Nycterohemeral airborne fungal and bacterial communities and health risks of potential pathogens in Shanghai†

Xueyun Geng,^a Changliang Nie,^{ib}*^a Hui Chen,^a Xu Tang,^b Min Wei,^c Yi Wang,^d Huanxiang Gao,^d Dan Li,^a Mingliang Fang,^a Ruiting Ju,^a Bo Li,^a Haidong Kan,^e Renjie Chen,^e Jinzhuo Zhao,^e Lin Wang,^{ib}*^{ab} and Jianmin Chen,^{ib}*^{abf}

Urbanization-influenced airborne microorganisms and megacity bioaerosols have garnered particular attention due to their importance in the atmospheric environment. Herein, the diurnal variation of airborne microbes in PM_{2.5} between day and night was unveiled by a culture-independent approach and morphological analyses. The results demonstrated that airborne fungi, with values of 8636 copies per m³ (daytime) and 9443 copies per m³ (nighttime), and bacteria, with values of 38 725 copies per m³ (daytime) and 38 613 copies per m³ (nighttime), were observed under improved air quality. The recurrent diel cycle's airborne fungal and bacterial concentrations had no discernible difference. The airborne microbial community structure displayed robustness, in which Formitopsidaceae, Meruliaceae, Aspergillaceae, Rhizobiaceae, Caulobacteraceae, and Moraxellaceae dominated. The LefSE analysis revealed *Sistotrema*, *Moesziomyces* and *Acinetobacter* as diurnal biomarkers and *Cercospora* and *Blastomonas* as nocturnal biomarkers. In assessing the health risks of potential pathogens, the nocturnal samples contained a higher fungal relative abundance (38.52%), and diurnal samples had a higher proportion of potentially pathogenic bacteria (21.92%). SO₂ inhibited the fungal concentrations significantly. The observation of fungi by Scanning Electron Microscope (SEM) revealed the intact cell structure presumably annotated to Basidiomycota and Ascomycota and acted as the independent atmospheric particle matters of which surface harboured chemical composition. This study offers important insights into airborne fungi and bacteria in metropolitan cities, coupled with high throughput sequencing technologies and morphological observation under low PM_{2.5} concentration.

Environmental significance

Airborne microbiota plays significant roles in causing health and climate effects, and its distribution in urban areas has attracted much attention. The fate of airborne microbiota is associated with environmental factors, including air quality and meteorological parameters. Shanghai is a megacity. Despite the improved air quality, the metropolitan airborne microbial community structure displayed robustness and included many potential pathogens. The understanding can help unveil the megacity's airborne bacteria and fungi community and state the environmental effects, including nycterohemeral changes and air pollution, on the airborne microbiota.

1. Introduction

Airborne microbiota is ubiquitous and essential in airborne particulates.¹ The airborne microbes can not only adhere to PM_{2.5} but also directly exist as fine particles.² Atmospheric microbes have attracted attention in recent years^{3–6} as they influence the ecosystem,⁷ play a role in climate change,⁸ and cause potential threats to human health.⁹ Bioaerosols refer to fungi, bacteria, viruses, plant fragments, protozoa, archaea, and algae,⁴ of which fungi and bacteria are currently hot hubs owing to their high proportion of 21% and 70% in atmospheric particle matter, respectively.¹⁰ The airborne microbiota in metropolitan regions has attracted much attention owing to its

potential harmful effects on human health.^{3,11} As urbanization goes on, over half of the people live in cities, and this trend will predictably grow to 70% by the year 2050.^{12,13} The civil lifestyle alters the microbial communities to which people are exposed. For instance, a higher rate of asthma and allergies in urban areas is linked to urban microbial communities.¹² Different cities, such as Beijing,¹⁴ Tianjin,¹⁵ Jinan,¹⁶ *etc.*, can shape specific airborne microbiota. Shanghai is an international megacity with over 24 million permanent residents, and the airborne microbiota received little attention.

