Background: The profile of metal(loid)s in human milk is essential for infant growth and development, yet its impact on the development of the infant microbiota remains unclear. Elements, such as manganese, zinc, iron or copper, play crucial roles in influencing infant health. **Aim:** To investigate the metal(loid) content within human milk and its influence on the infant's gut microbiota within the first 2 months after birth. **Methods:** Human milk samples and infant stool samples from 77 mother–infant dyads in the MAMI cohort were collected at two time points: the early transitional stage and the mature stage. Metallomic profiling of human milk was conducted using inductively coupled plasma-mass spectrometry (ICP-MS). The infant gut microbiota was profiled through 16S rRNA amplicon sequencing and maternal–infant clinical data were available. Spearman's rank correlation coefficients provided insights into metal(loid)–microbiota relationships. **Results:** Independent cross-sectional analyses of mother–infant pairs at two time points, significant variations in metal concentrations and differences in microbial abundances and diversities were observed. Notably, *Bifidobacterium* genus abundance was higher during the mature lactation stage. During early lactation, we found a significant positive correlation between infant gut *Corynebacterium* and human milk nickel concentrations, and negative correlations between *Veillonella* spp. and antimony, and *Enterobacter* spp. and copper. Additionally, Simpson's diversity was negatively correlated with iron. In the mature lactation stage, we identified eleven significant correlations between metals and microbiota. Notably, *Klebsiella* genus showed multiple negative correlations with iron, antimony, and vanadium. **Conclusion:** Our study highlights the significance of metal(loid)–microbiota interactions in early infant development, indicating that infant gut *Klebsiella* genus may be particularly vulnerable to fluctuations in metal(loid) levels present in human milk, when compared to other genera. Future research should explore these interactions at a strain level and the implications on infant health and development. This trial was registered as NCT03552939.

Introduction

Human milk (HM) plays a crucial role in infant health, growth, and development, recommended for exclusive breastfeeding during the first 6 months post-birth.^{1,2} While HM bioactive components interact with gut microbiota,³ HM's mineral com-

position, which constitutes up to 0.5%,⁴ also raises questions about the role of metals in influencing the infant's microbiota.^{5–10} This is due to the predictive role of the infant gut microbiota in long-term health,^{11–13} and the impact of environmental pollutants.¹⁴ Maternal exposome during pregnancy can modulate HM metal composition,^{15–18} influenced by solute carrier transporter expression and hormone levels during lactation,^{19,20} making the metal composition dependent on various factors.

Metal(loids) influence microbial growth and metabolism, resembling prebiotic and biocide effects, and play a significant role in metallobiology.^{21–24} Bacteria and the innate immune system compete for control over ions like iron, zinc, and manganese, impacting bacterial abundance.²³ Iron and zinc are essential nutrients for specific microbes, shaping the diversity and richness of microbial genera.^{25,26} HM can dynamically modulate the microbiota through glycoproteins like lacto-

ferrin, which sequesters iron ions, altering bacterial availability.^{27,28} By adjusting metal concentrations, HM might adapt to infant needs, influencing bacterial survival and microbiota modulation. Furthermore, metal ions present in extracellular environments are readily available for incorporation into major bacterial pathways. These ions become part of metalloproteins that play crucial roles in various metabolic processes. For instance, metal ions such as iron, zinc, nickel, manganese, and copper are integral to transcriptional regulators like the ferric uptake regulator family, as well as enzymes such as succinate dehydrogenase, which is involved in the tricarboxylic acid cycle.²⁹

Metal(loid)–microbiota interactions, enhancing enzyme catalysis and supporting reaction stability, have potential to modify the gut environment.²³ This may influence infant health by altering bacterial metabolism,³⁰ and metabolite production, affecting metal bioavailability. Such variations could mediate infant health and developmental outcomes. Metal(loid)s may also influence bacterial virulence development *via* metal-related processes.³¹ We hypothesize that differences in early and mature HM metal(loid) concentrations contribute to the infant gut microbial ecosystem. Thus, we investigated the metal(loid) content in HM and its impact on infant gut microbiota within the first 2 months after birth.

