Faraday Discussions

Accepted Manuscript

This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the <u>Information for Authors</u>.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.

This article can be cited before page numbers have been issued, to do this please use: A. Pradhan, S. Nishimura, Y. Kondo, T. Kaneko, Y. Katayama, K. Sodeyama and Y. Yamada, *Faraday Discuss.*, 2024, DOI: 10.1039/D4FD00038B.

Stabilization of lithium metal in concentrated electrolytes: effects of electrode potential and solid electrolyte interphase formation

Abstract

Lithium (Li) metal negative electrodes have enticed a wide attention for high-energy-density batteries. However, its low Coulombic efficiency (CE) due to parasitic electrolyte reduction has been an alarming concern. Concentrated electrolytes are one of the promising concepts that can stabilize the Li metal/electrolyte interface, thus increasing the CE; however, its mechanism has been still controversial. In this work, we used LiN(SO₂F)₂ (LiFSI) and weakly solvating 1,2-diethoxyethane (DEE) as a model electrolyte to study how its liquid structure changes upon increasing salt concentration and how it is linked to the Li plating/stripping CE. Based on previous works, we focused on Li electrode potential (Ei; with reference to the redox potential of ferrocene) and solid electrolyte interphase (SEI) formation. Although the $E_{
m Li}$ shows a different trend in DEE as compared to conventional 1,2-dimethoxyethane (DME), which is accounted for by different ion-pairing states of Li⁺ and FSI⁻, the E_{Li} -CE plots are overlapped for both electrolytes, suggesting that the E_{Li} is one of the dominant factors of the CE. On the other hand, the extensive ion pairing results in the upward shift of FSI⁻ reduction potential, as demonstrated both experimentally and theoretically, which promotes FSI-derived inorganic SEI. Both E_{Li} and SEI contribute to increasing the Li plating/stripping CE.

Introduction

Lithium (Li) metal negative electrode has been broadly employed in advanced rechargeable batteries. The basic reason for this is that Li (alkali metal group) bears the lowest atomic number among all metal elements, and hence a high theoretical capacity of 3,860 mAh g⁻¹ can be achieved with its plating and stripping reaction. At the same time, a high battery voltage can be attained due to its low electrode potential of –3.0 V vs. standard hydrogen electrode (SHE). However, the Li metal shows a lower plating/stripping Coulombic efficiency (CE), which has hampered its practical applications.^{1,2} The poor CE is due to the strong reducing ability of Li metal. In general, the electrode potential of Li is set far outside the potential window of organic electrolytes, which accelerates the reductive decomposition of the electrolytes. Practically, the reduction products get accumulated on the negative electrode to form an interphase known as the solid electrolyte interphase (SEI).³ This SEI is Li*-conducting but electron-insulating and thus kinetically retards further electrolyte decompositions by blocking direct contact between the electrode and electrolyte.^{4,5} Hence, the nature of SEI is an important factor that dominates the CE of Li metal electrodes.

To minimize the reductive decomposition of the electrolytes, various electrolyte concepts have been proposed. State-of-the-arts are a) concentrated electrolytes, $^{6-11}$ b) localized concentrated electrolytes, 12,13 c) electrolyte additives, 14,15 d) weakly solvating electrolytes, $^{16-18}$ and e) liquefied gas electrolytes, 19,20 etc. Among them, concentrated electrolytes are one of the most fundamental concepts that have suggested the importance of liquid structures, from which various electrolyte design concepts have been developed. We reported in 2014 that concentrated electrolytes with extensive ion pairing promote the preferential reduction of salt anions, thus leading to anion-derived SEI, which may contribute to stabilizing the Li metal/electrolyte interface. 9,21 This mechanism is widely accepted and applied to various electrolyte systems, including aqueous electrolytes. 22,23 On the other hand, we discovered in 2022 that the extensive ion pairing induced by, for example, increasing salt concentration can remarkably upshift the E_{LI} , which decreases the E_{LI} -potential window gap, thus suppressing electrolyte reduction and leading to higher CE of Li plating/stripping. 24 As a result, there are several factors to be discussed for the stabilization mechanism of Li metal electrodes in concentrated electrolytes, namely (i) liquid structure, (ii) E_{LI} , and (iii) SEI formation.

Here, we have chosen LiN(SO₂F)₂ (LiFSI) and 1,2-diethoxyethane (DEE) as a model electrolyte to discuss how each factor contributes to increasing the CE of Li plating/stripping. Compared to conventional 1,2-dimethoxyethane (DME), DEE is known as a weakly Li⁺-solvating solvent due to the steric hindrance effect of the bulkier ethyl groups.^{17,25} The LiFSI/DEE system exhibits a high CE of Li plating/stripping even at a low 1 mol dm⁻³ (M)

concentration and further increased CE at a higher salt concentration. Here we compared Lifsi/DEE3 with FD00038B LifSI/DEE3 with FD00038B LifSI/DEE 3 with FD00038B LifSI/DEE to highlight the effects of Li*-solvation ability as well as salt concentration on (i) liquid structure, (ii) E_{Li} , and (iii) SEI formation. Based on our previous work that highlights E_{Li} , we first evaluated the E_{Li} in LifsI/DEE with reference to the ferrocene redox potential (Fc/Fc+) and discussed its shift based on the liquid structures. Next, we evaluated the CE of Li plating/stripping in LifSI/DEE as compared to LifSI/DME and discussed its relationship with E_{Li} . In addition, with an eye to the SEI formation, we also investigated the reduction potential of the electrolyte with reference to Fc/Fc+ and discussed its variation in salt concentrations based on density functional theory-based molecular dynamics (DFT-MD) simulations.