Besides the geographical factors, contemporary research indicated that airborne bacteria and fungi are influenced by air quality.¹⁷ More microbes were found in atmospheric particulate matter during polluted days while decreasing under heavily polluted days.¹⁷ In Shanghai, the annual average concentration of PM_{2.5} decreased to 32 $\mu\text{g m}^{-3}$ in 2020 from 62 $\mu\text{g m}^{-3}$ in 2013.¹⁸ Air pollution control has encouragingly made substantial achievements by significantly dropping annual average particulate matter concentrations, but knowledge gaps are still confronted.¹⁹ The contemporary literature mainly focuses on airborne microbial community structure on polluted days,^{20–22} while the features of airborne microbes on ‘clean’ days are poorly understood. In addition, the urban daily anthropological activities following the nycterohemeral patterns might shape the airborne microbial community.²³ Zeng *et al.* (2019) compared the airborne fungal community from diurnal and nocturnal samples and found a higher species richness at night in Wuhan.²⁴ Hu *et al.* (2020) reported that the total bacteria community structure turned similarly in the daytime, while pathogenic bacteria became homogeneous during the nighttime in Hangzhou.²³ The nycterohemeral changes of the airborne microbiota community in Shanghai during clean days remain unknown.

Therefore, we attempt to profile the characteristics of airborne bacteria and fungi communities on clean days and elucidate the urban effects on their discrepancy. The hourly air quality data were recorded to analyze the association with the airborne bacteria and fungi community. qPCR was employed to quantify the airborne microbial concentration. The community composition of diurnal and nocturnal fungi and bacteria communities was revealed through high throughput sequencing (HTS) aimed at the ITS and 16S rRNA gene. Additionally, microscopic observation can provide direct information on airborne particulates,²⁵ and we used the scanning electron microscope (SEM) to observe the particle matter. The present work would provide scientific insights to understand air microbial communities and the impacts of the nycterohemeral discrepancy in the urban atmosphere.

2. Methods and materials

2.1 Sample collection

PM_{2.5} samples were collected at urban sites in Shanghai, the Yangtze River Delta Region of China, from September to October 2020. The urban site was on the rooftop of Shanghai Primary School attached to the Shanghai Teachers' Professional College building, a five-storey building in Huangpu district

(31.21°N, 121.49°E). This building is located in residential dwellings and a commercial area. We collected fifty-two PM_{2.5} samples and classified those based on a diurnal or nocturnal period (details in the ESI†). The quartz fibre filters (QM-A, Whatman International Ltd, U.K.) with 47 mm diameter for PM_{2.5} were obtained using low-volume (16.67 L min⁻¹) air samplers for 11 h 55 min (6 : 05 to 18 : 00 for daytime and 18 : 05 to 6 : 00 for nighttime), as shown in Table S1.† The filters were baked in a Muffle furnace at 500 °C for five hours and then placed into sterilized aluminium foil before being deposited into a sealed bag. The blank filters were collected by placing a sterilized quartz filter inside the sampler without operation. Before sampling, the sampling filter holder and materials used for changing filters were treated with 75% ethanol. The hourly air quality data, including PM₁₀, PM_{2.5}, O₃, NO₂, SO₂, and CO, were obtained from the real-time air quality system established by China's Environmental Monitoring Station of the Ministry of Ecology and Environment. The collected samples were classified based on PM_{2.5} concentration, following clean samples (less than 35 $\mu\text{g m}^{-3}$), slightly polluted samples (from 35 to 75 $\mu\text{g m}^{-3}$), and polluted samples (more than 75 $\mu\text{g m}^{-3}$).²⁶ Detailed information is shown in the ESI, Fig. S1.†

2.2 DNA extraction and qPCR

The samples were cut into small pieces. Then, the total genomic DNA was extracted from the filters using the TIANamp Soil DNA Kit based on the manufacturer's instructions. The bacterial 16S rRNA and fungal ITS genes were detected by qPCR. The primers were chosen 341F (5'-CCTAYGGGRBGCASCAG-3'), 806R (5'-GGACTACNNGGGTATCTAAT-3') and ITS1F (5'-CTTGGTCATTAGAGGAAGTAA-3'), ITS2R (5'-GCTGCGTTCTTCATCGATGC-3'). The qPCR was conducted using the StepOnePlus™ real-time PCR detection system (Thermo). A 20 μL volume contained 10 μL 2 \times TB Green Premix Ex Taq II (Takara), 0.4 μL 50 \times ROX Reference Dye, 0.8 μL of each primer (10 μM), and 2 μL template DNA. The procedure was initiated at 95 °C for 10 min, with 40 cycles of denaturation for 20 s at 95 °C and annealing for 30 s at 55 °C. The last was elongation for 30 s at 72 °C. Three replicates for the qPCR test were carried out, and autoclaved water was chosen as a negative control. We plotted the standard curves using 10-fold serial dilutions of plasmids (10 to 10⁷ copies per mL). A Student's *t*-test was employed to identify significant differences in bacteria and fungi concentrations under different groups.