Methods

Study design and volunteers

The present study is a double cross-sectional study involving 77 mother–infant dyads from a longitudinal prospective MAMI cohort study.³² Briefly,³³ participants were followed during the period of the first two months post-birth (Fig. S1†). Maternal–neonatal clinical parameters were collected including maternal antibiotic exposure, BMI and weight gain during pregnancy, mode of delivery and feeding type. All participants received oral and written information about the study and written consent was obtained. The study was approved by the Hospital Ethics Committees (Hospital Universitario y Politécnico La Fe and Hospital Clínico Universitario de Valencia), and is registered on the ClinicalTrials.gov platform, with the registration number NCT03552939.

Human milk samples

A total number of 98 HM samples from 77 healthy women were collected at two different lactational stages: $n = 64$ samples at an early transitional stage (between 7 and 15 days postpartum), and $n = 34$ samples at a mature stage (between 30 and 60 days postpartum). Of these, 19 women provided samples at both early and mature stages (Fig. S1†).

HM collection followed a standardized protocol, adhering to the recommended procedures as described previously.³⁴ In brief, breast skin was cleaned with water and soap and the first drops were discarded. Subsequently, milk was collected by using a sterile pumper in sterile bottles to normalize the collection among the participants. Morning collection was rec-

ommended. Finally, HM samples were stored immediately at $-20\text{ }^{\circ}\text{C}$ in a freezer and sent to the hospital to be stored at $-80\text{ }^{\circ}\text{C}$ until further analysis.

Human milk metallomic profile

An aliquot of 500 μL of whole HM was used to determine the metallomic profiles by inductively coupled plasma-mass spectrometry (ICP-MS) as described in Arias-Borrego *et al.*³⁵ Briefly, mineralization was carried out by using MiniXpress polytetrafluoroethylene (PTFE) vessels. Then, 4 mL of nitric acid and 1 mL of hydrogen peroxide (4 : 1, v/v) were added to 500 μL of whole HM samples. After 10 min of pre-mineralization, the PTFE vessels were closed and introduced into a model MARS microwave oven (CEM, Matthews, NC, USA). The power was set at 400 W and a temperature program was applied from room temperature to 160 $^{\circ}\text{C}$ in 15 min and held at this temperature for 20 min.

Isotopes monitored in the ICP-MS analysis were ²⁷Al, ⁵¹V, ⁵³Cr, ⁵⁵Mn, ⁵⁷Fe, ⁵⁹Co, ⁶⁰Ni, ⁶³Cu, ⁶⁵Cu, ⁶⁴Zn, ⁶⁶Zn, ⁷⁵As, ⁹⁵Mo, ¹⁰³Rh, ¹¹²Cd, ¹¹⁴Cd, ¹²¹Sb, ²⁰⁵Tl, and ²⁰⁸Pb with a dwell time of 0.3 s per isotope. A tuning aqueous solution of Li, Co, Y, and Tl at 1 $\mu\text{g L}^{-1}$ was used to tune the ICP-MS system. A multi-element calibration standard–2A solution at 10 mg L^{-1} of Al, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, As, Se, Cd, Tl, and Pb was obtained from Agilent Technologies. Moreover, stock solutions at 1000 mg L^{-1} of Mo and Sb (Merck Millipore) were used for the preparation of the calibration curves of these elements. Rh at 100 ng L^{-1} was used as internal standard. Most of the analysed elements required 4.5 mL min^{-1} flow rate of helium. For As, a mixture of hydrogen (2 mL min^{-1}) and oxygen (40%) was used in the MS/MS mode. The experiments were performed in triplicate. The quality control validation parameters investigated were the limits of detection (LODs), limits of quantification (LOQs), precision, and accuracy.³⁵ Moreover, as only 19 HM samples and 12 infant fecal samples had complete data available for both early and mature lactation stages, visualizations were created to illustrate the trends of metal(loid)s from HM samples, as well as the 10 most abundant bacteria, and alpha diversity indices in the infant's gut (Fig. S2–S4†). To verify the accuracy of the ICP-MS method, a milk powder certified reference material (NIST-1849) was also analysed for the determination of elements such as ⁶⁶Zn, ⁶⁴Zn, ⁶⁵Cu, ⁶³Cu, ⁵⁷Fe, ⁵⁵Mn and ⁵³Cr.

