Lignocellulose has the great potential as a sustainable resource to replace fossil-based raw materials, however, properties, such as a complicated crosslinked structure, create a significant obstacle for utilization, as the isolation of lignocellulose components has hardly been achieved under mild conditions. Here, we demonstrate that the use of an aromatic hydrogen bond donor (thymol) creates a supramolecular interaction between the delignification medium and lignin, which is key to removing almost all the lignin from the softwood within minutes, at near-ambient temperatures. Strong support for supramolecular interactions was demonstrated *via* the formation of a room temperature liquid between two solids (lignin and thymol). The concept of supramolecular interaction between lignin and thymol will help elevate the feasibility of biobased materials across a wide range of applications.

### 1. Introduction

The complex structure of lignocellulose hinders or prevents its utilization in many applications.<sup>1</sup> In fact, lignin is commonly considered an obstacle because it holds other compounds together to create a barrier for many outside influences, such as chemical attacks.<sup>2</sup> For example, direct hydrolysis of a lignin-containing carbohydrate fraction results in a poor yield of monomeric units due to the inhibition of enzyme activity by lignin.<sup>3</sup> Therefore, the fractionation of lignocellulose is a pivotal step in many traditional as well as new applications that aim to use renewable biomaterials to replace fossil-based resources.<sup>4,5</sup> Historically, fractionation, or delignification, has

focused on the isolation of carbohydrate fractions; but lately, lignin has also been recognized as a valuable resource<sup>6–8</sup> and research has steered toward a method that can allow fractionation to be achieved in milder conditions. Several strategies, including lignin-protecting fractionation<sup>9,10</sup> and the use of lignin-like or lignin-derived compounds,<sup>11</sup> have elevated the potential of lignocellulose into applications that are beyond the capabilities of current industrial lignin. Despite the notable advantages of recent fractionation methods, their high temperature, long treatment times, and harsh reaction conditions still hamper their wider usability. Although methods based on hydrophobic and lignin-like chemicals have been introduced,<sup>11,12</sup> the full potential of these concepts has not yet been revealed. An important key to lignin removal is to understand the chemical structure of lignin and to maximize the interaction between the solvent system and lignin.

Here, we present a supramolecular interaction-driven delignification process using thymol as an aromatic, naturally occurring (it is present in high quantities in thyme oil), and biodegradable phenolic compound. Due to its aromatic structure, partial delocalization makes thymol a strong hydrogen bond donor *via* its phenolic group.<sup>13</sup> Conversely, lignin, despite being the polymer of phenolic monomers, has a minor amount of free phenolic units.<sup>14</sup> Instead, lignin has numerous ether bonds, which act as hydrogen bond acceptors, as well as aliphatic hydroxyl groups, which exhibit both hydrogen bond-acceptor and -donor properties (also, a few carbonyls present in lignin are hydrogen bond acceptors) (Fig. 1a). Therefore, we postulated that thymol can participate in both aromatic  $\pi$ - $\pi$  stacking and hydrogen bonding with lignin, and that these noncovalent, supramolecular interactions can enable the removal of lignin from lignocellulose under acidic conditions. Methanesulfonic acid (MSA) was utilized as an acidic component to cleave lignin–lignin and lignin–carbohydrate chemical bonds. MSA has environmentally friendly characteristics, such as biodegradability and low volatility, and it can be produced from methanol or methane,<sup>15</sup> making MSA a sustainable alternative to other oil-based sulfonic acids. MSA is also less reactive than sulfuric acid (ESI†). To demonstrate the high

efficiency of this supramolecular interaction-based delignification, softwood (refined Norway spruce chips) was chosen as a raw material because it has been generally recognized as highly resistant to delignification/fractionation.<sup>16,17</sup> Furthermore, nature and high lignin content notable hampers the enzymatic hydrolysis of softwood, when compared to other lignocellulose sources.<sup>18,19</sup>