2.3 PCR amplification

Nested PCR was performed for bacteria and fungi due to the low DNA yield.^{27,28} Primer details and references are listed in ESI Table S1.† ITS1F/ITS4R and ITS1F/ITS2R served as the first and second PCR amplification for fungi. Primers of 27F/1492R and 331F/806R were carried out for the PCR of bacteria. The PCR mixtures contain 15 μL 2 \times buffer, 0.6 μL dNTP, 1.2 μL forward primer (5 μM), 1.2 μL reverse primer (5 μM), 0.6 μL DNA polymerase, ten ng template DNA, and finally, ddH₂O up to 30 μL . The procedure of the first round was initiated for 3 min at 95 °C, 25 cycles of 95 °C for 15 s, 52 °C for 15 s, and 72 °C for 90 s (for

bacteria) or 60 s (for fungi), and extended at 73 °C for 5 min. The second round was initiated for 3 min at 95 °C, 25 cycles of 95 °C for 15 s, 52 °C for 15 s, and 72 °C for 30 s, and extended at 73 °C for 5 min. PCR was performed in triplicate to reduce the amplification variability, and the final PCR product was a mixture of triplicates. The PCR product was extracted from 2% agarose gel and purified using the AxyPrep DNA Gel Extraction Kit (Axygen Biosciences, Union City, CA, USA) according to the manufacturer's instructions and quantified using a Quantus™ Fluorometer (Promega, USA).

2.4 Illumina MiSeq sequencing and data processing

Purified amplicons were pooled in equimolar and paired-end sequenced on an Illumina MiSeq PE300 platform (Illumina, San Diego, USA) according to the standard protocols by Majorbio Bio-Pharm Technology Co. Ltd (Shanghai, China). The raw 16S rRNA and ITS gene sequencing reads were demultiplexed, quality-filtered using fastp version 0.20.0 (ref. 29) and merged using FLASH version 1.2.7.³⁰ The 300 bp reads were truncated at any site receiving an average quality score of <20 over a 50 bp sliding window, and the truncated reads shorter than 50 bp were discarded, and reads containing ambiguous characters were also discarded. Only overlapping sequences longer than ten bp were assembled according to their overlapped sequence. The maximum mismatch ratio of the overlap region is 0.2. Reads that could not be assembled were discarded. Samples were distinguished according to the barcode and primers. The sequence direction was adjusted, and the exact barcode matching and two nucleotide mismatches were in primer matching. Operational taxonomic units (OTUs) with a 97% similarity cutoff^{31,32} were clustered using UPARSE version 7.1,³² and chimeric sequences were identified and removed. The taxonomy of each OTU representative sequence was analyzed using RDP Classifier version 2.2 (ref. 33) against the 16S rRNA database (SILVA) and fungal database (UNITE) using a confidence threshold of 0.7.

2.5 Data analysis

Significantly different bacterial and fungal concentrations between day and night were analyzed by a one-way ANOVA test at 95% confidence intervals ($*p < 0.05$). Subsequent analyses of alpha and beta diversity were performed based on normalised data. Alpha diversity will reveal the complexity of species diversity, including Sobs, Chao1, Shannon, and Good-coverage.¹⁷ Beta diversity analysis was used to evaluate the differences of samples in species complexity. LEfSe analysis was employed to detect the differential abundant features in the two groups and estimate the effect size of each differentially abundant feature by using linear discriminant analysis (LDA > 3.0). Spearman correlations between the microbiota and air quality were analyzed. The metabolic function of the bacterial community can be predicted according to the FAPROTAX database. FUNGuild is an environmental function database of fungi. Based on the existing literature's support, fungal ecological functions were classified.³⁴

2.6 The individual particle sample collection

Individual particle samples were collected on copper (Cu) TEM grids coated with carbon film (carbon type-B, 300-mesh copper; Tianld Co., China) by a single-stage cascade impactor called the DKL-2 sampler (Genstar Electronic Technology, China).²⁵ We collected one sample for 15 min, and the sample details are shown in the ESI.†

2.7 Scanning electron microscopy analysis

Scanning electron microscopy (SEM) was performed using an electron microscope that can determine the particle surface by scanning it with a high-energy beam of electrons in a raster scan pattern. An SEM system (Apreo, Thermo Fisher) with a field emission gun operating at 3–4 kV was used to obtain detailed information on the surfaces of individual aerosol particles. The SEM can efficiently obtain coarse particles' surface morphology and size without any coating process on the substrate. We used SEM to observe the surface morphology of the particles.