Infant gut microbiota profiling by 16S rRNA amplicon sequencing

Infant clinical data and 16S amplicon sequences were available from previous studies.³⁶ In this study, a subsample corresponding to the 77 healthy mother–infant pairs was selected for the integrative analysis. In brief, total DNA was isolated from the fecal samples as described elsewhere,³⁷ using the Master-Pure DNA Extraction Kit (Epicentre, Madison, WI, USA) by following the manufacturer's instructions with some modifications including physical and enzymatic treatments. Gut microbiota composition and diversity were determined by the V3–V4 variable region of the 16S rRNA gene sequencing, following Illumina protocols. A Nextera XT Index Kit (Illumina,

CA, USA) was used for the multiplexing step and a Bioanalyzer DNA 1000 chip (Agilent Technologies, CA, USA) was used for checking the polymerase chain reaction (PCR) product quality. Libraries were sequenced using a 2×300 bp paired-end run (MiSeq Reagent Kit v3) on a MiSeq-Illumina platform (FISABIO Sequencing Service, Valencia, Spain), according to the manufacturer's instructions (Illumina). The original raw sequences have been re-processed using the DADA2 bioinformatics tool,³⁸ and taxonomically classified using the Silva Small Subunit rRNA Database v132.³⁹ Relative abundances at genus levels and alpha diversity indices, including richness (Observed, Chao1 and ACE) and diversity (Shannon, Simpson, InvSimpson and Fisher), were calculated using the Phyloseq package (version 4.3.1).⁴⁰

Metadata pre-processing and integration of metallomics and 16S rRNA gene sequencing

A Shapiro–Wilk test for normality on HM metal and metalloid concentrations was conducted, and subsequently, an explora-

tion *via* violin plots revealed the presence of outliers that explained the variability of the data (Fig. 1). Then, metal and metalloid values for concentrations were scaled using the centered log ratio. Finally, an unpaired *t*-test was conducted to explore differences between the lactation stages for metal and metalloid concentrations in HM. A Spearman's rank correlation coefficient matrix was created to examine the correlation between the HM metal and metalloid concentrations and the infant gut microbiota, filtering bacteria using 0.001% relative abundances. The significance of each correlation coefficient was tested and *p*-values were adjusted for multiple comparisons using the Benjamini–Hochberg method for false discovery rate (FDR). Moreover, as only 19 HM samples and 12 infant fecal samples had complete data available for both early and mature lactation stages, visualizations were created to illustrate the trends of metal(loid)s from HM samples, as well as the 10 most abundant bacteria, and alpha diversity indices in the infant's gut (Fig. S2–S4†). These figures were created using GraphPad Prism 8 software.⁴¹

Fig. 1 Violin plots of metals and metalloids in human milk samples. Concentrations of metals and metalloids were measured in 98 human milk samples. Among these, 71 samples were analysed for lead (Pb), aluminium (Al), arsenic (As), and cadmium (Cd). Values below the limits of detection were not included in the plots (see Table 2).

Results

Cohort descriptives

Our cohort descriptive analysis included full clinical records from 77 mother–infant dyads. Characteristics of the cohort are presented in Table 1, while data on HM and infant stool samples are detailed in Table 2 and Fig. S5,† respectively. A Shapiro–Wilk test for normality and violin plot visualization of HM metal(loid) concentrations (Fig. 1)—including Sb, Mo, Co, Pb, Cu, Zn, V, Fe, Cr, As, Tl, Mn, Ni, and Al—indicated non-normality in the distributions, with Cd excluded due to its detection in only one sample. Additionally, a longitudinal subset of 19 HM samples and 12 infant fecal samples was isolated for visualization of their differences and trends (Fig. S2–S4†).

This subset of pairs indicates high variability in shifts, showing both minor variations and notable trends in changes in metal and metalloid concentrations, as well as the microbiota profile, from early to mature lactation stages.

HM metallomic profiles differed between lactational stages

In our independent cross-sectional analysis of mother–infant pairs from two categorically separate time points exploring changes in HM metallomic profiles, we observed significantly lower concentrations of Co, Cu, Zn, Mo, and Sb in mature HM samples compared to early HM samples (p -values <0.01) (Table 2).

Infant gut microbiota profile in early and mature lactational stages

Among the most abundant genera, *Bifidobacterium* exhibited the highest relative abundance in infant feces during the mature lactation stage, along with *Bacteroides* and *Streptococcus* genus. Conversely, *Enterococcus* and *Klebsiella* genus showed lower relative abundances in the infant microbiota during the mature lactation stage (Fig. S5†). However, no statistical differences were observed. Additionally, statistical differences were observed in alpha diversity indices, including Observed and Fisher indices being higher in samples from infants in the mature lactation stage (p -values <0.05) (Table S1†).