Results and Discussion

Li electrode potential (ELi)

The E_{Li} was evaluated with reference to Fc/Fc+ redox potential on the Pt electrode as an internal standard of electrode potentials recommended by IUPAC.26,27 For this, a three-electrode cell with Pt as the working electrode and Li metal as the counter and reference electrode was used (Fig. 1a). Fc (1 mM) was introduced to LiFSI/DEE electrolytes. Figure 1b shows cyclic voltammetry (CV) profiles of the Fc/Fc+ redox reaction at various LiFSI salt concentrations (mol kg $^{-1}$, m). The CV profiles are close to a fully reversible system (a peak separation of 59 mV at 25 °C) except for the lowest 0.12 m with high electrolyte resistance. The CV profiles show that the Fc/Fc+ redox potential with reference to Li/Li+ was shifted downward at higher salt concentrations. Supposing that the electrode potential of Fc/Fc+ is constant and independent of the electrolyte used, the different CV redox potentials resulted from the Li reference electrode, suggesting that E_{Li} (with reference to Fc/Fc $^{+}$) changes depending on the electrolyte used. We extracted the Fc/Fc+ redox potential (with reference to Li/Li+) from the half-wave potential at the middle of the oxidation and reduction peaks in the CV and then converted it to ELi (with reference to Fc/Fc+) by just adding a negative sign (e.g., Fc/Fc⁺ potential of 3 V vs. Li/Li⁺ corresponds to E_{Li} = -3 V vs. Fc/Fc⁺). For accurate assessment of $E_{\rm Li}$, we prepared two or three cells for each electrolyte and obtained average $E_{\rm Li}$ values (Fig. S1 and Table S1). Figure 1c and Table S2 summarize the relationship between $E_{\rm Li}$ and salt concentration. As a comparison, the data for LiFSI/DME reproduced from our previous publication are also shown. 24 For both DEE and DME systems, the $E_{
m Li}$ is upshifted concomitantly with increasing salt concentration, suggesting that the reducing ability of the Li metal is weakened at high salt concentration. 24,28 For LiFSI/DEE, the E_{Li} was the highest (-2.95 V vs. Fc/Fc+) for the highest

View Article Online salt concentration (10 m, corresponding to approximately 5 M), and it was the lowest (-3.42 V vs. FC/Fc¹¹) 1039/D4FD00038B lowest salt concentration (0.12 m, corresponding to 0.1 M).

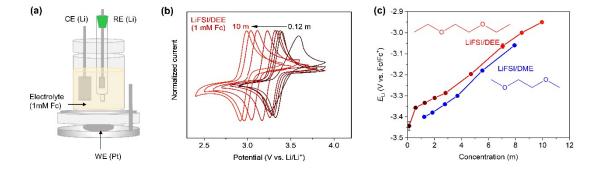

Fig. 1 Evaluation of E_{Li} with reference to Fc/Fc⁺. (a) Schematic of a three-electrode cell with Pt as a working electrode (WE) and Li metal as counter/reference electrodes (CE/RE). (b) Cyclic voltammograms (scan rate: 5 mV s⁻¹) of Fc/Fc⁺ redox in LiFSI/DEE at various LiFSI concentrations (mol kg⁻¹ = m) of 0.12, 0.60, 1.3, 2.0, 2.8, 4.7, 7.1, 8.5, 10 m. The 0.12 m and 10 m correspond to 0.1 M and 5 M, respectively. (c) E_{Li} at various LiFSI concentrations evaluated from the cyclic voltammograms. Average E_{Li} values obtained with two or three cells for each concentration are plotted with error bars (standard deviations). The data for LiFSI/DME are reproduced from ref. ²⁴ as a comparison.

A comparison of DEE and DME systems enables us to discuss from the viewpoint of Li*-solvation abilities. It was reported that DEE has a weaker Li*-solvation ability than DME due to the steric hindrance effect of its bulkier ethyl groups. 17,25 In a low concentration region below 4 m, LiFSI/DEE showed meaningfully higher E_{Li} than LiFSI/DME, suggesting that a weak solvation environment of Li* leads to high E_{Li} . Similar correlations are also reported for dimethoxymethane (DMM), DME, and diglyme (G2), whose solvation abilities are in the order of DMM<DME<G2 and E_{Li} values are in the order of DMM>DME>G2.24 To verify the effect of Li*-solvation abilities, we further measured the E_{Li} in 1.0 M LiFSI/DEE:toluene, in which toluene with almost no Li*-solvation ability was introduced at different molar ratios (DEE:toluene = 10:0, 7:3, and 4:6). As shown in Fig. S2, the three variations of 1.0 M LiFSI/DEE:toluene showed different E_{Li} even at the fixed 1.0 M concentration. The highest E_{Li} (-3.26 V vs. Fc/Fc*) was achieved by introducing the largest amount of toluene, suggesting that the weakly solvating environment of Li* leads to higher E_{Li} .

