Administering *Lactiplantibacillus fermentum* F6 decreases intestinal *Akkermansia muciniphila* in a dextran sulfate sodium-induced rat colitis model†

Qiuwen He,^{‡a,b,c,d} Tao Zhang,^{‡a,b,c,d} Weiqin Zhang,^{a,b,c,d} Cuijiao Feng,^{a,b,c,d} Lai-Yu Kwok,^{a,b,c,d} Heping Zhang^{a,b,c,d} and Zhihong Sun^{ID *a,b,c,d}

Probiotics are increasingly used to manage gut dysbiosis-related conditions due to their robust ability to manipulate the gut microbial community. However, few studies have reported that probiotics can specifically modulate individual gut microbes. This study demonstrated that administering the probiotic, *Lactiplantibacillus fermentum* F6, could ameliorate dextran sulfate sodium-induced colitis in a rat model, evidenced by the decreases in the disease activity index score, histopathology grading, and serum pro-inflammatory cytokine levels, as well as the increase in the serum anti-inflammatory cytokine levels. Shotgun metagenomics revealed that the fecal metagenomic of colitis rats receiving the probiotic intervention contained substantially fewer *Akkermansia muciniphila* than the dextran sulfate sodium group. Thus, the probiotic mechanism might be exerted by reducing specific gut microbial species associated with disease pathogenesis. A new paradigm for designing probiotics that manage diseases through direct and precise manipulation of gut microbes has been provided through this study.

1. Introduction

The close association between gut microbiota and human health has been demonstrated by a large body of correlational, observational, and fecal microbiota transplantation (FMT) studies conducted in the last decade examining alterations in its composition and function across a range of diseases using high-throughput multi-omics technologies.^{1–4} Metagenomics and metabolomics data from various distinct cohorts have shown changes in the gut microbiome and metabolome between people with the condition and healthy controls, as in the case of inflammatory bowel disease (IBD).^{5,6} IBD is a group of disorders characterized by chronic intestinal inflammation, including Crohn's disease and ulcerative colitis (UC). It is an example of digestive disease in that the gut microbiome and

metabolome are perturbed^{7,8} and clinical remission has been achieved by FMT in some high-quality clinical trials.^{9–11} The encouraging clinical intervention outcomes suggest that the gut microbiome might be a crucial determinant of the onset and progression of the disease and that restoring a healthier gut microbiota could mitigate its symptoms, opening up new clinical management opportunities for IBD and other diseases resulting from gut dysbiosis for which there are currently no cure-all treatments.

Akkermansia muciniphila (*A. muciniphila*) is a mucin-degrading bacterium that has often been detected in the gut of humans and animals with UC.¹² Some studies have reported a reduction in the abundance of *A. muciniphila*,^{13–16} while others have observed the opposite trend,^{17–23} suggesting a potential negative or positive correlation with UC. More importantly, these correlations have been further confirmed by some interventional studies showing that the consumption of *A. muciniphila* can alleviate^{24,25} or aggravate^{26–28} disease process, indicating that it has a dichotomous role in UC. Regardless, attempts to maintain the homeostasis of *A. muciniphila* in the gut would provide new insights into disease prevention and treatment.

Probiotics are “live microorganisms which when administered in adequate amounts confer a health benefit on the host”.²⁹ Evidence is accumulating that probiotics have become one of the most prevalent gut microbiome-management tools for a variety of gut-related disorders due to their robust capacity to modulate the gut microbial community.³⁰ As

reported in multiple studies, a common symptom-alleviating mechanism of probiotics on the disease is through modulating the gut microbiome.^{31,32} However, few studies have pinpointed the effect of probiotics on specific groups of gut microbes. Thus, this study hypothesized that probiotics can target and modulate specific gut bacterial taxa.

To confirm the hypothesis, we evaluated the modulatory effects of a probiotic, *Lactiplantibacillus fermentum* F6 (*L. fermentum* F6), on the gut microbiome in a dextran sulfate sodium (DSS)-induced rat colitis model. We found that probiotic administration to diseased rats could specifically modulate the abundance of intestinal *A. muciniphila* in the rats, which was accompanied by the remission of symptoms of UC. Our research provides a paradigm for probiotic-based precision therapy for gut-related diseases.

2. Materials and methods

2.1. Probiotic strain

The probiotic strain, *L. fermentum* F6, was originally isolated from traditional dairy products in Inner Mongolia, China. It is characterized by a high tolerance to simulated gastrointestinal juice and bile salts and a broad antibacterial activity.³³ Packaged live probiotic powder of *L. fermentum* F6 (200 billion CFU per g) was provided by the Key Laboratory of Dairy Biotechnology and Engineering, Ministry of Education, Inner Mongolia Agricultural University, China.

2.2. Construction of the DSS-induced colitis model and probiotic intervention

All experiments involving rats were approved by the Experimental Animal Ethics Committee of the Inner Mongolia Agricultural University (approval code: NND2021087), following the ARRIVE guidelines 2.0.³⁴ Twenty-four 8-week-old specific pathogen-free male Wistar wild-type rats were obtained from Vital River Laboratories (Beijing, China). The rats were housed in a standard specific pathogen-free environment in the animal house of the Key Laboratory of Dairy Biotechnology and Engineering, Ministry of Education, Inner Mongolia Agricultural University. Every two rats were maintained in an individually ventilated cage (temperature, 22 ± 2 °C; relative humidity, 45 ± 10%; a 12 h light/dark cycle) with *ad libitum* access to water and food. After a 7-day acclimatization period, all rats were randomly assigned to three groups ($n = 8$ each group; ESI Fig. 1†): (1) control group: given drinking water for seven days, followed by daily oral administration of 2 mL sterile saline (Solarbio, Beijing, China) for 14 days; (2) DSS group: given drinking water containing 3% DSS (molecular mass 36–50 kDa, MP Biologicals, Solon, OH, USA) for seven days, followed by daily oral administration of 2 mL sterile saline for 14 days; (3) probiotic group: given drinking water containing 3% DSS for seven days, followed by daily oral administration of 2 mL sterile saline containing probiotics (4×10^9 CFU per day) for 14 days.