2.8 Daily inhalation evaluation

The human inhalation daily intake (DI) of the airborne micro-organism, including potential pathogens, was estimated by using the following equations:

$$DI_{ITS}(\text{copies per day}) = \text{fungal genetic concentrations}(\text{copies per m}^3) \times \text{inhalation rate}(\text{m}^3 \text{ day}^{-1}) \quad (1)$$

$$DI_{16S}(\text{copies per day}) = \text{bacterial genetic concentrations}(\text{copies per m}^3) \times \text{inhalation rate}(\text{m}^3 \text{ day}^{-1}) \quad (2)$$

$$DI_{\text{pathogen}}(\text{copies per day}) = \text{genetic concentration}(\text{copies per m}^3) \times \text{relative abundance}(\%) \times \text{inhalation rate}(\text{m}^3 \text{ day}^{-1}) \quad (3)$$

The ITS and 16S rDNA concentrations were quantified by qPCR, and the relative abundance was obtained from HTS. The inhalation air rate was set at 20 m³ day⁻¹.^{35,36}

3. Results and discussion

3.1 The variation in microbial concentration

The ITS and 16S rRNA gene concentration revealed the airborne microbial concentration by qPCR determination, as shown in Fig. 1. The diurnal fungal ITS gene concentration ranged from 995 to 23 529 copies per m³, with an average value of 8636 copies per m³, lower than that in the nocturnal sample that fluctuated between 634 and 28 669 copies per m³, with an average value of 9443 copies per m³. Fungal ITS gene concentration did not exhibit a significant difference between day and night ($p > 0.05$), although some scholars reported that fungi could become dominant at nighttime when relative humidity rose and temperature declined.^{23,37} The bacterial 16S rRNA gene concentration ranged from 31 882 and 43 048 copies per m³ in the diurnal samples and 32 426 and 43 493 copies per m³ in the nighttime. The average values of the 16S rRNA gene were 38 725 and 38 613 copies per m³, corresponding to the diurnal and nocturnal samples. Due to

Fig. 1 The airborne fungal ITS gene and bacterial 16S rRNA gene concentrations (copies per m^3) for diurnal and nocturnal samples using qPCR tests. The line represents the $PM_{2.5}$ concentration.

anthropogenic activities, they have reported a higher total bacterial concentration in diurnal samples than in nocturnal samples.²³ However, it was not apparent in the present study ($p > 0.05$).

The fungal ITS gene concentration was lower than the bacterial 16S rRNA gene because the size of fungal particles was generally more prominent than bacterial particles. The suspended fungi often refer to the intact spores or hyphal fragments, and some multicellular spores exceed ten μm .² The diameters of unicellular fungal spores usually range from 1 to 10 μm , with only fractions of airborne fungi with a diameter of less than one μm .² Conversely, the bacterial size was smaller from 0.1 to 5 μm and easier to attach to fine particles.² Consequently, the fine particles possess lower fungal concentrations.

Compared to the references (seen in Table 1), the bacterial 16S rRNA gene copy number was similar to the concentration detected in Hangzhou, where the total bacterial DNA copy number was in the order of 10^4 copies per m^3 (ref. 23) but far

lower than that (10^5 cells per m^3) during heavy and severe pollution.¹⁷ However, copies of the 16S rRNA gene could vary significantly in different cities. Ma *et al.* (2023) compared the 16S rDNA copy variation of $PM_{2.5}$ in Harbin, following a seasonal and air quality pattern collection.³⁸ They found that the lowest 16S rDNA concentration occurred in winter with a high $PM_{2.5}$ concentration, and the highest value occurred in spring.³⁸ The spring, summer, and autumn results showed that the increased $PM_{2.5}$ induced a high 16S rDNA concentration. However, some unexpected factors altered the trend. For example, the low temperature lowered microbial metabolism, and the covered snow surface inhibited soil-associated bacteria emission, which resulted in low airborne bacteria concentration.³⁸ The concentration of fungal spores ranged from 10^3 to 10^5 particles per m^3 in the atmosphere,^{39–41} which exceeded the fungal concentration in the present work. The bacterial and fungal concentration in the present work suggested that clean days in Shanghai effectively control airborne fungal counts.