Early lactation stage and metal–microbiota interactions

In our cross-sectional analysis, significant correlations were identified between HM metal concentrations, infant gut microbiota genera, and alpha diversity indices in the infant fecal samples (Fig. 2A). During the early lactation stage, only one significant positive correlation was found between infant gut *Corynebacterium* members and HM nickel concentrations ($r \approx 0.15$, p -values <0.05). Additionally, negative correlations were observed between *Veillonella* genus and antimony, and *Enterobacter* genus and copper ($r \approx -0.2$, p -values <0.05). Simpson diversity was also negatively correlated with iron ($r \approx -0.2$, p -values <0.05) (Fig. 2B). Furthermore, Table S3† shows the correlations between the detected samples for Pb, Al, and

^aThe median concentration (interquartile range) of metal(loid) concentrations in ng mL⁻¹ or ng mg⁻¹ was calculated for 98 human milk samples. ^bUnpaired *t*-test at a confidence level of 95%. Analysis was not conducted for samples corresponding to the elements lead (Pb), aluminium (Al), arsenic (As), and cadmium (Cd). NA = not available, the values under the limits of detection precluded statistical comparison between lactation stages. ^cThe limit of detection (LOD) for the quality control parameter was determined by calculating three times the standard deviation of the procedural blank obtained from microwave digestion.³⁵ ^dIn total, 71 samples were analysed for Pb, Al, As, and Cd.

As. Spearman correlations were identified only for Pb, which was moderately and negatively correlated with Shannon ($r \approx -0.63$, p -values <0.05), Simpson ($r \approx -0.77$, p -values <0.05), and InvSimpson ($r \approx -0.73$, p -values <0.05) diversity indices, but not with bacterial abundances.

Mature lactation stage and metal–microbiota interactions

The correlations between HM metal concentrations and infant fecal microbiota observed during the mature lactation stage were not replicated when compared to those observed during the early stage. Notably, significant positive correlations were found between *Escherichia coli/Shigella* and magnesium, as well as *Bacteroides* genus and zinc ($r \approx 0.2$, p -values <0.05). Conversely, negative correlations were observed between *Streptococcus* genus and cobalt concentrations, and *Enterococcus* genus with manganese and vanadium. Particularly noteworthy was the interaction of *Klebsiella* genus with various metals, exhibiting significant negative correlations with iron, antimony, and vanadium. Furthermore, significant negative relationships were identified between *Bacteroides* and *Lactocaseibacillus* genera and antimony, with similar correlations observed for *Acinetobacter* with manganese ($r \approx 0.2$, p -values <0.05 for all) (Fig. 2A). Additionally, infant microbiota richness and diversity indices displayed significant negative correlations. These included manganese and nickel with Chao1. Specifically, only manganese exhibited a negative correlation with the Chao1 index ($r \approx -0.3$, p -values <0.05) (Fig. 2B).

Discussion

Our investigation unveiled significant variations in HM metal concentration and disparities in infant gut microbiota observed between early and mature milk lactation stages, shed-

ding light on potential relationships between individual metals and bacterial abundances, richness, and diversity within the first 2 months postpartum. We identified five significant correlations during early lactation and eleven during mature lactation. Analysis of individual metal–bacteria correlations suggests that *Klebsiella* genus is the most susceptible genus to metal concentrations. Moreover, variations in HM metals could pose health risks in infants.⁴² We detected Pb in 15.5% of our samples from the early lactation stage, while all samples from the mature stage were below the limit of detection (LOD). Research has shown that women exposed to metals such as Pb throughout their lives, potentially due to factors like residing in industrial/mining areas or smoking habits, often exceed dietary levels established by the European Food Safety Authorities (EFSA) by threefold and may accumulate these metals in tissues and bones.¹⁵ Subsequently, the accumulated metals may be transferred to the mammary gland *via* the maternal bloodstream.¹⁶ Although we identified Pb in all our samples, Freire *et al.* (2022)⁴³ utilizing ICP-MS identified Pb in only 50.6% of their samples. Heavy metals have not been shown as being involved in any biological process in humans.⁴⁴ When comparing our values with those reported in the external literature (Table S4†), we observed that the concentrations are highly heterogeneous, varying significantly between populations and across years. This variability warrants further exploration where toxicological guidance values are not yet defined; however, HM samples in this cohort are under toxicological levels as per the established tolerable intakes (Table S4†).