On the other hand, increasing the salt concentration above 4 m, both LiFSI/DEE and LiFSI/DME showed $\frac{10.1039}{E_{Li}}$ $\frac{10.1039}{E_{Li}}$ $\frac{10.1039}{E_{Li}}$ values at similar molalities. Hence, the E_{Li} in the concentrated region is not related to the Li⁺-solvation abilities of solvent molecules. In such a concentrated region, free solvent molecules that can solvate Li⁺ are remarkably decreased in number, which induces ion pairing of Li⁺ and FSI⁻. Hence, the commonly high E_{Li} values are owing to similar ion pairing states at high concentrations, as discussed later.

In essence, the upward shift of E_{Li} is achieved by (i) increasing salt concentrations or (ii) employing weakly Li⁺-solvating solvents. The resultant high E_{Li} can decrease the E_{Li} -potential window gap, which can weaken the driving force of electrolyte reduction on Li metal. Therefore, concentrated electrolytes and weakly solvating electrolytes are inherently less susceptible to its reduction in conjunction with Li metal. The influence of the E_{Li} on the CE of Li plating/stripping will be discussed in the following sections.

Liquid structure

Next, we discuss how E_{Li} is related to the liquid structure of electrolytes. A theoretical consideration shows that the E_{Li} is linearly correlated with Li⁺ chemical potential in the electrolyte (μ_{Li} +),

$$E_{\rm Li} \propto \frac{\mu_{\rm Li^+}}{F}$$

where F is Faraday constant.²⁴ It should be also noted that Li⁺ chemical potential in the SEI is cancelled out during the derivation of the equation; hence, the SEI chemistry does not theoretically affect the $E_{\rm Li}$.²⁴ Basically, the $\mu_{\rm Li}$ -indicates to what extent the Li⁺ is stable in its environment. Hence, $\mu_{\rm Li}$ - should be closely related to its coordination environment in the electrolyte. To this end, we studied the liquid structure of LiFSI/DEE.

The dissolution of LiFSI in DEE (an aprotic solvent) is illustrated as competitive coordination of DEE and FSI⁻ (both being Lewis bases) towards the Li⁺ (a Lewis acid). There are several random and driven interactions of Li⁺-DEE and Li⁺-FSI⁻ taking place in the solution structure, which generates various LiFSI-DEE solvates such as (a) solvent-separated ion pairs (SSIPs), (b) contact ion pairs (CIPs, FSI⁻ coordinating to a single Li⁺), and (c) aggregates (AGGs, FSI⁻ coordinating to two or more Li⁺) depending on the salt concentrations.²⁹ Broadly, an increase in the salt concentration results in (i) a cut down in free solvent molecules and (ii) a surge in the ionic association (CIPs and then to AGGs).²⁹ Focusing on the coordination environment of Li⁺, it is mainly coordinated by solvent molecules at low concentrations but is forced to be paired with FSI⁻ at high concentrations. To identify such Li⁺ coordination

environments, we study the ion pairing states in LiFSI/DEE at different concentrations using Raman spectroscopy

(Fig. 2a). We focused on the S-N-S vibration peak of FSI⁻ in a range of 650-800 cm⁻¹, whose wavenumber is sensitive to the ion pairing states of Li⁺ and FSI⁻.²⁹ A flat profile was observed for low concentrations (0.12 m and 0.60 m) because of the insufficient amount of FSI⁻ for detection. Over 1.3 m (corresponding to 1.0 M), the S-N-S vibration peak of FSI⁻ was observed, and it was shifted to a higher wavenumber with increasing salt concentration. This higher wavenumber shift has been attributed to more extensive ion pairing of Li⁺ and FSI⁻ from SSIPs to CIPs and AGGs.²⁹ At low concentrations, SSIPs and CIPs are dominant; Li⁺ is solvated by DEE molecules or partially coordinated by FSI⁻ anion. Considering the low E_{Li} (i.e., low μ_{Li^+}) at low concentrations, Li⁺ is highly stable in such solvent-dominant coordination environments. On the other hand, with an increase in the LiFSI concentration, CIPs and AGGs become dominant; Li⁺ is coordinated by more FSI⁻ anions in the -Li⁺-FSI⁻-Li⁺-FSI⁻-Li⁺- aggregate with partial DEE solvation. This situation results in high E_{Li} (i.e., high μ_{Li^+}), thus Li⁺ being highly unstable in such anion-dominant coordination environments.

