidation photocatalyst (OP). Upon closer contact, electrons in  $\text{In}_2\text{O}_3$  diffuse to  $\text{WO}_3$  resulting in the creation of electron depletion and accumulation layers in  $\text{In}_2\text{O}_3$  and  $\text{WO}_3$ , respectively (Fig. 11f).

$\text{WO}_3$  becomes positively charged while  $\text{In}_2\text{O}_3$  becomes negatively charged.<sup>56</sup> The flow of charge carriers, in consequence, induces an internal electric field (IEF) flowing from  $\text{In}_2\text{O}_3$  to  $\text{WO}_3$  accelerating the photoinduced electron transfer from  $\text{WO}_3$  to  $\text{In}_2\text{O}_3$ . When  $\text{WO}_3$  and  $\text{In}_2\text{O}_3$  comes into contact, an equilibration occurs as the Fermi levels align in the position of the least energy. This is achieved through an upward shift in the  $\text{In}_2\text{O}_3$  Fermi level and a downward shift in the  $\text{WO}_3$  Fermi level.<sup>57</sup> The band bending, IEF and coulombic attraction promote recombination between photogenerated electrons in the CB of  $\text{WO}_3$  with holes in the VB of  $\text{In}_2\text{O}_3$ . Consequently, the potent photogenerated electrons in the CB of  $\text{In}_2\text{O}_3$  and the holes in the VB of  $\text{WO}_3$  are preserved for photocatalytic processes, while the ineffective electrons in the  $\text{WO}_3$  CB and the holes in the  $\text{In}_2\text{O}_3$  VB are eliminated (Fig. 11g).<sup>58</sup> The observed interfacial charge-transfer behaviour of the  $\text{In}_2\text{O}_3/\text{WO}_3$  heterojunction accords with the XPS data, in agreement with the S-scheme heterojunction mechanism.<sup>59</sup> The positioning of  $\text{Ti}_4\text{N}_3\text{T}_x$  onto  $\text{WO}_3$  is based on its work function and its Fermi level, where the minimum energy is required for adjusting the Fermi level alignment during equilibration with that of the heterostructure ( $\text{In}_2\text{O}_3/\text{WO}_3$ ). Given the larger work func-

Fig. 9 Proposed band edge diagram.

Fig. 10 Work function of all as-synthesized materials measured by VB XPS and sketches of the internal electric field and charge transfer.

Fig. 11 Internal electric field and charge transfer.

tion of  $\text{WO}_3$  and its lower  $E_f$  closer to that of  $\text{Ti}_4\text{N}_3\text{T}_x$ , the photoinduced electrons can easily flow from the  $\text{WO}_3$  heterojunction to  $\text{Ti}_4\text{N}_3\text{T}_x$  (Fig. 11h). The weak van der Waal forces facilitate the adsorption of  $\text{Ti}_4\text{N}_3\text{T}_x$  onto the photocatalyst surface, where it serves as an electron-trapping center.<sup>60</sup>

## Conclusion

In conclusion, an S-scheme heterojunction photocatalyst was successfully fabricated based on the combination of an oxidative photocatalyst  $\text{WO}_3$  with  $\text{In}_2\text{O}_3$  and  $\text{Ti}_4\text{N}_3\text{T}_x$  MXene as co-catalysts. The pristine materials were prepared *via* solvothermal synthesis, with the binary and ternary composites being prepared *via* an electrostatic assembly followed by calcination. The photoelectrochemical analysis of the as-synthesized materials showed that  $\text{WO}_3$  loaded onto  $\text{In}_2\text{O}_3$  showed improved photoelectrochemical properties. There is a masking effect induced by  $\text{WO}_3$  at loadings above 30 wt%. Furthermore, the introduction of the MXene co-catalyst enhanced the properties of the ternary composite. In addition, the fabricated S-scheme multijunction photocatalyst ( $\text{In}_2\text{O}_3/\text{WO}_3@/\text{Ti}_4\text{N}_3\text{T}_x$ ) has a sufficient light harvesting capability and retained reduction and oxidative potentials for generating photoinduced reactive radicals with potential in energy and environmental remediation. The synthesized photocatalyst is recommended for application in the degradation of emerging pollutants (ARVs) in water.