In light of exploring potential mechanisms to explain the observed novel metal(loid)–microbiota interactions, we turn to the relevant literature. The most interactive genus was *Klebsiella*, experiencing negative correlations with iron, anti-

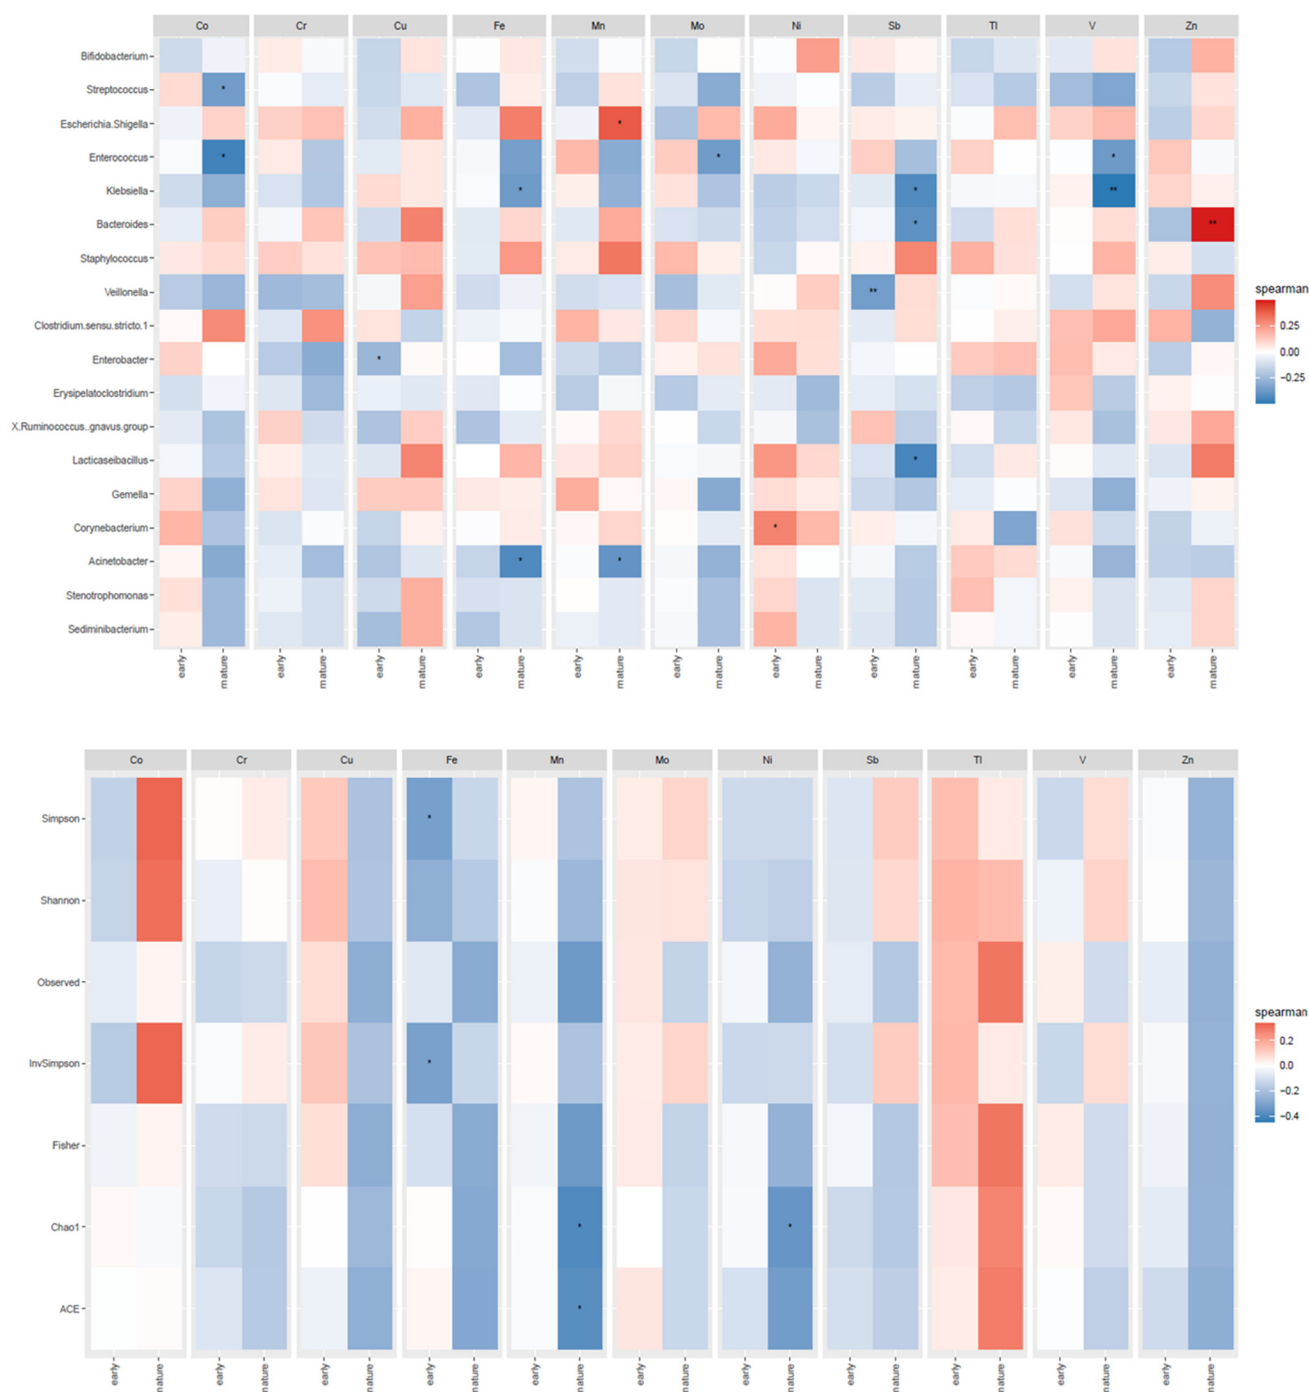

Fig. 2 (A) Spearman's correlation test between HM metals and infant fecal microbiota relative abundances at early and mature lactation stages. The correlation tests, adjusted for false discovery rate, did not yield statistically significant results ($p > 0.05$). mony, and vanadium. According to the external literature, during pathogenic activity, Ni and Co have been identified as substrates for yersiniabactin to chelate Fe ions,⁴⁵ and *K. pneumoniae* can also bind to Ni and Mn. In the context of

health and disease, a developed human innate immune system utilizes calprotectin to sequester these metals, limiting the survival of pathogens.⁴⁶ However, with regard to undeveloped innate immune systems, it remains unclear whether

2-month-old infants can effectively control bacterial pathogenicity in this way. It is important to note that *K. pneumoniae* strains have higher prevalence of multidrug resistance and metal gene resistance in the context of high concentrations of Fe (approximately $893 \mu\text{g mL}^{-1}$).⁴⁷ Our samples contained outliers with concentrations of iron approximately 1000-fold lower than those in similar contexts. Therefore, these outliers necessitate a more in-depth exploration to understand the features of these strains.

