# Controlling the electronic and magnetic properties of the GeAs monolayer by generating Ge vacancies and doping with transition-metal atoms†

D. M. Hoat,<sup>a</sup>  <sup>ab</sup> R. Ponce-Pérez,<sup>c</sup> Chu Viet Ha<sup>d</sup> and J. Guerrero-Sanchez<sup>c</sup>

Controlling the electronic and magnetic properties of two-dimensional (2D) materials is a key step to make new multifunctional candidates for practical applications. In this work, defects and doping with transition metals (TMs = V, Cr, Mn, and Fe) at Ge sublattices are proposed in order to develop novel features in the hexagonal germanium arsenide (GeAs) monolayer. The pristine GeAs monolayer is a non-magnetic indirect gap semiconductor with an energy gap of 1.20(1.82) eV as provided by PBE(HSE06)-based calculations. A single Ge vacancy metallizes the monolayer, preserving its non-magnetic nature. In contrast, significant magnetization with a total magnetic moment of 1.96  $\mu_B$  is achieved by a pair of Ge vacancies. Herein, the computed band structures assert the half-metallic behavior of the defective system. Similarly, half-metallicity is also obtained by V, Mn, and Fe doping. Meanwhile, the Cr-doped GeAs monolayer is classified as a diluted magnetic semiconductor 2D system. In these cases, magnetic properties are produced mainly by TM-3d electrons with total magnetic moments between 2.00 and 4.00  $\mu_B$ . Further, the effects of substituting a pair of Ge atoms with a pair of TM atoms (pTM<sub>Ge</sub> systems) are also investigated. Results indicate the ferromagnetic half-metallicity of the pV<sub>Ge</sub> system, meanwhile antiferromagnetic ordering is stable in the remaining cases. In all cases, TM impurities transfer charge to the host GeAs monolayer since they are surrounded by As atoms, which are more electronegative than dopant atoms. Results presented herein may introduce new 2D systems – made from the non-magnetic GeAs monolayer – for spintronic applications with suitable electronic and magnetic features controlled mainly by transition metals.

## 1. Introduction

Nano-scale systems have drawn enormous attention from the scientific community in order to develop new materials for rapid advances in technology.<sup>1–4</sup> In this regard, the successful exfoliation of graphene has stimulated extensive investigations in the field of two-dimensional (2D) materials. In particular, graphene holds exclusive properties including high carrier mobility, high thermal conductivity, excellent mechanical strength, high surface/volume ratio, 97.2% transparency, and single molecule adsorption.<sup>5–7</sup> At a rapid rate, the synthesis of 2D materials has taken place using different advanced methods such as mechanical and electrochemical exfoliation,<sup>8,9</sup> chemical

vapor deposition (CVD),<sup>10,11</sup> and molecular beam epitaxy (MBE).<sup>12,13</sup> Research efforts have been devoted to the discovery of a large variety of other 2D materials besides graphene derivatives.<sup>14,15</sup> For example, hexagonal boron nitride (h-BN),<sup>16,17</sup> transition metal dichalcogenides (TMDs),<sup>18,19</sup> silicene,<sup>20</sup> and phosphorene,<sup>21,22</sup> among others, have been fabricated successfully. Besides, theoretical calculations have been widely utilized to predict the stability as well as ground state properties of new 2D compounds.<sup>23,24</sup> Unique physical, chemical, and mechanical properties have made 2D materials potential candidates for a wide range of applications such as optoelectronics and electronics,<sup>25,26</sup> energy storage,<sup>27,28</sup> photodetection,<sup>29,30</sup> gas sensing,<sup>31,32</sup> catalysis,<sup>33,34</sup> and spintronics.<sup>35,36</sup>

Recently, along with other IV–V group 2D semiconductor materials, germanium arsenide (GeAs) has been considered by researchers. 2D GeAs has been grown by Barreateau *et al.*<sup>37</sup> using the melt-growth method under high pressure. Characterization demonstrates its layered structure and semiconductor behavior. Guo *et al.*<sup>38</sup> have fabricated p-type transistors based on few-layer GeAs with hole carrier mobility up to 99 cm<sup>2</sup> V<sup>−1</sup> s<sup>−1</sup> and an ON–OFF ratio of 10<sup>2</sup>. Moreover, a fast and intensive photoresponse is also observed in the mid-infrared regime. The promise of 2D GeAs crystals for polarization optical applications has been also

demonstrated by Zhou *et al.*,<sup>39</sup> where high dichroic ratios of  $I_{\text{pmax}}/I_{\text{pmin}} \sim 1.49$  and 4.4 at 520 and 830 nm are obtained, respectively. A field emission (FE) current from GeAs – with a turn-on field of  $\sim 80 \text{ V } \mu\text{m}^{-1}$  and current density higher than  $10 \text{ A cm}^{-2}$  – has been observed by Bartolomeo *et al.*,<sup>40</sup> which suggests the suitability of this 2D material to be used as a cold cathode for electron emission. With an energy gap in the desirable range, 2D GeAs has also been recommended for photocatalytic applications towards water splitting.<sup>41</sup>