The body weight of rats was recorded weekly throughout the animal trial. After two weeks of probiotic intervention, the fecal samples of rats were collected aseptically and stored immediately at –80 °C for subsequent metagenome analysis. Meanwhile, the parameters of weight loss, stool consistency, and fecal occult blood were monitored to determine the disease activity index (DAI) scores according to the guidelines listed in ESI Table 1.†³⁵ Rats were fasted for 12 h before they were sacrificed on day 22 by isoflurane (RWD Life Science, Shenzhen, China) administration. Blood and colonic tissues were collected for further processing and analyses.

2.3. Histopathology evaluation

A segment of the distal colon was cut off, flushed with sterile saline, and then fixed in 4% paraformaldehyde (Solarbio, Beijing, China) at room temperature for 24 h. Paraformaldehyde-fixed colon tissues were embedded in paraffin and sectioned (4 μm thick). Paraffin sections were stained with hematoxylin and eosin (Servicebio, Wuhan, China) using standard protocols. Images were acquired using an upright optical microscope (Nikon Eclipse E100, Nikon, Tokyo, Japan) with an imaging system (Nikon DS-U3, Nikon, Tokyo, Japan). The histopathology of the colon tissues was graded according to the guidelines provided in ESI Table 2.†³⁶

2.4. Enzyme-linked immunosorbent assays

To obtain rat sera, the collected blood samples were centrifuged at 3000 rpm at 4 °C for 10 min after standing at room temperature for 60 min. The obtained sera were stored at –80 °C until enzyme-linked immunosorbent assays for measuring the levels of inflammatory cytokines, including interleukin (IL)-6, IL-10, IL-1β, and tumor necrosis factor-α (TNF-α) with commercial kits (Elabscience, Wuhan, China). The measurements were performed according to the manufacturer's instructions.

2.5. Extraction of fecal DNA and whole-genome shotgun sequencing

Fecal metagenomic DNA was extracted from the frozen fecal samples using a QIAamp Fast DNA Stool Mini Kit (Qiagen, Hilden, Nordrhein-Westfalen, Germany) according to the manufacturer's instructions. The quality of the extracted DNA was assessed with a NanoDrop 1000 Spectrophotometer (Thermo Fisher Scientific, Waltham, MA, USA) and 1% agarose gel electrophoresis. Qualified DNA samples were stored at –80 °C before further analysis.

Sequencing libraries were generated with a NEBNext Ultra II DNA Library Prep Kit (New England Biolabs, Ipswich, MA, USA) following the manufacturer's recommendations. The quality of the constructed DNA libraries was confirmed with a Qubit 2.0 Fluorometer (Thermo Fisher Scientific, Waltham, MA, USA). Libraries were sequenced on a NovaSeq 6000 instrument (Illumina, San Diego, CA, USA). All samples were paired-end sequenced with a 150 bp read length to a targeted data size of 3 GB.

KneadData pipeline (<https://huttenhower.sph.harvard.edu/kneaddata>) was used to preprocess the raw reads, with its primary functions include filtering low-quality sequences *via* Trimmomatic,³⁷ and removing host-contaminated sequences through Bowtie 2.³⁸ The resulting clean data were taxonomically and functionally profiled using HUMAnN2 pipeline.³⁹

2.6. Statistical analysis

All statistical analyses and graphical output of the data were achieved using R (v4.2.3); and the graphics were combined with Adobe Illustrator (v26.5.0). Data are expressed as mean \pm standard deviation.

General data. All data were analyzed by one-way analysis of variance followed by Tukey's test using stats package (v4.3.3). Lowercase letters are used to indicate statistical significance. Different letters indicate statistically significant differences at the level of $P < 0.05$.

Metagenomic data. Taxonomic and functional alpha diversity metrics, represented by Shannon and Simpson indexes, were calculated with vegan package (v2.6-4), and statistically analyzed by Kruskal–Wallis test followed by Wilcoxon rank-sum test using ggpubr package (version 0.6.0). Taxonomic and functional beta diversity metrics were calculated with vegan package (v2.6-4) in combination with ape package (version 5.8), then statistically analyzed by permutational multivariate analysis of variance (PERMANOVA, also known as Adonis analysis, Bray–Curtis dissimilarity, permutations = 999) using vegan package (v2.6-4). Differential species and MetaCyc pathways between the two groups were determined by Wilcoxon

rank-sum test using rstatix package (0.7.2). Spearman's correlation analysis was performed using psych package (v2.4.3). The topological properties of co-occurrence network were calculated using ggClusterNet package (method: spearman, R threshold: 0.6, P threshold: 0.05, v0.1.0). Significance levels are as follows: * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$, **** $P < 0.0001$ and NS (not significant). A P value of < 0.05 was considered statistically significant.

3. Results

3.1. Administering *L. fermentum* F6 ameliorated DSS treatment-induced colitis in rats

To assess the protective effects of *L. fermentum* F6 administration in UC, a DSS-induced colitis rat model was constructed (ESI Fig. 1†). The body weight of all three groups of rats increased as the intervention trial progressed. A significant difference was only seen at day 14 when the increase in body weight was higher in the control and probiotic groups compared with the DSS group ($P < 0.05$; Fig. 1A), suggesting that the probiotic intervention could prevent DSS-related body weight loss.

The DAI score reflects the health conditions of the rats. We observed a significantly higher DAI score in the DSS group compared with the control and the probiotic groups on day 22 ($P < 0.05$; Fig. 1B). Such results were consistent with the colon histopathological examination and grading ($P < 0.05$; Fig. 1C and D). These results suggested that the probiotic intervention could reduce the severity of the disease.

Fig. 1 Dextran sulfate sodium (DSS)-induced colitis was ameliorated by oral administration of *Lactiplantibacillus fermentum* F6 to rats. (A) Body weight change of rats in the control, DSS, and probiotic groups. (B) Disease activity index scores at the end of the animal trial from the three treatment groups. (C) Representative histological images of distal colon sections stained with hematoxylin and eosin (scale bars, 100 μ m) and (D) histological scores of the colon tissue of each experimental group. Statistical differences were evaluated with one-way analysis of variance followed by Tukey's test. Different letters indicate statistically significant differences at the level of $P < 0.05$. Error bars represent standard deviations.