Our exploration also uncovered a novel potential negative relationship between *Streptococcus* genus with cobalt during the mature stage, showing a decline in *Streptococcus* abundance observed from the early to mature lactation stages. Although possibly due to a random effect, this trend was consistently reflected in the longitudinal paired sample 7, as shown in Fig. S2 and S3.† Conversely, the literature has shown that *S. agalactiae* and *S. pneumoniae* consistently display strong survival mechanisms to handle metal-induced stress.^{48–50} Studies indicate their effective regulation of stress related to metals, such as Zn in *S. agalactiae*⁵¹ and Mn in *S. pneumoniae*.⁵² These mechanisms likely support virulence by enhancing bacterial survival during infections.

Our samples revealed that *Bifidobacterium* genus had exhibited the highest change in relative abundance, being higher in feces of infants during the mature lactation stage. Interestingly, the literature reports that Zn and Fe can enhance the activity of the metal-dependent phosphoesterase enzyme of *B. adolescentis*.⁵³ Furthermore, *B. longum* and *B. lactis* can effectively remove Cd, Cu, Zn, As, and Pb from the media,^{54–56} and the growth of *B. bifidum var. pennsylvanicus* can be facilitated by Fe, Mn, Zn, and Cu.⁵⁷ Conversely, our samples demonstrated higher concentrations of *Bifidobacterium* in the mature stage, despite significantly lower levels of copper (Cu) and zinc (Zn) in the mature stage samples.