On the other hand, researchers have made efforts to develop new materials with desirable features for spintronic applications to meet the rapid advances of this field.<sup>42,43</sup> Spin-based electronics demand highly spin-polarized materials with significant magnetic properties. Nevertheless, most of the discovered 2D materials have no intrinsic magnetism, and the 2D GeAs semiconductor is an example. In this work, our main aim is to propose efficient approaches to achieve proper magnetization of the GeAs monolayer in a hexagonal structure (belonging to the  $P6m2$  space group) towards spintronic applications. Keeping in mind the effectiveness and simplicity of realizing vacancies and doping in 2D materials,<sup>44,45</sup> structural modification at Ge sites is proposed. Specifically, a single Ge vacancy and a pair of Ge vacancies are investigated. Moreover, doping with a single TM atom and a pair of TM atoms (TM = transition metal: V, Cr, Mn, and Fe) is also considered. Our calculated doping energy indicates that the Ge site is preferable for transition metals to be doped in the GeAs monolayer (see Fig. S1 of the ESI file†). It is anticipated that significant magnetization of the GeAs monolayer is achieved, where feature-rich half-metallicity, and diluted magnetic semiconductor and antiferromagnetic semiconductor characteristics are obtained. Results suggested the defective and doped 2D GeAs systems as prospective 2D spintronic alternatives.

## 2. Computational details

Theoretical calculations are performed employing the Density Functional Theory (DFT) framework<sup>46</sup> based on the Projector Augmented Wave method – as implemented in the advanced Vienna *ab initio* simulation package (VASP).<sup>47,48</sup> The Generalized Gradient Approximation with the Perdew–Burke–Ernzerhof (PBE) version is adopted for description of the electron exchange-correlation potential.<sup>49</sup> Considering the strong correlation effects of 3d electrons, the DFT +  $U$  method by Dudarev *et al.*<sup>50</sup> is utilized with the on-site coulombic interaction parameters  $U_{\text{eff}}$  of 3.25, 3.70, 3.90, and 5.40 for V, Cr, Mn, and Fe atoms,<sup>51</sup> respectively. The DFT-D3 method<sup>52</sup> is introduced in calculations to consider the effects of the weak van der Waals interactions. An energy cutoff of 500 eV is chosen to realize the plane-wave expansion. The energy convergence is determined with a criterion of  $10^{-6}$  eV. The structures are relaxed until the residual forces on individual atoms are less than  $10^{-2} \text{ eV } \text{\AA}^{-1}$ . A  $\Gamma$ -centered  $k$ -grid of  $20 \times 20 \times 1$  is generated using the Monkhorst–Pack method<sup>53</sup> to sample the Brillouin zone of the primitive cell GeAs monolayer. To simulate the defects and doping, a  $4 \times 4 \times 1$  supercell containing 64 atoms is constructed. In these cases, a Monkhorst–Pack  $k$ -mesh of  $4 \times 4 \times 1$

is used. Furthermore, a vacuum gap wider than  $14 \text{ \AA}$  is included in the direction perpendicular to the monolayer plane to avoid the inter-layer interactions.

## 3. Results and discussion

### 3.1 Pristine GeAs monolayer

A unit cell of the GeAs monolayer is visualized in Fig. 1a, where one can see two vertically aligned Ge atoms inserted between two As atoms to form the As–Ge–Ge–As atomic stacking. From the top-view, the monolayer has a hexagonal structure with alternating Ge and As atoms, such that the structure is ascribed to the  $P6m2$  space group (no. 187). From our calculations of structural relaxation, the following parameters are obtained for the GeAs monolayer unit cell: (1) lattice constant  $a = 3.82 \text{ \AA}$ ; (2) chemical bond lengths  $d_{\text{Ge–As}} = 2.49 \text{ \AA}$  and  $d_{\text{Ge–Ge}} = 2.50 \text{ \AA}$ ; (3) structural buckling height  $\Delta_{\text{total}} = 2 \times \Delta_{\text{As–Ge}} + \Delta_{\text{Ge–Ge}} = 2 \times 1.15 + 2.50 = 4.80 \text{ \AA}$ ; and (4) interatomic angles  $\angle \text{AsGeAs} = 100.36^\circ$  and  $\angle \text{AsGeGe} = 117.54^\circ$ . Once optimized, the stability of the GeAs monolayer was investigated using the following criteria:

- Phonon calculations are carried using the PHONOPY code,<sup>54</sup> for which the finite displacement method is adopted. Remembering that phonon frequency reflects the stiffness of material bonds, an imaginary frequency (corresponding to the negative second derivative of energy) asserts the dynamic instability of the material and *vice versa*. Phonon spectra of the GeAs monolayer are given in Fig. 1b. There are four atoms in a unit cell, thus, corresponding to two phonon branches (three acoustic and nine optical modes). Importantly, all phonon