3.2. Administering *L. fermentum* F6 reversed DSS treatment-induced inflammation

To evaluate the level of systemic inflammation of the rats, the serum concentrations of several pro- and anti-inflammatory cytokines were measured on day 22. The levels of all the measured pro-inflammatory cytokines (IL-6, IL-1 β , and TNF- α) were significantly higher in the DSS group compared with the control and probiotic groups ($P < 0.05$; Fig. 2A–C). DSS treatment induced a reduced serum IL-10 level, which was significantly reversed by probiotic supplementation ($P < 0.05$; Fig. 2D).

3.3. Administering *L. fermentum* F6 decreased the abundance of gut *A. muciniphila* in diseased rats

To investigate the changes in gut microbiota in association with colitis and probiotic intervention, a total of 24 stool samples from the three groups of rats were subjected to metagenomics sequencing analysis. The overall fecal metagenome dataset comprised two kingdoms, seven phyla, 11 classes, 14 orders, 28 families, 44 genera, and 86 species (Fig. 3A). The most dominant phyla were Firmicutes and Bacteroidetes (60.12% and 32.94%, respectively). There were 20 species with an average relative abundance greater than 1% across all samples, mainly including *Lactobacillus* sp. ASF360, *Subdoligranulum* unclassified, *Lactobacillus murinus*, *Lactobacillus johnsonii*, *Prevotella copri*, *Bacteroides massiliensis*, *A. muciniphila*, and *Bacteroides caccae* (Fig. 3B).

We then assessed the alpha and beta diversity of the species-level fecal gut microbiota. Both the values of the Shannon and Simpson's diversity indices (representing the alpha diversity) were non-significantly lower in the DSS group compared with the control and probiotic groups (Fig. 3C and D), suggesting that the probiotic intake could help conserve the gut microbial diversity of DSS-treated rats. The beta diversity analysis was assessed through principal coordinate analysis using Bray–Curtis dissimilarity distance, revealing a pronounced difference in the gut microbial community structure

between the control and DSS groups (Adonis test, $R^2 = 0.158$, $P = 0.034$; Fig. 3E) but not between the DSS and probiotic group (Adonis test, $R^2 = 0.053$, $P = 0.588$; Fig. 3F). These results suggested that the DSS treatment drastically affected the gut microbiota structure of the rats, which was not restored by probiotic intake.

Given that the probiotic intervention failed to improve the overall alpha and beta diversity of gut microbiota disrupted by DSS treatment, we then asked whether the probiotics acted on specific gut microbes in UC remission. We first identified significant differential taxa between the control and DSS groups ($P < 0.05$, Wilcoxon rank-sum test), yielding two phyla, two classes, one order, five families, and seven genera (ESI Fig. 2†). Nineteen significant differentially abundant species were identified, 14 and five of which were enriched in the fecal microbiota of the control and DSS groups, respectively (Fig. 4A). Specifically, the fecal microbiota of the control group had significantly more *Lactobacillus* sp. ASF360, *Bacteroides massiliensis*, and *Bacteroides uniformis* but fewer *Bacteroides thetaiotaomicron*, *Bacteroides fragilis*, and *Mucispirillum schaeffleri* compared with that of the DSS group ($P < 0.05$). Next, we identified the significant differentially abundant taxa between the DSS and probiotic groups, yielding one phylum, two classes, two orders, two families, and two genera (ESI Fig. 3†). At the species level, the abundance of one species, *A. muciniphila*, was significantly more in the fecal microbiota of the DSS group than in that of the probiotic group after probiotic intervention (Fig. 4B), indicating that administering *L. fermentum* F6 substantially lowered the intestinal abundance of this species in the diseased rats.

Spearman's correlation analysis was further performed to investigate whether these discriminatory species were associated with the colitis indices (including body weight change, DAI, and histopathology). Our results showed that 14 species enriched in the control group showed weak to moderate degree of negative correlations with DAI and histopathology grade, whereas five species enriched in the DSS group exhibi-

Fig. 2 Administering *Lactiplantibacillus fermentum* F6 to dextran sulfate sodium (DSS)-treated rats lessened inflammation. Serum levels of (A) interleukin (IL)-6, (B) IL-1 β , (C) tumor necrosis factor- α (TNF- α), and (D) IL-10 in rats of the control, DSS, and probiotic groups. Statistical differences were evaluated with one-way analysis of variance followed by Tukey's test. Different letters indicate statistically significant differences at the level of $P < 0.05$. Error bars represent standard deviations.