Additionally, our correlation analysis showed new potential metal–*Bacteroides* interactions with zinc and antimony. The genus *Bacteroides*, in particular, has demonstrated specific growth requirements, highlighting distinctions among various organic and metal–organic compounds.⁵⁸ Investigations have elucidated metal-binding sites in the structure of metallo-lactamases, potentially utilized by Fe, Ni, Cu, Mn, Co, and Zn, thereby enhancing enzymatic activity and contributing to antibiotic resistance, particularly in the case of *B. fragilis*.^{59–61} Moreover, *B. ovatus* has been shown to exhibit a metal-dependent glycosyltransferase featuring metal-binding sites for Mg and Mn, augmenting its ability to metabolize human milk oligosaccharides.^{62,63} Furthermore, other species such as *B. thetaiotaomicron* and *B. distasonis* possess Fe- and Mn-containing superoxide dismutase, fortifying their survival capabilities.⁶⁴ On the other hand, although research has shown potential interactions with the genus *Stenotrophomonas*, correlations with metals were not identified. The literature has extensively studied *S. maltophilia*, revealing that metallo-enzymes are essential for survival.^{91,92} This includes metallo-beta-lactamase, where Zn is required, and other divalent metals such as Cd and Cu can replace Zn

as ligands, indicating an increased potential for the bacteria to survive beta-lactam antibiotics.^{65–67} The same species has also demonstrated siderophore-mediated metal chelation, responding to Cd-induced toxicity with an exopolysaccharide reaction.⁶⁵ Nevertheless, *S. maltophilia* has exhibited mechanisms to overcome metal toxicity derived from Cu(II) and Co(II), such as detoxifying Cd into CdS and reducing oxyanions to nontoxic elemental ions.^{66,67} The prolonged exposure to high levels of Cd can enhance the production of lipopolysaccharide, resulting in a shift in bacterial abundance and the gut metabolite environment, including a reduction in butyrate production.⁶⁸

Additionally, previous studies have demonstrated metal toxicity in *Escherichia coli* when Cd and As ions non-specifically insert into different enzymes, such as molybdoenzymes. This inhibition is also observed for Mo, V, and Cu.⁶⁹ Consistent with these observations, Cd and As ($>1 \text{ ng mL}^{-1}$) have been shown to inhibit the growth of *E. coli*. However, at lower concentrations of Cd and As, bacterial growth remains unaffected, while antibiotic resistance is increased.⁷⁰ Further research has explored that Co, Ni, and Fe are related to high pathogenicity islands that secrete yersiniabactin in uropathogenic *E. coli*⁷¹ and extraintestinal *E. coli*.⁷⁰ Mn, Co and Cu have been implicated in catalytic enzymes,^{71–73} and Mn, Fe, Co, Cu, Zn, Cd, and Pb have been identified to increase *E. coli*'s chances of survival in response to antibiotics.^{74,75} Also, Fe and Zn are associated with enterotoxigenic *E. coli* pathogenesis,^{76,77} and Pb may influence mitochondrial apoptosis.⁷⁸ While research has shown that *E. coli* can interact with environmental metals and increase virulence factors, our study observed a decrease in the *Escherichia/Shigella* genus from the early to mature lactation stage, with a significant but weak correlation with manganese.

While we identified potential metal–*Corynebacterium* relationships, particularly with nickel during early lactation stages, the existing literature suggests more probable interactions between metals and *Corynebacterium*. Previous research has predominantly focused on the interaction of *C. diphtheriae* with divalent metal ions, including Mn(II), Co(II), Ni(II), Fe(II), and Zn(II). This interaction serves to shield the bacteria from oxidative damage, while modulating the activity of diphtheria toxin repressor (DtxR).^{79–85} Furthermore, *C. glutamicum* has been shown to interact with Ni, Mn, and Co to modulate metal efflux⁸⁰ and to regulate ZIP family ion transporters.⁸³

Finally, alpha diversity indices were negatively correlated in both lactation stages with HM metal(loids). However, Shen *et al.* (2022)⁸⁶ did not find significant associations between childhood and perinatal blood metals and alpha diversity, and although we found significant correlations between alpha diversity and individual metals, research in children did not demonstrate an influence of metal concentrations on gut microbial diversity.⁸⁶ Nevertheless, in line with our findings, a study among adults showed that long-term exposure to multiple metals, including As, Cd, Cu, Pb, and Zn in metal-polluted areas, was associated with increased alpha diversity.⁸⁷

Our findings might have been time-dependent rather than concentration-dependent.