## 2. Results and discussion

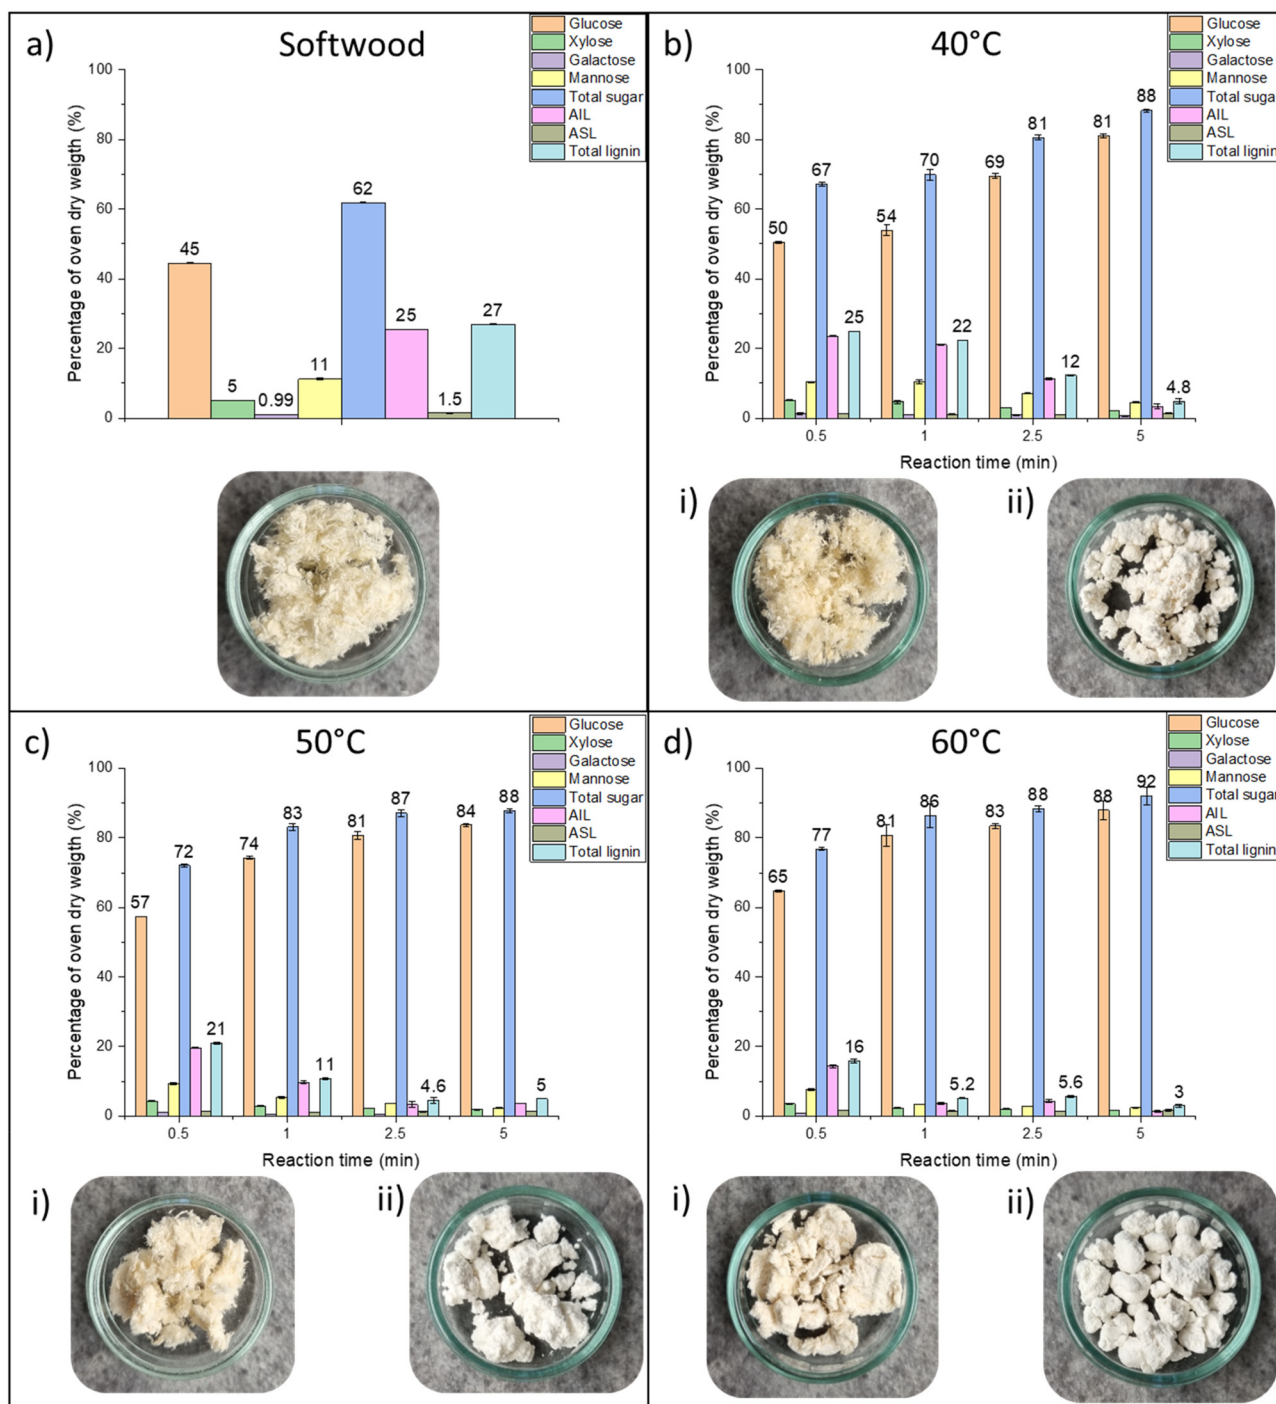

The delignification experiments were carried out at temperatures of 40, 50, and 60 °C with reaction times ranging from 0.5 to 5 min with a liquid:wood mass ratio of 10 : 1. Almost immediately after the addition of wood in the MSA–thymol mixture (with a molar ratio of 1 : 2), the solution began to change color to an intensively deep purple. After the addition of ethanol, filtration, and washing with ethanol, the color disappeared, and bright products were obtained at all investigated temperatures (Fig. 2). The color of the solid fraction is in stark contrast to that of many previously reported methods, including commercial kraft cooking, where the color of the delignified biomass is often notably darker than that of the raw material. Importantly, in addition to the production of brightly colored solid residues, the delignification efficiency was found to be exceptionally high (Fig. 2), especially when considering the low temperature and extremely short treatment times. At a temperature of 40 °C, the delignification efficiency remained relatively low during the first minute (remaining lignin content over 20%); however, at 2.5 min, the lignin content dropped to 12%, and at 5 min, the residual lignin content was