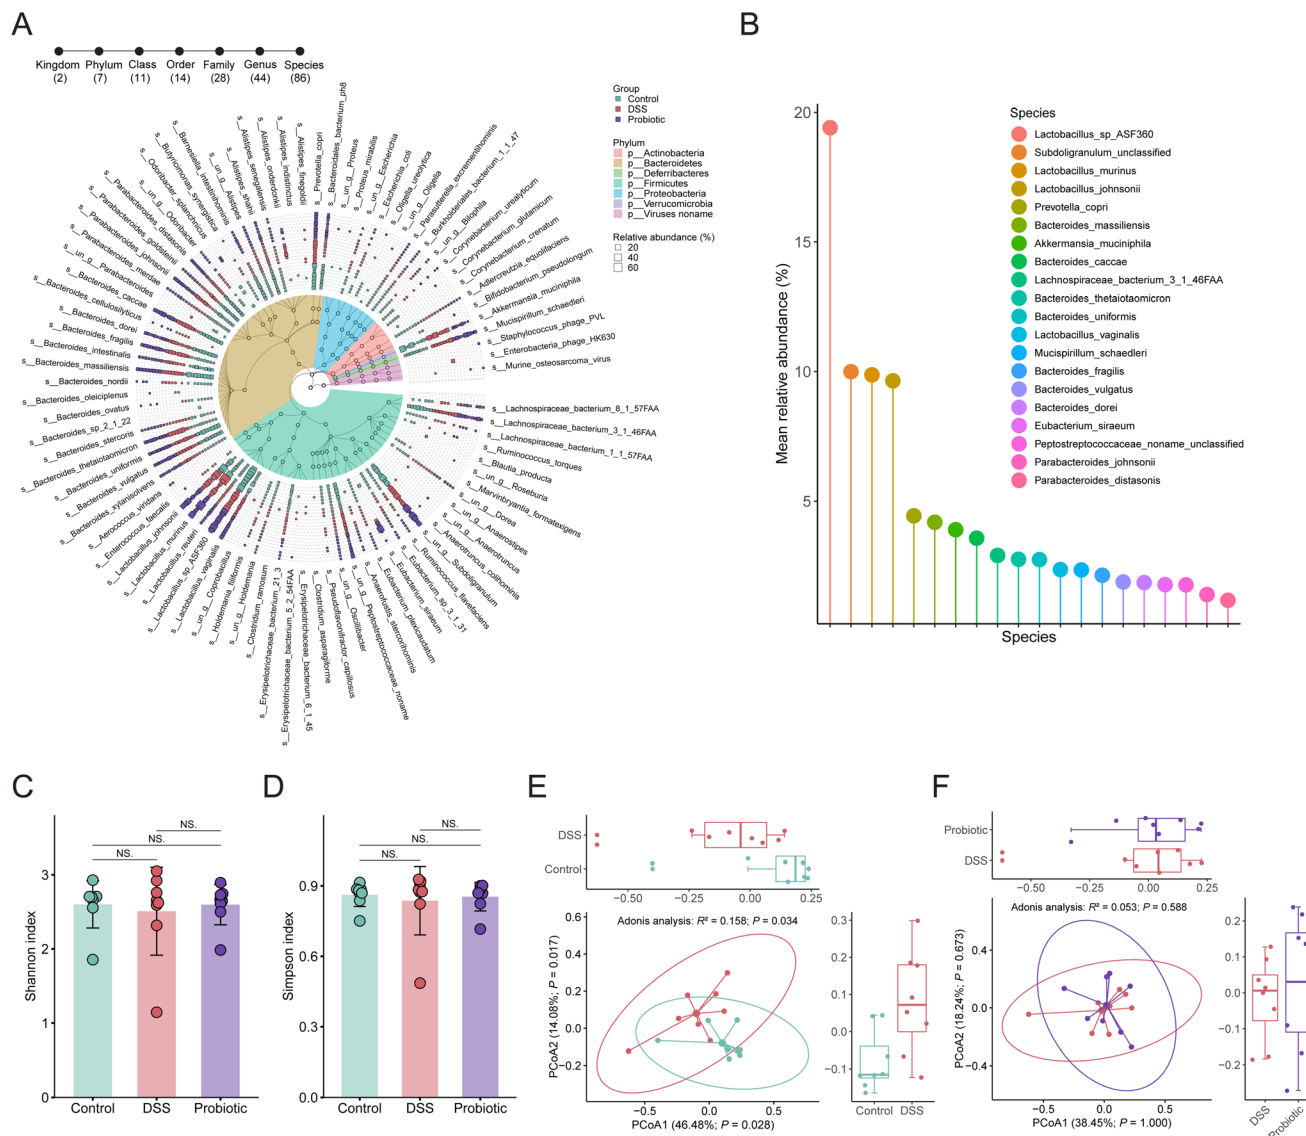

Fig. 3 Alpha and beta diversity analyses of the gut microbiota. (A) Taxonomic annotation of the fecal microbiota. The colors on the taxonomic tree represent the phyla. The circles on the branches of the taxonomic tree from outside to inside are genus, family, order, class, and phylum. The outermost layer of the graph represents the species identified in all samples. The square represents the distribution of relative abundance of each identified species in each sample. (B) Dominant bacterial species with a mean relative abundance greater than 1% in all samples. (C) Shannon and (D) Simpson's diversity indices of the species-level fecal microbiota of the control, dextran sulfate sodium (DSS), and probiotic groups. Statistical differences were evaluated by Kruskal–Wallis test followed by Wilcoxon rank-sum test. NS (not significant). Error bars represent standard deviations. Principal coordinate analysis (Bray–Curtis dissimilarity) score plots of species-level fecal microbiota of (E) control and DSS groups; (F) probiotic and DSS groups. Statistical differences were calculated with PERMANOVA by 999 permutations. Ellipses represent 95% confidence intervals. In the box-plots, the horizontal line represents the median of the data, the lower and upper bounds of the box represent the 25th and 75th percentile of data, and the lower and upper whiskers represent the minimum and maximum of the data. The scattered points in the bars and boxes represent the actual data points.

ted weak to moderate degree of positive correlations with DAI and histopathology grade (Fig. 4C). *A. muciniphila* showed a weak positive correlation with DAI (Fig. 4C). These results provide evidence that administering *L. fermentum* F6 did not drastically change the gut microbiota structure but fine-tuning the gut microbiota of diseased rats that flavored UC remission, accompanied by a drastic reduction in the intestinal abundance of *A. muciniphila*.

3.4. The gut microbiota interconnectedness was enhanced by the DSS treatment but reduced by the probiotic intervention

To investigate how the DSS treatment and probiotic intervention affect the interactions between the gut microbes, we then analyzed the gut microbiota interconnectedness by a co-occurrence network analysis. The fecal microbiota of the DSS group had the strongest interconnectedness among the three sample