Limitations and future directions

During our study, despite it being a longitudinal birth cohort, due to the high variability in breastfeeding duration and practices, we compared samples in a cross-sectional manner at two time points, namely HM from early and mature lactation stages, with only a limited number of women ($N = 19$) providing samples at both time points. This longitudinal sample size was small considering the different variables that may influence outcomes (secretor status, mode of delivery, infant sex, and also, maternal nutritional status, among others). This study adopts two independent cross-sectional approaches, complemented by longitudinal visualization of paired data available at two time points, to investigate metal–microbiota interactions during the first two months post-birth. The study utilizes ICP-MS for metallomic profiling and 16S rRNA sequencing for microbiota analysis. It identifies novel potential relationships *via* correlational approaches and holds clinical relevance by offering insights into how metal variations in HM may influence infant gut microbiota establishment. To achieve a better understanding of metal–microbiota interactions, metagenomic sequencing, short-chain fatty production, carbohydrate utilisation and other capabilities should be put to the test with different metal–ion and metal–organic compound concentrations. Most interesting is the mechanism by which some strains respond to high environmental concentrations of metals can lead to the expression of efflux systems to remove the cations from cells and these mechanisms are also attached to antibiotic resistance genes. Thus, higher exposure to metals might be increasing the expression of antibiotic resistance genes,^{88,89} contributing to a global health issue. Future research needs to consider whole genomes and the complexity of the microbiota. Although a larger sample size would improve generalizability and statistical power, where correlations lost significance after FDR adjustments, external validity is still needed to extrapolate and build predictable models. More detailed maternal information, such as diet and environmental exposure, would improve contextual understanding of observed HM metallomic variations. An additional limitation of this study is the inability to consider potential covariates due to the available data. These covariates include the absorption and utilization of elements by the infants, as well as the specific forms of the elements, such as isotopic composition, electronic or oxidation state, and molecular structure. Moreover, 80% of the women in this cohort were secretors (functional or non-functional variants of the FUT2 gene),⁹⁰ but the sample size was insufficient to compare secretors and non-secretors. Further research could explore the influence of metalloids on strain functionality in the mother–infant context. Extended follow-up periods may provide insights into this aspect, including potential impacts on infant health and development. Finally, strain specificity is also a factor to consider in future research, where some

studies have reported the capability of different strains from the same species interacting differently with metals.

Conclusions

Our investigation into the metal(loid) content within HM and its influence on the infant's gut microbiota within the first two months after birth has revealed dynamic changes in metallomic profiles. Our findings suggest the plausibility of *Klebsiella* genus as the most susceptible genus to changes due to metal (loid) fluctuations in human milk, shedding light on potential microbial responses to environmental exposure. Furthermore, our study contributes new insights into potential relationships between metals and the gut microbiota. Addressing existing knowledge gaps, further research is warranted to delve into the mechanistic aspects of these potential interactions and their long-term implications on gut microbiota and infant well-being. Future studies should extend their focus to organo-metallic derivatives to provide a comprehensive understanding of metal–microbiota interactions and their impact on infant health.

Author contributions

EFV: writing – original draft, conceptualization, methodology, data curation, formal analysis, investigation, validation, visualization, and data interpretation. MB, BCL, RCR, LY and JEC: investigation, methodology, and writing – review and editing. CMC, TGB and MCC: supervision, funding acquisition, resources, conceptualization, interpretation, project administration, and writing – review and editing. All authors contributed to the final version of the manuscript.

Data availability

All metadata utilized will be made available upon request to the corresponding authors.

Raw sequences are available through the NCBI Sequence Read Archive Database under project accession number BioProject ID PRJNA614975.

All R code necessary to replicate the data analysis is available in the following GitHub repository: https://github.com/EFV1995/BM_metallomic_16S_correlations.