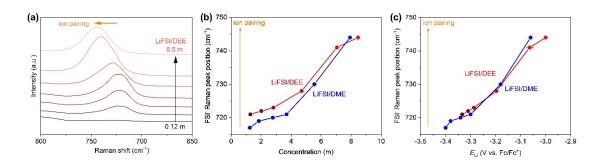

Fig. 2 Spectroscopic analysis on the liquid structures of LiFSI/DEE. (a) Raman spectra of LiFSI/DEE at various LiFSI concentrations of 0.12, 0.60, 1.3, 2.0, 2.8, 4.7, 7.1, 8.5, 10 m. The Raman peak in 650-800 cm⁻¹ is derived from the S-N-S vibration of FSI⁻. The wavenumber resolution was 1 cm⁻¹. (b) Raman peak positions of FSI⁻ in LiFSI/DEE and LiFSI/DME at various LiFSI concentrations. The Raman peak position is an indicator of how extensive FSI⁻ is paired with Li⁺. The data for LiFSI/DME are reproduced from ref. ²⁴ as a comparison. (c) Raman peak positions of FSI⁻ plotted versus E_{Li} .

To theoretically support the spectroscopic analysis, DFT-MD was applied to the dilute (LiFSI:DEE = 1:10 by mol, corresponding to 0.85 m) and concentrated (LiFSI:DEE = 1:2 by mol, corresponding to 4.2 m) electrolytes. Figure 3 shows the supercells and representative coordination environments of Li⁺ in dilute and concentrated electrolytes. In

the dilute electrolyte (Fig. 3b), Li* is mainly solvated by DEE molecules, though FSI* anion is partially coordinated to FD00038B Li*, suggesting that the coordination states are SSIPs and CIPs. On the other hand, in the concentrated electrolyte (Fig. 3e), Li* is more coordinated by multiple FSI* anions, suggesting the presence of AGGs. To quantitatively discuss the local coordination environment of Li*, we analyzed the pair distribution functions, g(r), in the DFT-MD (Figs. 3c and 3f). The integrals of the pair distribution function, shown as N(r), give the coordination number of each atom to Li*. We found that, in the dilute electrolyte, Li* is coordinated by four O atoms of DEE and less than one O atom of FSI* on average (Fig. 3c). In contrast, the average Li* environment in the concentrated electrolyte is that Li* is coordinated by three O atoms of DEE and one O atom of FSI* (Fig. 3f). All these results are consistent with the Raman spectroscopic analysis (Fig. 2a).

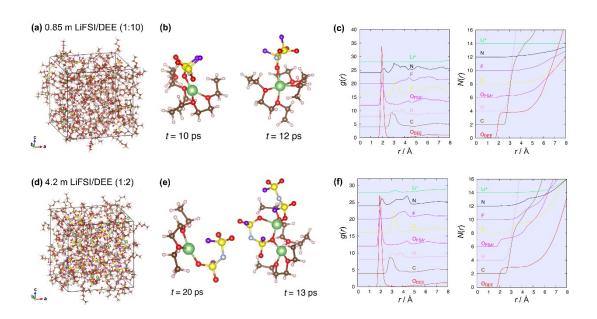

Fig. 3 DFT-MD simulations on the liquid structures of (a-c) dilute (0.85 m, LiFSI:DEE = 1:10 by mol) and (d-f) concentrated (4.2 m, LiFSI:DEE = 1:2 by mol) electrolytes. (a,d) Supercells used. (b,e) Representative local coordination states of Li⁺. (c,f) Pair distribution functions (g(r)) from Li⁺ and integrated coordination numbers (N(r)) to Li⁺. Atom color: Li, green; C, red; H, light pink; O, red; N, blue; S, yellow; F, purple. Li atoms are magnified in size.

Next, we compared the ion-pairing states in LiFSI/DEE and LiFSI/DME electrolytes to discuss the effects of Li⁺-solvation abilities. Figure 2b and Table S2 show the Raman peak positions of the S-N-S vibration of FSI⁻, which is an indicator of how extensive Li⁺ is paired with FSI⁻ to form SSIPs, CIPs, or AGGs.^{24,29} Both electrolytes showed higher

wavenumber shifts of the FSI⁻ vibration with increasing salt concentrations, suggesting progressive formation of long pairs. However, compared at similar concentrations, LiFSI/DEE showed more extensive ion pairing (i.e., higher wavenumber above a resolution error of 1 cm⁻¹) than LiFSI/DME, except at a high concentration region of around 8 m. This indicates that the ion pairing is promoted in a weakly Li*-solvating solvent, which may be a reason for higher E_{Li} for LiFSI/DEE than LiFSI/DME at similar concentrations. To demonstrate this, we made a plot of the E_{Li} vs. Raman peak position of FSI⁻ for LiFSI/DEE and LiFSI/DME (Fig. 2c).²⁴ The plots of LiFSI/DEE and LiFSI/DME are overlapped, and both represent a linear correlation. This suggests that the ion-pairing state of Li*, which can be controlled by modifying salt concentrations or Li*-solvation abilities, subdues the μ_{Li} and hence the E_{Li} in the various electrolyte system.