merely 4.8%. Approximately 5% residual lignin content was found at 2.5 min at 50. At 60 °C, the reaction time decreased to 1 min for obtaining a similar lignin content. Furthermore, a minimal residual lignin content of 3% was obtained at 5 min at 60 °C. After delignification, solid fraction contained mainly glucose, indicating the high cellulose content.

After removal of the solid fraction from the delignification mixture, a sodium salt of MSA with high purity (Fig. S1†) was precipitated with aqueous NaOH, and the MSA could be recycled using electrodialysis.<sup>21</sup> Thymol was recovered using column extraction with high purity (Fig. S2†) and could be directly reused. With column extraction, two lignin fractions (LF1 and LF2) with distinctively low molecular weights (Table S1†) were obtained (see ESI† for analysis of the two lignin fractions). The degrees of polymerization of the washed and dried solid fractions were found to be in the range of 312–216, similar to commercial microcrystalline cellulose (MCC). The industrial production of MCC mainly relies on the acid hydrolysis of bleached wood pulp, thus requiring multi-step synthesis and large consumption of hazardous chemicals (halogen-based bleaching chemicals, particularly).<sup>22</sup> MCC is a safe food additive (E-number E460)<sup>23</sup> used in the cosmetic, pharmacy, and food industries and is a widely used starting material for various cellulose-based materials and chemicals,<sup>24</sup> including nanomaterials<sup>25</sup> (see ESI† for the production of nanocellulose from MSA–thymol-treated softwood).