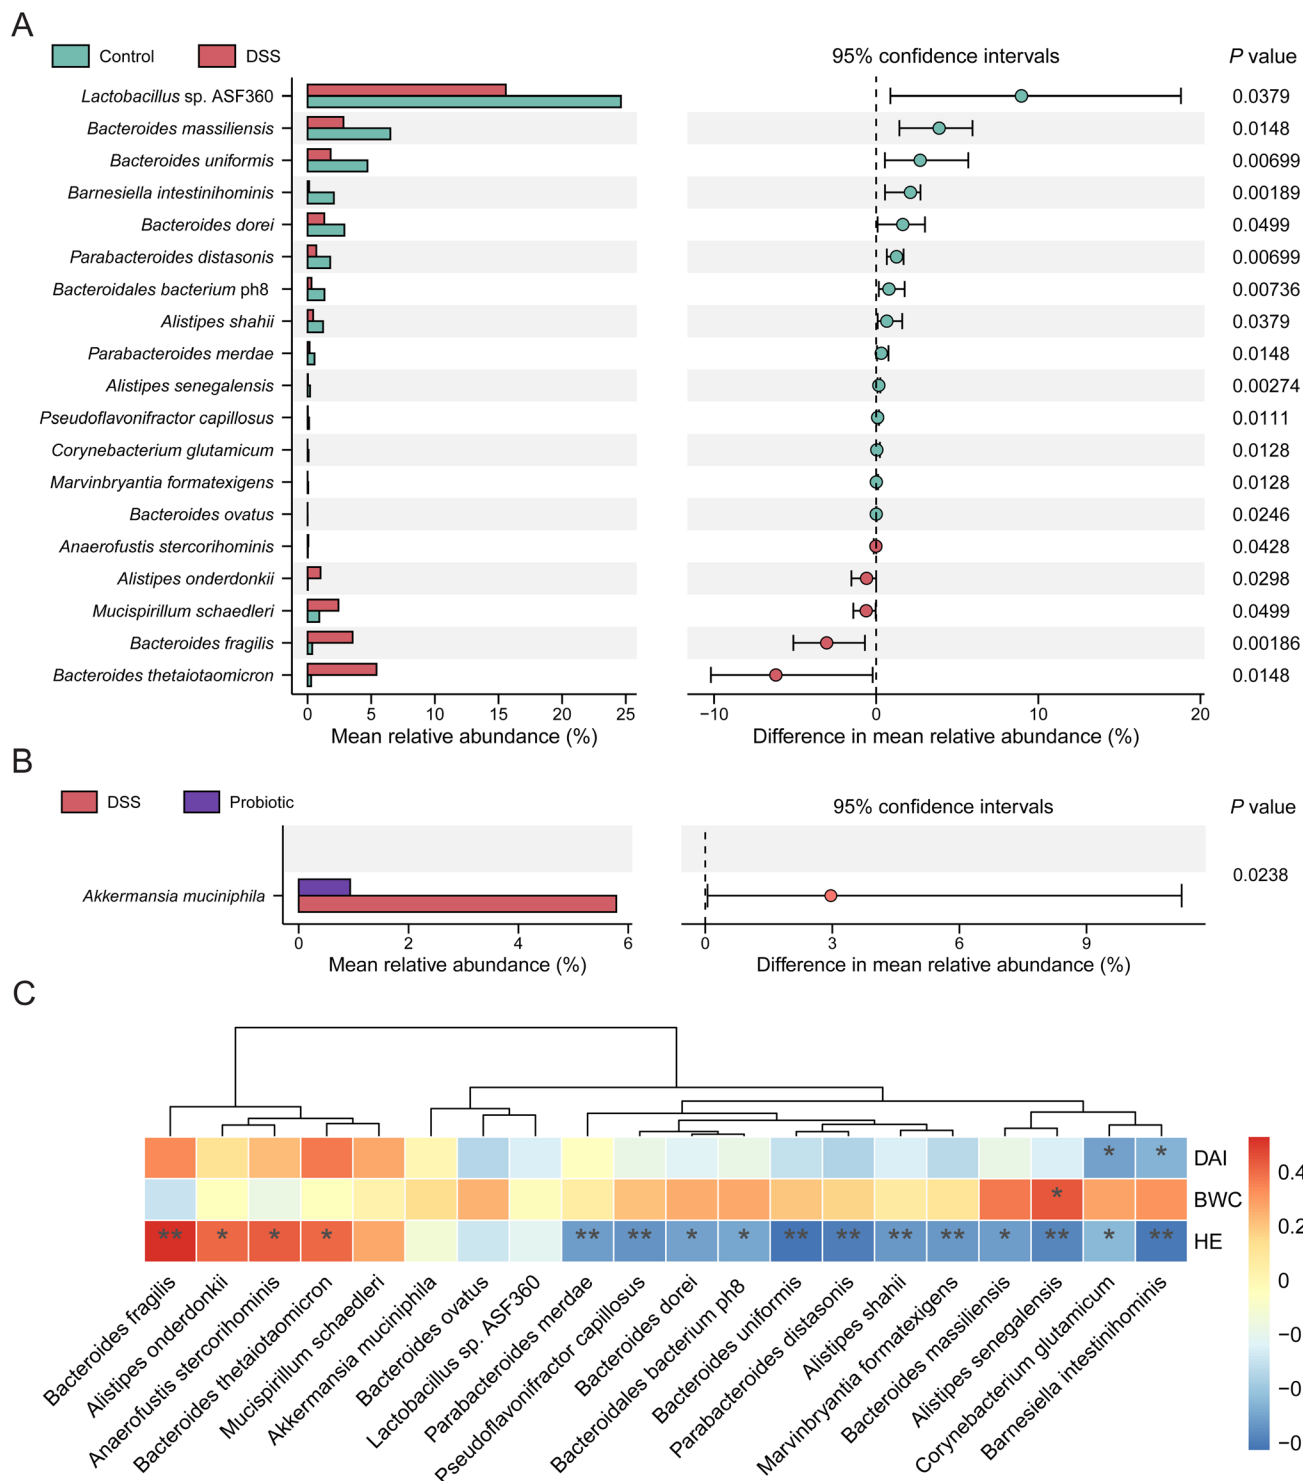

Fig. 4 Differential gut microbes and their association with colitis symptoms. Differentially abundant bacterial taxa between (A) the control and dextran sulfate sodium (DSS) groups; and (B) the DSS and probiotic groups; evaluated by Wilcoxon rank-sum test. (C) Heatmap of the Spearman's correlation between the discriminatory species and clinical parameters after the trial. The clinical parameters included the body weight change (BWC), disease activity index (DAI) score, and histopathology grading (hematoxylin and eosin, HE, stained tissues). The color scale represents correlations; red and blue represent positive and negative correlations, respectively. Significant correlations are marked with * $P < 0.05$; ** $P < 0.01$.

groups (DSS group: 246 correlations including 187 positive and 59 negative correlations; probiotic group: 227 correlations including 168 positive and 59 negative correlations; control

group: 194 correlations including 160 positive and 34 negative correlations; Fig. 5A, B, and ESI Fig. 4,† respectively). These results suggested that the DSS treatment could enhance the

Fig. 5 Interconnectedness of the gut microbiota of the dextran sulfate sodium (DSS) and probiotic groups. Co-occurrence networks of the (A) DSS and (B) probiotic groups based on the Spearman correlation algorithms. The node size represents the relative abundance of each bacterial taxon (arranged clockwise in descending order of abundance along the circle), and the node color indicates phylum. The red and blue lines between nodes represent negative and positive associations, respectively. Only correlations with absolute values of correlation coefficients above 0.6 and P values less than 0.05 were shown.

gut microbiota interconnectedness, while such effect was reversed by the probiotic intervention.