Li plating/stripping reaction

Having found the link between E_{Li} and liquid structure, Li plating/stripping in LiFSI/DEE was studied in a Cu/Li half-cell configuration. The charge-discharge voltage profiles are presented in Fig. S3. To accurately evaluate the CE of Li plating/stripping at various salt concentrations, we prepared three cells for each concentration. Based on the charge-discharge profiles, we evaluated the average CE of Li plating/stripping (Fig. 4a, Table S2, and Table S3). Here we extracted the CE values of 2nd to 20th cycles for the average CE. The CE in 1st cycle was excluded from the average CE because it is mostly affected by the irreversible capacity for SEI formation, which is not suitable for discussing the stability of Li metal after SEI formation. In both LiFSI/DEE and LiFSI/DME, the average CE increased concomitantly with the increase in salt concentration (Fig. 4a). Such trends have been widely reported in various electrolytes.²⁴

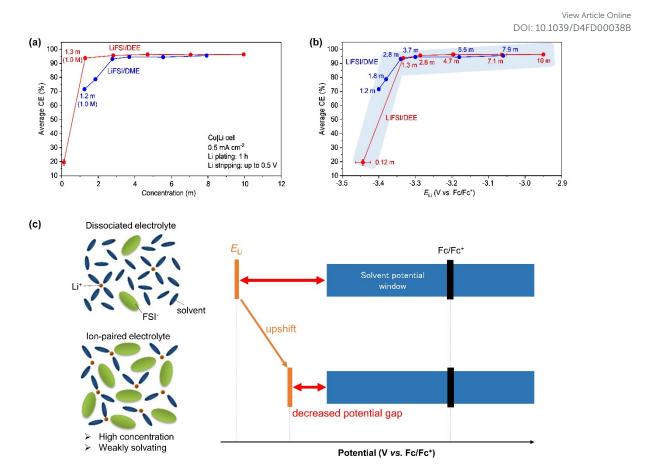

Fig. 4 Average CE of Li plating/stripping in LiFSI/DEE and LiFSI/DME plotted versus (a) LiFSI concentrations and (b) $E_{\rm Li}$. The average CE was evaluated from the 2nd to 20th cycles in three Cu|Li cells for each LiFSI/DEE electrolyte. The error bars are standard deviations. The current density was 0.5 mA cm⁻². Li plating on Cu was performed for 1 h, followed by Li stripping up to 0.5 V. The data for LiFSI/DME, evaluated under a similar condition, are reproduced from ref. ²⁴ as a comparison. (c) Potential diagrams and liquid structures of dilute (dissociated) and concentrated (ion-paired) electrolytes. The upward shift of $E_{\rm Li}$ can decrease the $E_{\rm Li}$ -potential window gap.

Comparing LiFSI/DEE and LiFSI/DME, we found a significant difference in CE at a low concentration region of <2 m. As shown in Fig. 4a, LiFSI/DEE showed a high CE of 93.8 % at 1.3 m (corresponding to 1.0 M), while LiFSI/DME showed a remarkably lower CE of 71.6 % at a similar 1.2 m (corresponding to 1.0 M). Such a difference was also reported previously, highlighting the usefulness of weakly Li⁺-solvating solvents, but its mechanism was not clear. Inspired by our previous paper, here we focused on the E_{Li} as an influential factor and replotted the average CE versus the E_{Li} in both electrolyte systems (Fig. 4b). We found that the plots of LiFSI/DEE and LiFSI/DME are

overlapped with each other; different electrolytes with similar E_{Li} values result in similar average CE values. It should FD00038B also be noted that, even for weakly Li⁺-solvating DEE, further dilution from 1.3 m (1.0 M) to 0.12 m (0.1 M) LiFSI/DEE resulted in much lowered CE of only 19.6 %. This can be also accounted for by the E_{Li} -CE correlation because the E_{Li} is significantly lower at 0.12 m (-3.44 V vs. Fc/Fc⁺) than that at 1.3 m (-3.33 V vs. Fc/Fc⁺). All the results suggest that the E_{Li} is one of the dominant factors of the CE for Li plating/stripping.

Next, we discuss how the E_{Li} affects the Li metal CE or the stability of Li metal/electrolyte interface (Fig. 4c). The E_{Li} is usually far below the cathodic limit of the potential window of organic electrolytes. However, when the E_{Li} is upshifted by forming extensive Li⁺-FSI⁻ pairs in electrolyte, the gap between the E_{Li} and the potential window can be decreased.²⁴ Since the E_{Li} -potential window gap corresponds to the driving force for the reductive decomposition of the electrolyte (or the reducing ability of Li), the decreased gap can prevent the unnecessary reductive decomposition of the electrolyte, thus leading to higher CE of Li plating/stripping. This way, the Li loss is minimized in an electrolyte with high E_{Li} , which brilliantly paves the path for longer cycling life of Li metal batteries.

It is also worth noting that there is a change in trend in the E_{Li} -CE correlation. Below $E_{Li} = -3.33$ V vs. Fc/Fc⁺, the CE is drastically increased with increasing E_{Li} , whereas above $E_{Li} = -3.33$ V vs. Fc/Fc⁺, the CE is only gradually increased. As a result, there should be at least two mechanisms that describe the E_{Li} -CE correlation. At present, however, it is an open question what the two mechanisms are and what the E_{Li} for the trend change (-3.33 V vs. Fc/Fc⁺) means.