The delignification results clearly demonstrated that by using the MSA–thymol mixture, a delignification that has historically been carried out at high temperature for several hours can be performed in minutes at near-ambient temperature. Table S2† lists various delignification/fractionation methods

**Fig. 2** Chemical constituents and appearance of (a) original wood and solid residue after delignification at (b) 40 °C, (c) 50 °C, and (d) 60 °C. The appearance of delignified wood at (i) 0.5 and (ii) 5 min.

published in the literature for softwood and hardwood. Furthermore, selected previous delignification systems reported in the literature were tested with our raw material. Mixture of choline chloride-lactic acid has been recognized as one of the most typical DES capable to delignify lignocellulose biomass.<sup>26</sup> Excellent delignification efficiency was also noted as remaining lignin content after choline chloride-lactic acid

treatment were 6.8%, similar to those of MSA-thymol systems. However, choline chloride-lactic acid operated at notable higher temperature (120 °C) and longer reaction time (180 min). Furthermore, severe darkening of the solid residue was observed. Compared to DESs, acidic hydrotropes can usually be applied in delignification at lower temperatures and with shorter reaction times.<sup>12</sup> *p*-Toluenesulfonic acid was

introduced as one of the first acidic hydrotropes for nearly complete dissolution of lignin from hardwood.<sup>27</sup> However, notable lower delignification efficiency has been observed in case of softwood.<sup>28</sup> Here, when delignification of refined softwood was done using 80% aqueous *p*-toluenesulfonic acid solution at 80 °C for 20 min, lignin content remained relatively high, around 18%, and similarly to choline chloride-lactic acid DES, solid residue was dark in color. The highest delignification efficiency in the studied reference systems was observed with an aqueous 4-hydroxybenzenesulfonic acid<sup>29</sup> after 120 min at 60 °C, as the remaining lignin content was 5.9%. Furthermore, the aqueous 4-hydroxybenzenesulfonic acid was the only studied system aside the MSA–thymol to produce mildly colored solid residue. However, when the reaction time was decreased to 5 min, the remaining lignin content was 15%, being higher than what was obtained using MSA–thymol system at temperature of 40 °C after half shorter reaction time. Although studied reference systems represent a small fraction of various delignification systems reported in literature, they are amongst the most notable example of novel systems used biomass delignification. Therefore, MSA–thymol exhibits a clear advantage over traditional and emerging delignification methods, and to the best of our knowledge, MSA–thymol is the fastest high-efficiency delignification method (defined by a remaining lignin content  $\leq 5\%$ ) demonstrated on any type of biomass, while operating at the lowest reported temperature. It is also noteworthy, that although phenolic pulping has been reported previously,<sup>30–32</sup> these systems request high temperature and hours of treatment time, most likely due to the presence of large extent of competing hydrogen bond acceptor/donor (*i.e.*, water). Therefore, MSA–thymol is unique method for treatment of lignocellulose biomass.

Conversion of cellulose to glucose was investigated to evaluate the enzymatic digestibility of wood before and after MSA–thymol treatment at 40, 50, and 60 °C for one minute. The glucose yield and hydrolysis efficiency notable increased from original wood by applying the delignification (Fig. 3). Although

the sample prepared at 60 °C exhibited slightly lower hydrolysis rate during the first 36 h of enzymatic hydrolysis, the final hydrolysis efficiency order is by the increased temperature. The glucan hydrolysis efficiency of the samples obtained at 40, 50 and 60 °C increased by 30, 45 and 51%, respectively, when compared to the original wood sample, demonstrating that the very short MSA–thymol delignification treatment is suitable method to increase the glucose yield from softwood. Although the overall hydrolysis efficiency of MSA–thymol treated softwood cannot match with those reported for example for high temperature organosolv treated of softwood,<sup>16</sup> or other lignocellulose sources,<sup>33</sup> low temperature and extremely short reaction provides notable ecologic and economic advantage over most of the previous method. Furthermore, MSA–thymol enzymatic hydrolysis efficiency of delignified softwood was notable higher compared to the other low-temperature ( $<100$  °C) delignification methods reported in literature. For example, hydrolysis efficiency around 20% was reported for *p*-toluenesulfonic acid treated Masson pine at 80 °C,<sup>34</sup> whereas hydrolysis efficiency around 10% was obtained by Lewis acid-based deep eutectic solvent delignification at 80 °C.<sup>35</sup> Slightly higher hydrolysis rate (around 55%) compared to MSA–thymol delignified softwood was reported from Chinese fir after formic acid treatment at 90 °C.<sup>36</sup> However, 240 times longer reaction time was utilized compared to the study presented here.