Table 1 Dominant bacteria and fungi among some typical locations

| Location | 16S rDNA concentration | ITS DNA concentration | Sample type | Method | Ref. |
|----------|---|-------------------------------------|------------------------|--------|------------|
| Shanghai | 3.87×10^4 copies per m^3 | 8.63×10^3 copies per m^3 | $PM_{2.5}$ (daytime) | qPCR | This study |
| | 3.86×10^4 copies per m^3 | 9.44×10^3 copies per m^3 | $PM_{2.5}$ (nighttime) | qPCR | |

| | 7.15×10^5 copies per m^3 | | TSP (autumn) | qPCR | |

3.2 The airborne fungal and bacterial community

Basidiomycota and Ascomycota predominated the airborne fungal communities at the phylum level (Fig. 2). Similar results occur in several domestic megacities like Beijing,⁴² Tianjin,¹⁵ and Wuhan.²⁴ These fungal phyla are ubiquitous in foreign international megacities, like Lecce in Italy⁴³ and Madrid in Spain.³ Some research indicated that Ascomycota is more abundant than Basidiomycota, as shown in Table 1. However, the Basidiomycota proportion in the present work was higher than that of Ascomycota, which was in line with Frohlich-Nowoisky's study.⁴⁴ It speculated that the Basidiomycota mainly originated from the atmosphere–biosphere interface, namely, the soil and vegetation surface, and the efficiency of spore dispersion was reinforced in the autumn period.⁴⁴

Fig. 2(b) and (d) display airborne microbial communities at the family level. Formitopsidaceae, Meruliaceae, and Aspergillaceae were the mainly detected genera at the family level, with 26.60%, 21.34%, and 9.14% in diurnal samples and 15.25%, 19.28%, and 17.75% in nocturnal samples. Formitopsidaceae and Meruliaceae were abundant and belong to Agaricomycetes. Agaricomycetes include many mushroom species and are abundant in wet deposition.¹⁵ Some fungal species belonging to Agaricomycetes prefer to release spores under precipitation. For instance, *Schizophyllum*, a typical Agaricomycetes, was frequently detected, with average values of 6.15% (daytime) and 5.17% (nighttime). It is often found in fallen leaves and wood.⁴⁵ It survives in a saprophytic manner and is prone to grow in humid environments.¹⁵ This could explain the high Agaricomycetes proportion in the present work. As Fig. S6† depicts, based on FUNGuild analysis, the fungal function was mainly classified as an undefined saprotroph, which occupied 52.41% and 62.51%, corresponding to the day and night samples, and a wood saprotroph, which accounted for 33.80% and 24.29%, corresponding to the day and night samples.

Proteobacteria was the representative phyla in diurnal (an average value of 87.1%) and nocturnal (an average value of 85.8%) samples, followed by Actinobacteriota, Firmicutes, and Bacteroidota, as shown in Fig. 2(c). Proteobacteria are reported as the most abundant phylum in the atmospheric samples,⁴ whereas the relative abundance varied with different sampling locations, as shown in Table 1. For example, Yu *et al.* (2019) revealed that the Proteobacteria occupied 95.6% of fine particles during the non-hazy days in Changsha.⁴⁶ Liu *et al.* (2018) reported that the average relative abundance of Proteobacteria in Hangzhou was 32.2%.⁴⁷ Rhizobiaceae, Caulobacteraceae, and Moraxellaceae were the top three widely detected families, Fig. 2(d). Rhizobiaceae belongs to *Rhizobiales*, known as plant-associated bacteria,⁴⁸ and spread in soil.⁴⁹ The high fraction of these bacteria implied a significant influence of plant sources on shaping the airborne bacterial community. Urban parks can provide plant and soil-related niches.⁵⁰ Moreover, the seasonal variability also affected the bacterial community structure. As the samples were collected in autumn, agricultural practices such as crop harvesting and ploughing may lead to the plant or soil-associated bacteria being abundant in the airborne particle matter.^{5,10} The peak of soil-derived bacteria commonly occurred in late summer and fell as low soil moisture and increased temperatures resulted in high dust loads,⁵ which could explain the bacterial community structure.

3.3 The diversity of the airborne microbiota community

The fungal and bacterial α -diversity index, including Sobs, Shannon, Chao, and Coverage, is shown in ESI Fig. S2.† Non-metric multidimensional scaling (NMDS) analysis revealed the discrepant characteristics of fungi and bacteria in community composition based on Bray–Curtis. The diurnal fungal (Fig. 3(a)) and nocturnal bacterial samples (Fig. 3(c)) are inclined to cluster. Moreover, the two groups (day and night samples) shared a major area, implying that the nycterohemeral

Fig. 2 The characteristics of airborne fungi and bacteria at phylum and family (top 15 genera only) levels in diurnal and nocturnal samples. (a) and (b) represent the airborne fungi community. (c) and (d) represent the airborne bacteria community.