Electronic structure and SEI formation

Having established the E_{Li} as an influential factor, we next discuss other factors, namely (i) Li deposition morphology and (ii) SEI formation. The two factors have been widely studied for various dilute and concentrated electrolytes, including the specific cases of LiFSI/DEE and LiFSI/DME (both 1 M and 4 M).²⁵ For (i), Li is deposited in a rounded shape in both LiFSI/DEE and LiFSI/DME, and there is no remarkable difference between low (1 M) and high (4 M) salt concentrations.²⁵ Hence, (i) Li deposition morphology may not be a major factor that accounts for the high CE in weakly solvating solvents as well as at high concentrations. As for (ii), a widely accepted notion is that, in concentrated electrolytes, Li-salt anion is preferentially reduced over solvent to generate inorganic-rich SEI, which can stabilize the Li metal/electrolyte interface to prevent unfavorable electrolyte decomposition.⁹ We proposed this mechanism in 2014 based on the unique electronic structure at high concentrations, in which the lowest unoccupied molecular orbital (LUMO) energy level of Li-salt anion is shifted downward to be more susceptible to

reduction.^{9,21} Hence, when discussing the concentration effect, we need to consider the electronic structure and FD00038B resulting SEI chemistry as well.

For LiFSI/DEE, the SEI on Li has been reported in detail at low (1 M) and high (4 M) concentration.²⁵ A unique feature of this specific electrolyte is that, even at the low (1 M) concentration, the SEI is derived primarily from LiFSI, thus being rich in inorganic species with Li, F, O, and S elements.²⁵ As a result, there is no remarkable difference in SEI chemistries in 1 M and 4 M LiFSI/DEE. Hence, the observed gradual increase in the CE (93.8 % to 96.3 %, Fig. 4a) from 1.3 m (1.0 M) to 10 m (over 4 M) LiFSI/DEE cannot be accounted for by the SEI chemistries. The increased CE may result from the upshift of E_{Li} that can decrease the E_{Li} -potential window gap.

To understand this similar SEI formation process in dilute and concentrated LiFSI/DEE, DFT-MD was applied to the dilute (LiFSI:DEE = 1:10 by mol, corresponding to 0.85 m) and concentrated (LiFSI:DEE = 1:2 by mol, corresponding to 4.2 m) electrolytes. Figures 5a and 5b shows the projected density of states (PDOS) of equilibrium trajectories. The curves in blue and red denote the density of electronic states of LiFSI and DEE, respectively. To discuss the electrolyte reduction, we focus on the lowest edge of the conduction bands (i.e., unoccupied orbitals), which corresponds to the LUMO and directs the nature of reduction reactions. Notably, the LUMO structures of the PDOS profiles are not remarkably different in dilute and concentrated LiFSI/DEE; in both electrolytes, the LUMO is mainly composed of FSI⁻. This means that under a reducing atmosphere (e.g., on Li metal), FSI⁻ receives an electron and thus is reduced to form FSI-derived SEI. The similar LUMO structures at low and high concentrations result from two factors. First, there is only a small difference in the ion pairing states of FSI- (SSIPs and CIPs in both cases) owing to the weakly solvating nature of DEE (Fig. 3). Second, the inherently high unoccupied orbital level of ethers (i.e., high reduction stability) makes the unoccupied orbital of FSI to be the lowest energy level at any concentrations. This accounts for the similar SEI chemistries observed for dilute and concentrated LiFSI/DEE. This theoretical study indicates that weakly solvating solvents are useful in promoting the preferential reduction of FSI for inorganic-rich SEI formation as well as in increasing the E_{Li} , both of which are beneficial to stabilizing the Li metal/electrolyte interface.

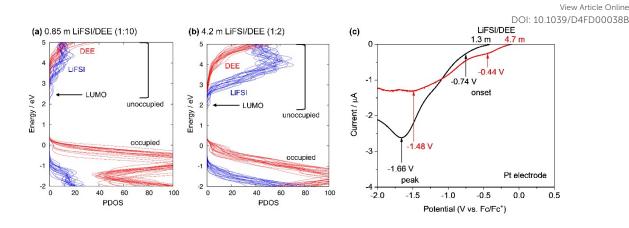

Fig. 5 Theoretical and experimental investigations on FSI $^-$ reduction potential. PDOS profiles of (a) dilute (0.85 m, LiFSI:DEE = 1:10 by mol) and (b) concentrated (4.2 m, LiFSI:DEE = 1:2 by mol) electrolytes. (c) LSV curves of Pt electrode in 1.3 m and 4.7 m LiFSI/DEE at 1 mV s $^-$ 1. The onset and peak potentials of reduction reactions are indicated. The onset potential was defined at the cathodic current flow of 0.25 μ A.

Another notable feature of the PDOS profiles is that the lowest edge of the unoccupied orbitals of FSI⁻ is shifted downward at high concentrations, which is also observed in other concentrated electrolytes. ^{9,21} This downward shift is qualitatively explained by the coordination of Li⁺ (a strong Lewis acid) to FSI⁻, which results in partial electron donation from FSI⁻ to Li⁺. This electronic feature indicates that the reduction potential of FSI⁻ is upshifted at higher concentrations, thus promoting the reduction of FSI⁻ to generate inorganic SEI. To experimentally identify the reduction potential, linear sweep voltammetry (LSV) was performed for a Pt electrode in 1.3 m (1.0 M) and 4.7 m (3.0 M) using a three-electrode cell with Li metal counter and reference electrodes. Figure 5c shows LSV curves, in which the potential is shown with reference to Fc/Fc⁺. Here we focus on the reduction onset potential, which results from the reduction of FSI⁻ to form inorganic SEI. We found that the reduction onset potential of FSI⁻ was -0.74 V vs. Fc/Fc⁺ in 1.3 m LiFSI/DEE but was upshifted to -0.44 V vs. Fc/Fc⁺ in 4.7 m LiFSI/DEE. This FSI⁻ reduction potential (well over 2 V vs. Li/Li⁺) seems to be quite high but it was also observed in FSI-based ionic liquids with LiFSI salt. ^{30,31} Otherwise, focusing on the reduction current peak, it was also shifted from -1.66 V to -1.48 V vs. Fc/Fc⁺. This upshift in the FSI⁻ reduction potential is consistent with the PDOS profiles.