To demonstrate that the hydrogen bond-donating properties of phenolic compounds are the key feature of delignification using MSA–thymol mixtures, several reference experiments were conducted. Neither 2-isopropyl-5-methylanisole (a methyl ether of thymol that has no hydrogen bond donating property) nor *p*-cymene (a thymol analog without a hydroxyl group) (Fig. 1b) formed a clear liquid with MSA and were thus not suitable for delignification. More notably, when thymol was replaced with nonaromatic menthol (hexahydrothymol) (Fig. 1c), room temperature liquid was obtained, yet no removal of lignin or carbohydrate was observed. Menthol is an

Fig. 3 (a) Glucose releasing rate and (b) hydrolysis efficiency of original and after one minute treatment with MSA–thymol at various temperature at different enzymatic hydrolysis times.

aliphatic alcohol, and its hydroxyl group can function both as a hydrogen bond acceptor and donor.<sup>13</sup> Therefore, it can be assumed that the hydrogen bonding interaction between menthol and the hydrogen bond-accepting groups of lignin is weaker than that between thymol and lignin. Furthermore, because menthol lacks aromaticity, there is no  $\pi$  stacking between menthol and lignin. Due to the weak interactions, no removal of lignin occurred when menthol was used with MSA.

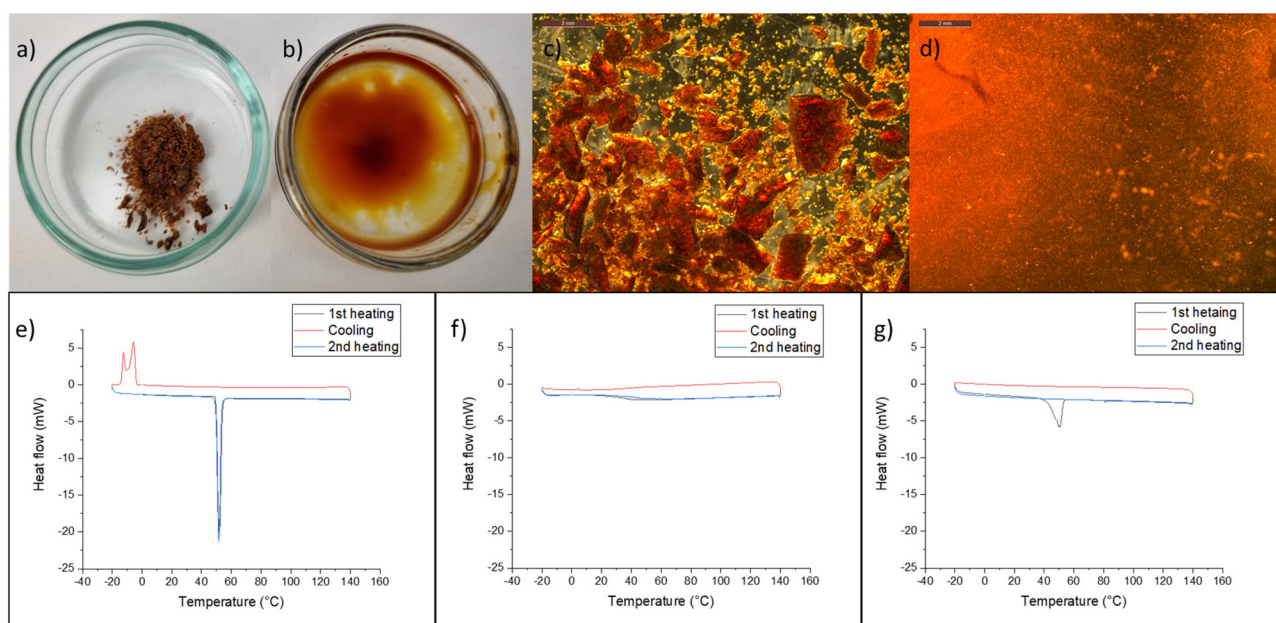

When water was used instead of thymol (molar ratio between MSA and water was 1 : 2, water content of 18.02 wt%), the lignin content was observed to increase from 27 to 32 wt%, which was mainly due to the removal of carbohydrate (*i.e.*, hemicelluloses). The inability of aqueous MSA to dissolve lignin indicates that MSA acts merely as an acid catalyst during the delignification, and does not function as a hydrotropic component for delignification, as previously shown with aromatic sulfonic acids.<sup>27,29,37</sup> Furthermore, when water was used at similar mass ratio that in case of thymol (water content of 75.75 wt%), practically no reaction occurred as lignin and carbohydrate content remained in similar range compared to original softwood.

Further experiments were conducted to demonstrate the interaction between thymol and lignin. The isolated lignin (LF1) was solid at room temperature and did not melt when heated in an oven at 80 °C. However, when lignin was manually mixed with thymol at a mass ratio of 1 : 2 and heated for approximately 30 min at 80 °C, solid particles disappeared and a viscous liquid was obtained. After cooling this liquid to room temperature, no precipitation of either component was observed, and the mixture was a homogeneous and strong gel-