Fig. 3 The NMDS analysis of the diurnal and nocturnal distinction in (a) fungi and (c) bacteria community. (b) and (d) represent the distribution of airborne fungi and bacteria at the genus level. The bar chart above represents the number of genera contained in each type of group. The bar chart at the bottom left represents the number of genera included in the day and night samples.

discrepancy of the fungal and bacterial communities is not apparent, with stress values of 0.162 and 0.112, respectively. The distinction is partly explained when the stress value is between 0.1 and 0.2. The shared or exclusive fungal and bacterial genus distribution of diurnal and nocturnal samples is shown in Fig. 3(b) and (d). The results illustrated that 71 fungal and 44 bacteria genera conjointly exist in diurnal and nocturnal samples. The daily sample contained 26 fungi and 23 bacteria, less than the nocturnal sample, with 40 fungi and 35 bacteria. The taxonomic diversity of day-to-day or month-to-month samples tended to the robustness of the community structure in one sample site.³⁷

The linear discriminant analysis effect size (LEfSe) was performed to determine the biomarker of diurnal and nocturnal samples from the phylum to the genus level (LDA scores greater than or equal to 3). Fig. S2(c) and (d)† show that two fungal taxa were significantly enriched in the diurnal samples, including *Sistotrema* and *Moesziomyces*, at the genus level. *Cercospora* was enhanced considerably in the nocturnal sample. Seven bacterial taxa were significantly enriched in the daytime, including a taxon at the class level (Gammaproteobacteria), two taxa at the order level (Burkholderiales and Pseudomonadales), two taxa at the family level (Burkholderiaceae and Moraxellaceae), and two taxa at the genus level (*Acinetobacter* and *Blautia*). *Blastomonas* was characterized as

the significantly enriched taxa in the nocturnal samples. The phenomenon can reflect the difference between diurnal and nocturnal microbiota induced by anthropological activities, with an example of the biomarker genus *Acinetobacter*, which is prevalently found in association with the human microbiota.⁵¹

3.4 The potential pathogens

Airborne potential pathogenic or allergic fungi and bacteria adversely affect human health. Owing to the limitation of the next generation high throughput sequencing technologies, Fig. 4 shows the potentially pathogenic fungi and bacteria at the genus level. Through sequence alignment, we found ten potential pathogenic fungi genera with a relative abundance of 24.45% in the daytime and twelve potentially pathogenic genera (38.52%) in the nighttime. The dominant genera in diurnal samples included *Schizophyllum* (6.15%), *Cladosporium* (5.81%), *Penicillium* (4.97%), *Aspergillus* (3.47%), and *Candida* (3.07%). The nocturnal sample was predominantly composed of *Candida* (11.00%), *Aspergillus* (10.53%), *Penicillium* (7.11%), *Schizophyllum* (5.17%), *Cladosporium* (1.92%), and *Stachybotrys* (1.56%). *Candida* species, such as *albicans* and *tropicalis*, are responsible for causing opportunistic human infections.⁵² *Cladosporium*, *Aspergillus*, and *Penicillium* are the sources that cause allergic rhinitis or asthma.⁵³

Fig. 4 The potential pathogen at the genus level in diurnal and nocturnal samples. (a) and (b) represent the potential pathogenic fungi. (c) and (d) represent the potential pathogenic bacteria.

Regarding the potentially pathogenic bacteria, the result displayed 14 bacterial genera detected with a relative abundance of 21.92% in the daytime and 13 potential pathogenic genera (8.42%) in the nighttime. The potentially pathogenic bacteria accounted for a higher percentage during the day than the nighttime. *Acinetobacter* (14.37%), *Ralstonia* (4.00%), and *Burkholderia* (1.11%) were the dominant genera in the diurnal samples (with relative abundance >1%). The pathogenic bacterial community in nocturnal samples was represented by the abundant *Acinetobacter* (2.96%), *Legionella* (2.06%), and *Flavobacterium* (1.55%). *Acinetobacter* is an opportunistic pathogenic bacteria that can cause infection in different human body parts, such as lung infection and pneumonia.⁵⁴ *Ralstonia* is a potential opportunistic plant pathogen.⁵⁵ Some *Burkholderia* strains are known as pathogens of animals, plants, and humans.⁵⁶ Compared to the daytime, the nocturnal samples were more enriched in *Legionella*, which can cause a troublesome Legionnaires' disease and Pontiac fever,⁵⁷ and *Flavobacterium*, which is an opportunistic or true pathogen and induces disease in a variety of organisms, including fish, plants, and humans.⁵⁸