3.5. Administering *L. fermentum* F6 modulated the functional gut microbial metagenome

To investigate how the functional gut microbiota was associated with UC remission, we comparatively analyzed the fecal metagenomic potential of the three groups using the HUMAnN2 pipeline with default parameters. The functional fecal metagenome of both the DSS and probiotic groups had a significantly lower alpha diversity (represented by Shannon and Simpson's diversity indices) than the control group (Fig. 6A and B; $P < 0.05$), suggesting that the DSS treatment disrupted the diversity of MetaCyc pathways encoded in the fecal metagenome, which was not restored by the probiotic intervention. The beta diversity of the functional fecal metagenome was analyzed by non-metric multidimensional scaling (Bray–Curtis dissimilarity distance). On the score plot, the symbols representing the functional metagenome of the control and DSS groups (but not between the DSS and probiotic groups) showed a significant group-based clustering pattern (Adonis test of control and DSS groups: $R^2 = 0.190$, $P = 0.029$; DSS and probiotic group: $R^2 = 0.039$, $P = 0.557$; Fig. 6C). Such results suggested that the DSS treatment disrupted the functional potential of rats' fecal metagenome, and such effect was not reversed by the probiotic intervention.

We then investigated the changes in the distribution of specific MetaCyc pathways of the functional fecal metagenome of the three groups. Our results identified a total of 277 enriched MetaCyc pathways across all samples; and the top

pathways were involved in adenosine ribonucleotides *de novo* biosynthesis (0.12%), starch degradation V (0.09%), and UMP biosynthesis (0.08%) (ESI Fig. 5†).

Three over-represented and 42 under-represented pathways were detected in the DSS group compared with the control group (ESI Fig. 6†). In addition, we identified 13 differential pathways between the DSS and probiotic groups (Fig. 6D), with 11 pathways enriched in the probiotic group, mainly involved in amino acid and carbohydrate metabolism. These results suggested that despite the probiotic intervention did not restore the functional metagenome of DSS-treated rats to the original healthy state, it did improve the functional potential of the intestinal microbiota.

4. Discussion

In the present study, we examined the impact of a probiotic, *L. fermentum* F6, on UC using a rat colitis model induced by DSS. We found that *L. fermentum* F6 administration could ameliorate the disease, as evidenced by the lower DAI, histopathology scores, and serum levels of pro-inflammatory cytokines but higher levels of anti-inflammatory cytokines. Even though administering *L. fermentum* F6 did not change the gut microbiota diversity, the intestinal abundance of *A. muciniphila* notably decreased in the probiotic-supplemented rats compared with the DSS-treated rats. Meanwhile, our correlation analysis revealed that *A. muciniphila* was likely involved in the development of UC. Our study provides intriguing insights into the pathogenesis of UC.