like material (Fig. 4). On the other hand, when isolated lignin was mixed with menthol and heated in an oven, melting of menthol was observed, the lignin remained as solid particles, and the mixture was as an uneven solid at room temperature. These observations with menthol are in line with its delignification results, as the mixture of menthol and MSA showed no removal of lignin.

To verify that the formation of a liquid between lignin and thymol was not exclusively related to the isolation method, two commercial lignins were also investigated: ethanolytic lignin oligomers are obtained by high-temperature organosolv-type fractionation,<sup>38</sup> and kraft lignin is the most widely produced lignin and is obtained by sulfate cooking.<sup>39</sup> When either ethanolytic lignin or kraft lignin was heated together with thymol at a mass ratio of 1 : 2 in an oven at 80 °C, they formed liquid with no visible solid particles. The kraft lignin–thymol mixture was a strong, gel-like material at room temperature, similar to the mixture of thymol and LF1. On the other hand, oligomeric lignin and thymol formed a mixture that stayed liquid, albeit highly viscous, even at room temperature (Fig. S3†). Ethanolytic lignin formed a homogenous mixture with thymol even at a mass ratio of 1 : 1, a condition where it was a homogeneous, hard gel at room temperature.

Differential scanning calorimetry (DSC) analysis showed that neither LF1, LF2, ethanolytic, nor kraft lignin exhibited a melting point in the range of –20–140 °C (Fig. 4f and Fig. S4†). On the other hand, the melting peak of pure thymol was observed at approximately 51 °C (49–51 °C in the literature<sup>40</sup>) (Fig. 4e), and when solid mixtures of thymol and LF1 were heated in DSC, thymol melting was observed at the same temperature during the first heating cycle (Fig. 4f). However,

**Fig. 4** Visual appearance of lignin and deep eutectic supramolecular polymer, and their thermal behavior (a and b) and isolated lignin (LF1) after heating with thymol at a mass ratio of 2 : 1 at 80 °C for 30 min (c and d) and differential scanning calorimetry curves of (e) thymol, (f) isolated lignin (LF1), and (g) a mixture of thymol and isolated lignin at a mass ratio of 2 : 1.

unlike pure thymol, no crystallization of the thymol–lignin mixture was observed when cooled to  $-20\text{ }^{\circ}\text{C}$ , and during the second heating cycle, no melting peak was observed. The results from DSC analysis indicate that after the melting of thymol, a homogeneous mixture of lignin and thymol was formed, which showed no crystallization at  $-20\text{ }^{\circ}\text{C}$ . The results with ethanolytic and kraft lignin are in line with those of isolated lignin fractions (Fig. S4†). Furthermore, a lower interaction between menthol and lignin was demonstrated with ethanolytic lignin (Fig. S4†).