We also used the daily inhalation equation to estimate the total inhalation of airborne fungi, bacteria concentration, and potential pathogens, as shown in Table 2. In line with the relative abundance, the average fungal inhalation concentration reached 86 364 copies, lower than the value (94 425 copies) in the nighttime. The bacteria showed a high value of 387 254 copies in the daytime compared to that (386 134 copies) in the

nighttime. Regarding the potential pathogens, *Schizophyllum* (5311 copies), *Cladosporium* (5015 copies), and *Penicillium* (4296 copies) were the top 3 in diurnal samples, and *Candida* (10 390 copies), *Aspergillus* (9942 copies), and *Penicillium* (6709 copies) were the top 3 in nocturnal samples. *Acinetobacter* (55 650 copies) was the most abundant, followed by *Ralstonia* (15 482 copies) and *Burkholderia* (4280 copies) in the daytime. *Acinetobacter* (11 424 copies) was still the most abundant genus in the nighttime, followed by *Legionella* (7953 copies) and *Flavobacterium* (5994 copies).

The potential pathogenic fungi possessed higher relative abundance in the nocturnal samples compared to the daytime. This phenomenon can probably be ascribed to the prevalence of fungi in the nighttime. The more abundant fungi appeared at night, and the possibility of potentially pathogenic fungi increased. The diurnal sample contained a higher pathogenic bacterial relative abundance. It might be attributed to the high proportion of human-associated genera, *Acinetobacter*,⁵¹ spreading by anthropological activities during the daytime. The 16S rRNA gene function prediction based on FAPROTAX indicated a higher human pathogenic gene in the daytime samples with a significant difference ($p < 0.05$), as shown in ESI Fig. S7.†

3.5 The correlation between the environmental factors and airborne microbiota

Environmental factors play an essential role in airborne microbes. Gaseous pollutant levels (PM_{2.5}, PM₁₀, NO₂, SO₂, and

Table 2 Average values of intake ITS, 16S rDNA, and potentially pathogenic microbial DNA copies

| Inhalation types | Daytime (copies) | Nighttime (copies) |

| <i>Enterococcus</i> | 2 | 1 |

CO) probably increase the similarity of airborne microbial communities in the urban atmosphere,¹⁹ and the pollutants can benefit the growth of pollutant-degrading strains, resulting in higher relative abundances.³ However, there is a view that the effects of air pollution are limited but still have different effects on airborne microorganisms.⁵⁹ Furthermore, the meteorological factors, including temperature, relative humidity, and wind, also determined the airborne microorganism distribution. We constructed the correlation analysis based on the airborne microbiota and environmental parameters, as shown in ESI Fig. S3–S5.† The air quality was recorded as shown in Fig. S1.†

Some work indicated that meteorological parameters played a more critical role in shaping the airborne microbiota, owing to the apparent meteorological variation.⁶⁰ The meteorological factors, including temperature, relative humidity, and wind speed, exerted limited effects on airborne microbes in this work, perhaps influenced by the narrow deviation of environmental parameters. Specifically, the diurnal temperature was only 0.96–1.29 times higher than that of nighttime. The relative humidity ratio between day and night ranged from 0.88 to 1.38. The deviation was too close to differentiate the airborne microbe distribution. All the same, *Paracoccus*, *Acinetobacter*, *Cladosporium*, *Amyloporia*, and *Crustoderma* were significantly positively associated with temperature.

The clean air quality follows a standard (lower than 35 $\mu\text{g m}^{-3}$).^{17,48} The average $\text{PM}_{2.5}$ concentrations were 22.68 $\mu\text{g m}^{-3}$ for diurnal samples and 24.09 $\mu\text{g m}^{-3}$ for nocturnal samples (ESI Fig. S1). ESI Fig. S5† indicates a positive correlation between the fungi and bacterial concentrations and $\text{PM}_{2.5}$ (0.11 and 0.36), but not significantly, probably due to the narrow variation range of $\text{PM}_{2.5}$ concentration. Wei *et al.* (2020) compared the 16S rDNA copy concentration under different air qualities based on the $\text{PM}_{2.5}$ concentrations and demonstrated an uptrend of bacteria concentration accompanied by the pollution increase, but the highest concentration was observed in moderate pollution (up to 10^6 cells per m^3). Subsequently, the bacterial concentration (10^5 cells per m^3) decreased during heavy and severe pollution.¹⁷ $\text{PM}_{2.5}$ usually comes from local fugitive dust emissions and regional transportation⁶¹ or as vehicles to carry the microorganism. The airborne microbiota concentration and diversity are profoundly subjected to the location sources and, in turn, affect local climate, atmosphere, and health.⁶² The responses to the pollutant level of relative abundance are species-dependent. $\text{PM}_{2.5}$ was positively linked with *Schizophyllum* and *Phanerodontia*, respectively, and negatively related to six fungal genera, such as *Ceriporia*, *Bjerkandera*, and *Sistotremastrum*. Two bacterial genera (*Ochrobactrum* and *Micrococcus*) correlated negatively with $\text{PM}_{2.5}$.