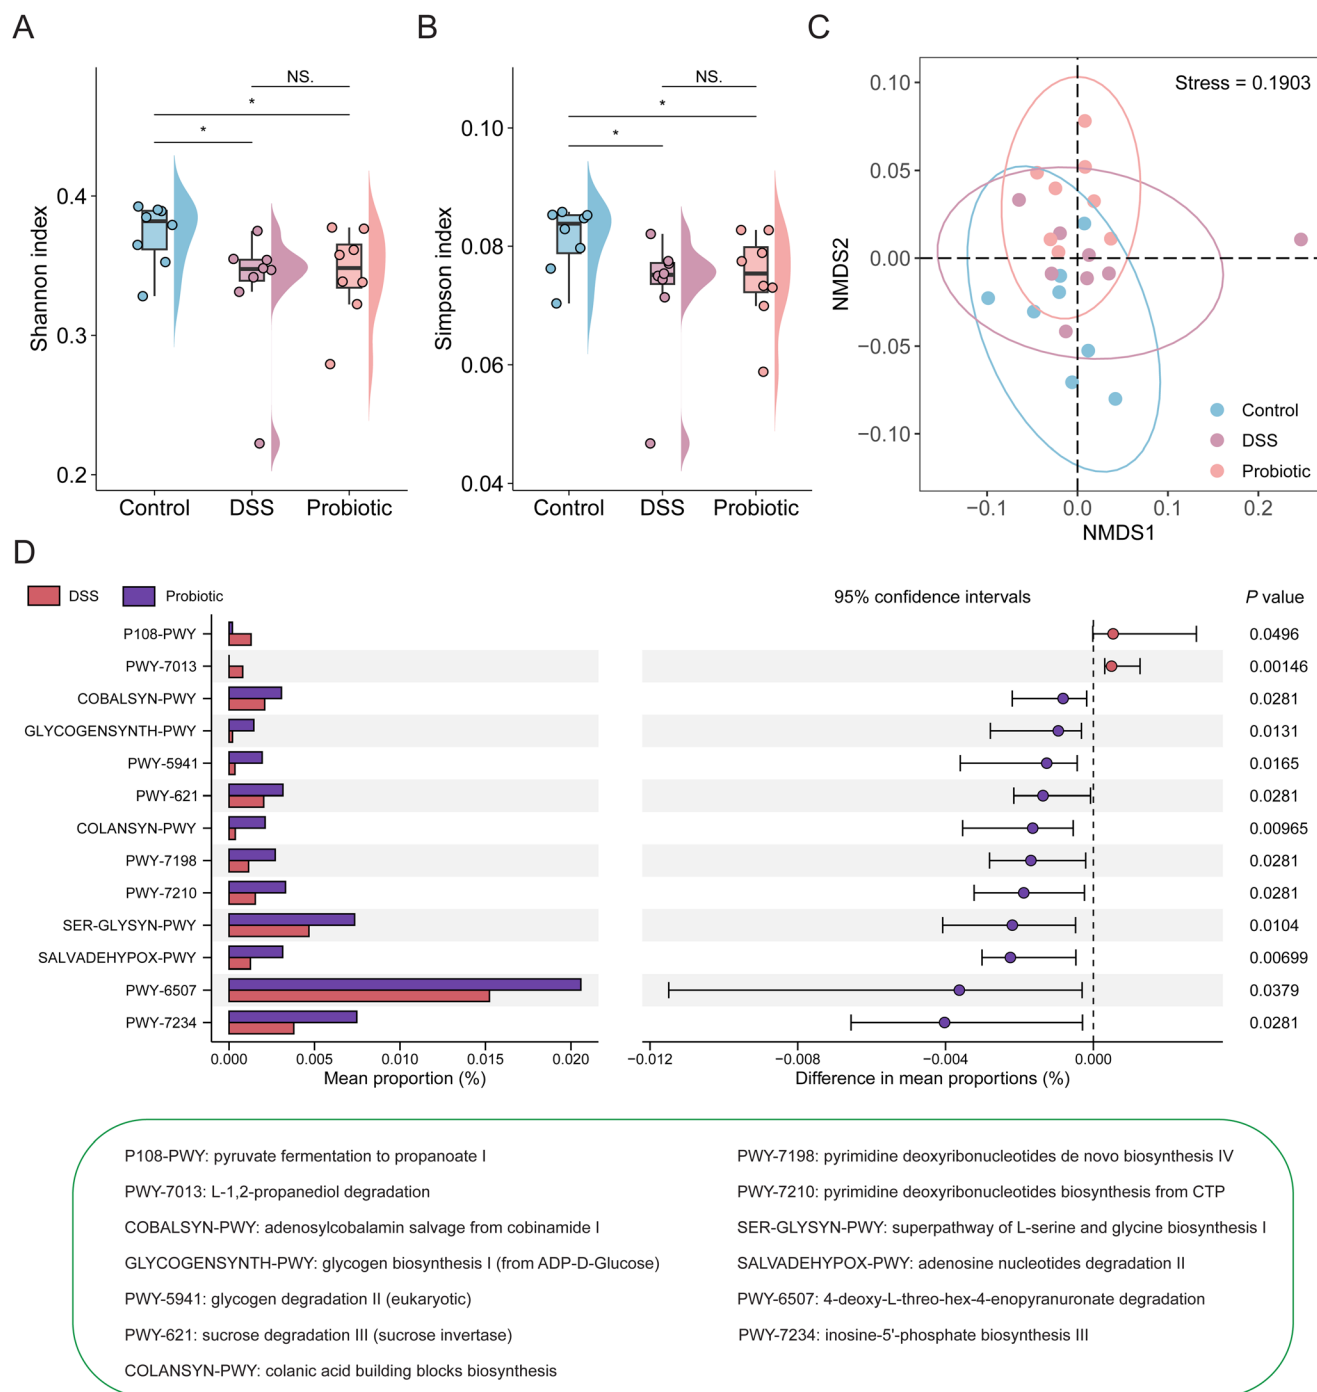

Fig. 6 Changes in functional fecal metagenome in colitis rats after the probiotic intervention. The alpha diversity of the functional fecal metagenome of the control, dextran sulfate sodium (DSS), and probiotic groups was assessed by the (A) Shannon and (B) Simpson's diversity indices. Statistical differences were evaluated by Kruskal–Wallis test followed by Wilcoxon rank-sum test. $*P < 0.05$ and NS (not significant). In the boxplots, the horizontal line represents the median of the data, the lower and upper bounds of the box represent the 25th and 75th percentile of data, and the lower and upper whiskers represent the minimum and maximum of the data. The scattered points in the bars and boxes represent the actual data points. (C) The beta diversity was evaluated by non-metric multidimensional scaling based on the Bray–Curtis dissimilarity. Statistical differences were calculated with PERMANOVA by 999 permutations. Ellipses represent 95% confidence intervals. (D) Differentially abundant MetaCyc pathways in the functional fecal metagenome between the DSS and probiotic groups were evaluated by Wilcoxon rank-sum test.

Differences in the gut microbiota diversity metrics between healthy and colitis rodents have been widely reported. For example, when analyzed using multivariate analysis methods

like principal coordinate analysis, experimental colitis mice induced by 2.5% or 5% DSS showed a distinct difference in the gut microbiota structure from healthy mice, and a lower

alpha diversity (assessed by Chao 1, Ace, Shannon, and Simpson indices) was noted in diseased mice compared with the healthy ones.^{14,40} Similar outcomes were also observed in a rat model of UC induced by 4% DSS supplement.⁴¹ The common features between these studies are that DSS induction resulted in significantly reduced microbial community richness and evenness and altered gut microbiota structure. In our study, we observed obvious changes in the gut microbiota composition in DSS-treated rats compared with healthy controls, confirming an intestinal dysbiotic state in these rats. The identification of colitis-associated alterations in the gut microbiota would be helpful to further understand how the gut microbiota relates to the disease onset and pathogenesis.

In fact, some previous studies have used 16S rRNA gene sequencing to determine the composition of the gut microbiota in UC. For example, one study reported the enrichment in the genera *Rikenellaceae_RC9_gut_group*, *Escherichia-Shigella*, *Romboutsia*, *Bacteroides*, and *Parabacteroides* in colitis mice, whereas the genera *Anaeroplasmata*, *Ruminococcaceae_UCG-014*, and *Prevotellaceae_UCG-001* showed decreased abundances compared with the control group.⁴² Another study observed the under-representation of *Lactobacillus*, *Ligilactobacillus*, and *Lachnospiraceae_NK4A136_group* but over-representation in *Prevotellaceae_UCG-001* and *Bacteroides* in DSS-induced mice relative to healthy mice.⁴³ A third study found that DSS-treated mice had more *Muribaculum*, *Akkermansia*, and *Escherichia-Shigella* but fewer *Coriobacteriaceae_UCG-002*, *Lactobacillus*, and *Parabacteroides* compared with the healthy controls.¹⁷ The resolution of amplicon-based sequencing, however, is restricted to the genus level, making it difficult to collect information at the species or strain level, which is essential for shedding light on the disease pathogenesis. Thus, this work implemented higher-resolution shotgun metagenomics rather than 16S rRNA gene sequencing to track the changes in rats' gut microbiota after DSS treatment and the probiotic intervention.