Discussion

An important attribute of concentrated electrolytes and weakly solvating electrolytes is the extensive on-pairing of FD00038B Li⁺ and FSI⁻. This extensive ion-pairing provides two features to the concentrated electrolytes: (i) an upshift of E_{Li} , resulting from more unstable Li⁺ (i.e., high μ_{Li^+}), and (ii) an upshift of FSI⁻ reduction potential, resulting from partial electron donation from FSI⁻ to Li⁺. The feature (i) weakens the reducing ability of Li metal, while the feature (ii) promotes the formation of FSI⁻-derived inorganic SEI, both of which contribute to stabilizing the Li metal/electrolyte interface and leading to higher Li plating/stripping CE. However, it still needs to be vivid to quantitatively evaluate each contribution.

A thing to note is that the observed E_{LI} -CE correlation may hold true in the presence of similar good SEI. In this study as well as the previous paper, we used LiFSI in all electrolytes, in which LiFSI more or less contributes to the SEI formation in various solvents and at various concentrations, thus highly stabilizing the Li metal/electrolyte interface.²⁴ On the other hand, when using LiPF₆, although similar E_{LI} -CE correlation was observed, the CE values were much lower than LiFSI in the same solvents.²⁴ This suggests that the SEI chemistry is undoubtedly important to increase the CE. However, even in the FSI-derived good SEI, the interface is only kinetically stabilized outside the potential window. In this situation, the upward shift of the E_{Li} plays a vital role in decreasing the E_{Li} -potential window gap to weaken the driving force of electrolyte reduction.

To achieve 100 % CE for Li plating/stripping, an ultimate goal is to enable a greater upward shift of E_{Li} inside the potential window of the electrolyte. This situation causes no decomposition of Li salt or solvent, leading to SEI-free Li metal electrodes. In this regard, a further question arises to the two upshifts of E_{Li} and FSI⁻ reduction potential; which upshift is larger? To answer this question, the overall potential diagram is presented in Fig. 6. Comparing 1.3 m (1.0 M) and 4.7 m (3.0 M) LiFSI/DEE, the E_{Li} is upshifted by +0.13 V, while the FSI⁻ reduction potential is further upshifted by +0.30 V for the onset and by +0.18 V for the peak. This implies that we cannot shift the E_{Li} beyond the FSI⁻ reduction potential; hence, the reduction of FSI⁻ is inevitable on Li metal. This difficulty lies essentially in the fact that both (i) upshift of E_{Li} and (ii) upshift of FSI⁻ reduction potential are currently achieved by the same strategy of forming extensive ion pairs. To overcome this situation, the upshift of E_{Li} (i.e., higher μ_{Li}) must be achieved independently of ion pairing. This requires a full reconsideration of the design concept of both anion and solvent but may be a promising step forward.

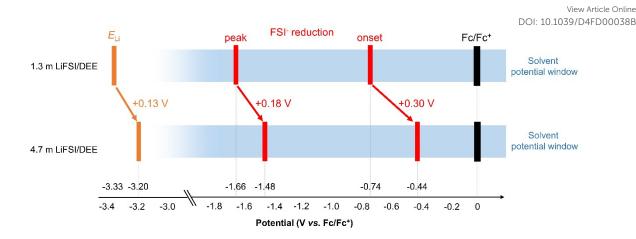

Fig. 6 Potential diagram of dilute (1.3 m) and concentrated (4.7 m) LiFSI/DEE that highlights the upward shift of E_{Li} and FSI⁻ reduction potential.

Conclusions

Using LiFSI/DEE as a model electrolyte, we studied the effects of salt concentration and solvation ability on the liquid structure, the shift of E_{Li} , and the shift of FSI⁻ reduction potential and discussed their contributions to stabilizing the Li metal/electrolyte interface and increasing the Li plating/stripping CE. Generally, increasing the salt concentrations or employing weakly Li⁺-solvating solvents leads to more extensive ion pairing of Li⁺ and FSI⁻ (i.e., from SSIPs to CIPs and AGGs). This structural feature stabilizes the Li metal/electrolyte interface and thus increases the Li plating/stripping CE in two ways. First, the extensive ion pairing decreases the LUMO level of FSI⁻ owing to the strong Lewis acidity of Li⁺, which results in the upward shift of the FSI⁻ reduction potential to promote inorganic SEI formation. Second, increasing the extent of ion pairing can shift the E_{Li} upward owing to the unstable Li⁺ (i.e., increased μ_{Li} ⁺), which decreases the E_{Li} -potential window gap and weakens the driving force of electrolyte reduction. As a result, there is a clear correlation between E_{Li} and CE in various solvents.