SO_2 , which is toxic to microorganisms,^{3,43} exerted adverse effects on fungal concentration, with a value of -0.46 at a significant level ($p < 0.05$), while it played a minor role in shaping the airborne bacteria concentration and community. It adversely affected fungi like *Flavodon*, *Trametes*, and *Schizophyllum*. O_3 commonly inhibits the airborne microbes, but low concentration delivers no evident impact on the airborne microbes.⁶³ NO_2 was positively related to fungi (*e.g.* *Emmia*, unclassified_Meruliaceae, *Sistotrema*), partly because it could be the nitrogen source for supporting the microorganisms.⁶³ The CO emitted by fossil fuel combustion and vehicle exhaust⁶⁴ promoted fungal and bacterial genera, *e.g.*, *Emmia*, *Lentinus*, *Diplomitoporus*, *Sphingobacterium*, *Allorhizobium–Neorhizobium–Pararhizobium–Rhizobium*, and *Staphylococcus*.

3.6 The airborne microbe morphology

The high throughput sequence can help identify the airborne microbiota and the microscopic observation benefits from understanding the airborne microbes' physiological features. Detailed microscopic characteristics can help to distinguish microbiological features, including apical apparatus in the ascus, position, size, and shape. Researchers highlighted the importance of combining HTS and morphological approaches to reveal airborne fungal diversity.^{65,66} We observed the intact cells of airborne fungal spores, which were bigger than two μm , suggesting that the fungal spore was suspended in the air as an independent particle. The detected airborne fungi in more fine particle matter, such as $\text{PM}_{1.0}$, were likely to be segments of fungal cells. The separate fungal particle also acted as a vehicle that can carry some chemical composition, as shown in the position with yellow arrows in

Fig. 5 Scanning electron microscopic images of fungal spores that were speculated to be (A) Basidiomycota and (B) Ascomycota. Spores were of varying sizes and shapes. The scale varies for each panel and is shown at the bottom.

Fig. 5(B). The bacteria could hardly be recognized by direct observation as they are usually globular, rodlike, or fusiform.

Some fungal genera (with white arrows) could be identified based on the cell size and morphological characteristics. Most spores appeared single, as shown in Fig. 5, while some were either aggregated or in chains (Fig. S8[†]). Fig. 5(A) indicates that spores are presumably categorized as Basidiospores based on their distinct morphological characteristics. They mostly appeared in ovoid, subglobular, or elongated shapes with slightly wrinkled surfaces and an apiculus at one end. General morphology further suggested that these spores were Agaricomycetes.^{67,68} Ascospores are shown in Fig. 5(B) and exhibited versatile morphology. We speculated that the spore (Fig. 5(g)) belonged to the genus *Daldinia*. The morphological characteristics of *Daldinia* are that it has an ellipsoidal shape with narrowly rounded ends and transverse striation on its surface.^{68,69} Fig. 5(h) can tentatively be attributed to the conidia of a *Penicillium* or an *Aspergillus* species following Wittmaack studies.⁷⁰

Fig. 5(i)–(l) showed spores which could presumably belong to the *Cladosporium*.^{68,70}

4. Conclusion

This study unveiled the airborne fungi and bacteria in PM_{2.5} in the megacity Shanghai, and nycterohemeral cycle effects on airborne microbiota under good air quality. The improved air quality effectively resulted in low airborne fungal and bacteria counts. For nycterohemeral comparison, no apparent discrepancy was found in fungal and bacterial DNA concentration. The airborne microbial community structure displayed similarities, dominated by Formitopsidaceae, Meruliaceae, Aspergillaceae, Rhizobiaceae, Caulobacteraceae, and Moraxellaceae. In assessing the health risks of potential pathogens, the nocturnal samples contained a higher fungal relative abundance, and diurnal samples had a higher proportion of potentially pathogenic bacteria. The air quality exerted limited effects, except SO₂, which inhibited

the fungal concentrations significantly. The observation of fungi by SEM revealed the intact cell structure and the surface harboured chemical composition. This study provides important insights into airborne fungi and bacteria.