It can be assumed that the formation of a liquid/gel between thymol and lignin is due to the strong interaction between the two components, preventing the crystallization of otherwise solid compounds. The interaction between lignin and thymol can result in the formation of a deep eutectic supramolecular polymer (DESP),<sup>41</sup> previously shown with cyclodextrin (a macrocyclic oligosaccharide of glucose) and various hydrogen bond donors, such as carboxylic acids.<sup>42</sup> DESP between cyclodextrin and carboxylic acid was assumed to form due to the strong hydrogen bonding interaction between these two components, similar to the formation of DES. When cyclodextrin and carboxylic acid were dissolved in water followed by evaporation of the solvent, hydrogen bonding interactions prevented the crystallization of individual compounds and a gel-like material was obtained.<sup>41</sup> In the case of thymol and lignin, the melting of thymol, as well as the strong interaction between the two compounds, enables the formation of DESP even without an external solvent. Therefore, in addition to the demonstration of efficient biomass fractionation with the thymol-based system, we present a novel concept of lignin-based DESP. In addition to thymol, other aromatic alcohols, such as carvacrol (an isomer of thymol), phenol, and eugenol, formed liquid with lignin, and preliminary results showed that other phenolic compounds are also suitable for biomass fractionation (we note that eugenol was solidified with MSA, indicating that the usability of vinylic phenols is limited).

Based on the abovementioned observations, supramolecular interactions can be proposed as the driving force in delignification. The strong interaction between thymol and lignin allows the amphiphilic MSA to diffuse to the reaction site, resulting in the acid-catalyzed formation of carbocations on the lignin.<sup>43</sup> In a thymol-rich environment, the carbocation is thymolated (similar to phenolation<sup>44</sup>), followed by the fragmentation (depolymerization) of lignin and the rapid dissolution of these lignin fragments due to supramolecular interactions. The fragmentation is backed by the low molecular weight of lignin fractions, and thymolation is verified with nuclear magnetic resonance analyses (see ESI†). Thymolation prevents the self-condensation of lignin, which is generally recognized as the main side reaction in delignification that can lead to mixture darkening and the poor removal of residual lignin.<sup>45</sup> The lack of condensation during MSA–thymol delignification could explain the mild color of the cellulosic fraction still containing a small quantity of lignin (*cf.* brown color of unbleached kraft pulp).

### 3. Conclusion

This work demonstrates the existence of supramolecular interaction between lignin and phenolic compounds. The finding can provide a novel route and technological breakthrough in the development of selective fractionation chemistry. Here it was shown that this phenomenon can lead to a highly effective delignification of lignocelluloses to be used, for instance, in the production of monomeric or oligomeric platform chemicals, strongly supported by notable increase in enzymatic digestibility of softwood even after one minute treatment. Both used chemicals in this study (thymol and methanesulfonic acid) can be regarded as green compounds and their recovery with high purity demonstrated that they are recyclable, making concept presented here environmental feasible and sustainable alternative for treatment of lignocellulose biomass. The possibility of the use of near ambient temperature with exceptional short reaction times will increase economic feasibility due to lower operation and investment costs associated to low processing energy need and simplified process equipment. The low visible light and high UV radiation absorption could elevate the feasibility of lignin fraction in composite application. Furthermore, low molecular weight enables good solubility of lignin, which could allow lignin to be utilized in various applications. Furthermore, it can be envisioned that DESP between lignin and various aromatic alcohols could be used as water-tolerance adhesive or for example as bio-based wood preservative, due to the antimicrobial effect of phenolic compounds. As the chemical and physical structure of various lignocellulose sources can notable different from each other, in the future studies, delignification of biomass, such as hardwood and non-wood sources will be investigated.

### Author contributions

J. A. S. conceived of the presented idea, designed and carried out the experiments and data analysis, and wrote the manuscript; I. R., J. A., S. F., J. P. H. performed the analysis and helped with writing; A. Ä. contributed to the experimental design and writing of the manuscript.