There are still many open questions as listed below.

- 1. Which extent do the two factors (ELI and SEI) contribute to stabilizing the Li metal/electrolyte interface?
- 2. Why is the FSI⁻-derived SEI good? Is there any alternative for FSI⁻?
- 3. How does the solvent reduction potential change at high concentrations?

View Article Online DOI: 10.1039/D4FD00038B

4. How is the $\it E_{\rm Li}$ or $\it \mu_{\rm Li^+}$ theoretically described and linked to the liquid structure?

5. Is it possible to independently shift the ELi and FSI reduction potential without controlling the ion pairing state?

6. Can the $E_{\rm Li}$ be moved into the potential window and achieve an SEI-free Li metal electrode?

Experimental

Materials

LiFSI was provided by Nippon Shokubai. Ferrocene (Fc) and DEE were purchased from Sigma Aldrich and Tokyo Chemical Industry, respectively. DEE was dried to a H_2O content of 16 ppm (Karl Fischer titration) with activated molecular sieves. Super dehydrated toluene (H_2O content of 6 ppm) was purchased from Fujifilm. All the electrolytes were prepared by adding LiFSI to solvent in an argon-filled glove box. For the evaluation of the Li electrode potential (E_{Li}), 1 mM Fc was added to the electrolyte.

Electrochemical measurement

All the electrochemical measurements were done in argon atmosphere. For the E_{Li} measurement, a three-electrode cell, with Pt as the working electrode and Li metal as the counter and reference electrodes, was used. The temperature of the cell was maintained at 25°C for 2 hours using a thermostatic oven. The cell was then subjected to cyclic voltammetry (CV) with Celltest 1470E, Solartron. The redox potential of the Fc/Fc+ couple was measured with reference to the Li reference electrode, and the E_{Li} of the various electrolytes was evaluated given that the redox potential of Fc/Fc+ is constant.

Electrochemical Li plating/stripping tests were performed using Cu|Li coin cells with various electrolytes (not containing Fc). The surface area of the Cu electrode was 1.13 cm². The coin-cell parts were purchased from Hohsen. Cu foil and Li foil were purchased from Hohsen and Honjo Metal, respectively. A glass fiber (GC-50, Advantec) was used as the separator. The Li plating/stripping tests were conducted with a charge-discharge unit (TOSCAT-3100, Toyo System) at a constant current density of 0.5 mA cm⁻² for 1 h during Li plating on Cu and up to a cut-off voltage of 0.5 V during Li stripping. The average CE (2nd-20th cycle) was calculated, excluding the first cycle because it is mostly affected by SEI formation process.

The FSI⁻ reduction potential was estimated by linear sweep voltammetry (LSV) with VMP3, Biologic using the similar FD00038B cell used for the E_{Li} measurement. A Pt plate is used as the working electrode and Li metal foil is used as the counter and reference electrodes. Using the E_{Li} value in each electrolyte, the observed potential vs. Li/Li⁺ was converted to that vs. Fc/Fc⁺ to show LSV curves.

Material characterization

Raman spectroscopy was applied to understand the liquid structure of the electrolytes with the laser excitation wavelength of 532 nm and the resolution of 0.8 cm⁻¹ employing NRS-5100 spectrometer from JASCO. The instrument was calibrated with a standard Si peak of the wavelength value 520 cm⁻¹. The electrolytes were properly sealed in quartz cells in an argon-filled glove box and were excited using the 532 nm laser.

Computational Details

DFT-MD simulations were performed using CP2K code³². A DZVP-MOLOPT-SR-GTH type mixed Gaussian and plane wave basis sets were used where the cutoff energy of the plane wave was chosen as 400 Ry. The PBE functional³³ with the D3 type semi-empirical van der Waals correction³⁴ and the GTH norm-conserving pseudopotentials³⁵ were employed. In our DFT-MD simulations, the NVT ensemble with a time step of 1 fs was performed using a Nosé-Hoover chain thermostat^{36–38} with the chain length of three. DEE and LiFSI molecules were randomly distributed in the cubic unit cell whose lattice constants were determined by experimental densities of electrolytes. The number of molecules and atoms are summarized in Table S4. Firstly, we roughly optimized the atomic positions by the Hellman-Feynman's force. Secondly, the liquid structures were annealed by the DFT-MD simulations for 30 ps at 450 K. Using the annealed structures, we performed DFT-MD simulation for 30 ps at 300 K. For the trajectories of the last 20 ps were used for the calculations of the pair distribution functions. The structures from 10 ps to 30 ps every 1 ps were chosen to calculate the projected density of states (PDOS).

Author contributions

Y.Y. proposed and supervised the project. A.P., S.N., Y. Kondo, Y. Katayama, and Y.Y. designed the experiments. A.P. and S.N. conducted the experiments. T.K. and K.S. designed and conducted the theoretical calculations. All authors contributed to the discussion. A.P., Y. Kondo, and Y.Y. wrote the manuscript.