Specifically, the fecal microbiota of the DSS group had significantly more *Bacteroides thetaiotaomicron*, *Bacteroides fragilis*, *Mucispirillum schaedleri*, *Alistipes onderdonkii*, and *Anaerofustis stercorihominis*, but fewer *Lactobacillus* sp. ASF360, *Bacteroides massiliensis*, *Bacteroides uniformis*, *Bacteroides dorei*, *Parabacteroides distasonis*, and *Bacteroidales bacterium* ph8 than that of the control group. The species *Mucispirillum schaedleri* enriched in the DSS-induced rats might link to UC pathogenesis as a previous study have shown that *Mucispirillum schaedleri* could drive the development of Crohn's disease-like colitis in mice with severe immune deficiency.⁴⁴ Moreover, consistent with previously reported studies,^{17,18,43} our study also confirmed an inverse correlation between the genus *Lactobacillus* and UC, which is worth further investigating in future studies. *Parabacteroides distasonis* is a species that is often associated with different health statuses. For example, it was diminished in patients with rheumatoid arthritis and hepatic fibrosis, and administering this bacterium could ameliorate disease pathogenesis in mouse models.^{45,46} On the other hand, *Parabacteroides distasonis* administration exerted beneficial effects in diseases such as type 2 diabetes⁴⁷ and

non-alcoholic steatohepatitis.⁴⁸ Although our data revealed that *Parabacteroides distasonis* was diminished in DSS-induced rats, its impact on disease is unclear. Notably, several *Bacteroides* species exhibited opposite patterns of intestinal abundance in DSS-induced rats in this study, highlighting the importance and value of identifying microorganisms at a greater taxonomic resolution. The differential bacterial species identified in healthy and colitis rats deserve further attention in future studies to determine whether they are beneficial or harmful to the disease.

Given that gut dysbiosis is associated with UC, attempts to engineer gut microbiota to reach a pre-morbid state might open up new therapeutic avenues for managing UC. This notion has given rise to much research on manipulating the gut microbial community to ameliorate UC, especially with probiotic intervention.^{15,19,49–52} These studies showed that probiotic administration can beneficially modulate the host gut microbiota by promoting the beneficial microbes (such as *Clostridium sensu stricto-1* and *Butyricoccus*) while reducing the harmful ones (such as *Escherichia-Shigella*).⁵² A surprising observation in our study is that administering *L. fermentum* F6 specifically decreased the intestinal abundance of *A. muciniphila*, and the species was positively correlated with the severity of colitis. A diminished abundance of gut *A. muciniphila* was seen in various diseases,⁵³ but some studies reported the opposite result (summarized in ESI Table 3†). For instance, some recent experimental evidence noted a marked increase in the intestinal abundance of *A. muciniphila* in DSS-induced colitis mice compared with healthy controls.^{17–23} In addition to UC, this phenomenon was also seen in some neurodegenerative disorders, such as multiple sclerosis^{54,55} and Parkinson's disease.^{56,57} Our study also observed an elevated level of gut *A. muciniphila* in DSS-treated rats, although no significant difference was seen between the control and DSS groups (ESI Fig. 7†). *A. muciniphila* is increasingly recognized as a next-generation probiotic,⁵⁸ but its role in diseases including UC remains to be clarified. Overall, our study suggested that administering probiotics can modulate the gut microbiota composition, and the capacity to accurately regulate species that trigger or aggravate the disease would be a crucial basis for probiotic-based precision therapy for gut-related diseases.

Another interesting observation of this work was that the DSS-induced gut dysbiosis was accompanied not only by an abnormal shift of the gut microbiota but also an enhanced interconnectedness of the overall gut microbiota compared with that of the healthy rats. Moreover, this stronger interconnectedness among the gut microorganisms was abated by probiotic intake. The relationship between dysbiosis and the interconnectedness of the gut microbiota and their impact on diseases remain obscure and warrant further study.

On the one hand, even though we observed a positive association between *A. muciniphila* and the pathogenesis of colitis, we were unable to prove the causality of *A. muciniphila* in the disease, which might need to be validated in a separate experiment by exogenous supplementation of *A. muciniphila* to the DSS-treated rats with and without receiving the probiotic

Fig. 7 Schematic diagram of the proposed mechanism by which probiotic *Lactiplantibacillus fermentum* F6 ameliorated colitis in a rat model. Dextran sulfate sodium (DSS) induced the development of ulcerative colitis, which was inhibited by probiotic *Lactiplantibacillus fermentum* F6 treatment, presumably through decreasing the abundance of *Akkermansia muciniphila*.

intervention. On the other hand, despite our seminal demonstration that probiotics could specifically regulate individual gut microbes, whether this function is generalizable in other colitis models or diseases requires further investigation. Nonetheless, our study offers valuable insights into target modulation of gut microbes of interest or disease causation to change the course of the disease (Fig. 7), which is an essential basis for precision probiotic therapies.

Data availability

The sequencing data generated in this study have been made available to the public with no restrictions at the NCBI Sequence Read Archive under BioProject accession number (PRJNA1007659).

Author contributions

Q. H. and T. Z. contributed equally to this work. Q. H. designed the experiments, T. Z., W. Z., and C. F. conducted the animal experiments. T. Z. analyzed the results and wrote the manuscript. Q. H. and L. K. extensively revised the manuscript and provided advice. H. Z. and Z. S. supervised all data analysis. All authors read and approved the final manuscript.

Conflicts of interest

The authors declare no competing financial interest.

Acknowledgements

We are profoundly thankful to the National Natural Science Foundation of China (32325040, U22A20540), the National Key R&D Program of China (2022YFD21007002), and the Earmarked Fund for CARS36.