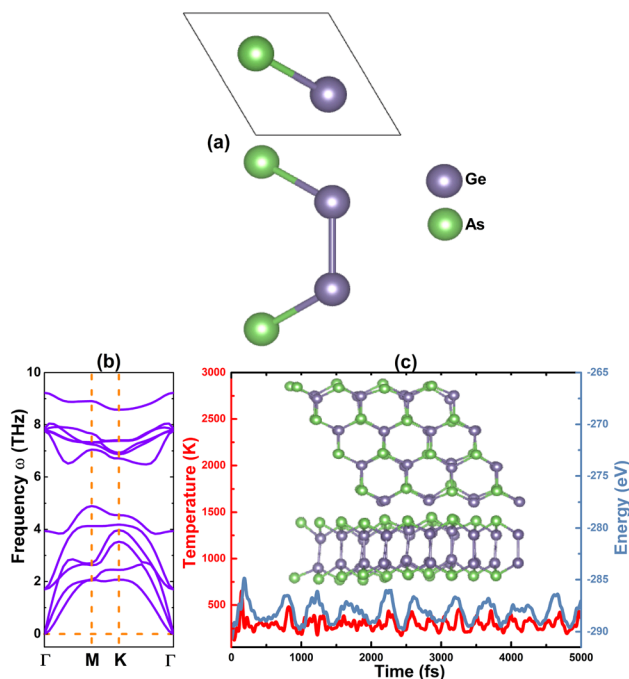

Fig. 1 (a) Atomic structure unit cell, (b) phonon dispersion curves, and (c) AIMD simulations at 300 K (Inset: atomic structure  $4 \times 4 \times 1$  supercell after simulations) of the GeAs monolayer.

frequencies meet the condition of  $\omega > 0$  (with positive values) of material stability. These results indicate that the GeAs monolayer is dynamically stable.

- *Ab initio* molecular dynamic (AIMD) simulations are carried out at room temperature 300 K using the  $4 \times 4 \times 1$  supercell of the GeAs monolayer. Herein, a NVT ensemble and Nose–Hoover thermostat are utilized,<sup>55,56</sup> and the time step is set to 5 fs with a total time of 5 ps. Results displayed in Fig. 1c show a slight movement of Ge and As atoms from their equilibrium sites, where no broken Ge–As and Ge–Ge bonds or geometric reconstruction (the initial hexagonal geometry is well-preserved) is observed. These results evidence that the GeAs monolayer is thermally stable.

- Elastic constants are calculated using the stress–strain method, where two constants  $C_{11}$  and  $C_{12}$  are required for the 2D hexagonal symmetry. According to Born's criteria, 2D materials hold good mechanical stability if  $C_{11} > 0$  and  $C_{11} > |C_{12}|$ .<sup>57</sup> For the GeAs monolayer, our computations yield values of 81.95 and 30.65 N m<sup>−1</sup> for  $C_{11}$  and  $C_{12}$  constants, respectively. Note that these values satisfy Born's criteria, suggesting that the GeAs monolayer is mechanically stable.

Once its stability is confirmed, the electronic properties of the GeAs monolayer are investigated. First, the electronic band structure is computed using PBE and the hybrid HSE06 functional.<sup>58</sup> Theoretically, it can be expected that the HSE06 functional provides a more accurate calculation of the band gap of materials by including a 25% fraction of the exact Hartree exchange potential. Results plotted in Fig. 2a indicate that the GeAs monolayer is an indirect gap semiconductor, in which the valence band maximum and conduction band minimum are noted at the  $\Gamma$  and  $M$  points, respectively. Our PBE- and HSE06-based computations yield energy gaps of 1.20 and 1.82 eV, respectively. Note that these values are smaller than those of the monoclinic monolayer,<sup>41</sup> indicating the important role of the structure in the GeAs monolayer energy gap. Then, the projected density of states (PDOS) of Ge and As atoms is calculated to analyze band structure formation. From PDOS spectra in Fig. 2b, a significant contribution from s and p orbitals of both constituent atoms is noted. Focusing on the regions close to the Fermi level, it can be seen that the upper part of the valence band is formed mainly by Ge- $p_z$  and As- $p_z$  states, while the Ge-s state generates mainly the lower part of the conduction band. To further investigate the chemical bonds, charge valence and electron localization in the GeAs monolayer are calculated, whose results are illustrated in Fig. 2c and d. Significant charge accumulations centered at As sites can be noted, indicating the ionic character of the Ge–As chemical bond. This feature is derived from the difference in the electronegativity of Ge and As atoms, which causes the charge transfer from the Ge (less electronegative) atom to the As (more electronegative) atom. This process is further confirmed by the Bader charge analysis, which indicates that a charge amount of  $0.28 e$  is transferred from the Ge atom to the As atom. However, it will be flawed neglecting the covalent character, considering significant electronic hybridization of Ge-p and As-p orbitals (as observed in PDOS spectra). Therefore, the Ge–As chemical bond exhibits a mix of ionic and covalent characters. In addition, the Ge–Ge chemical bond is predominantly

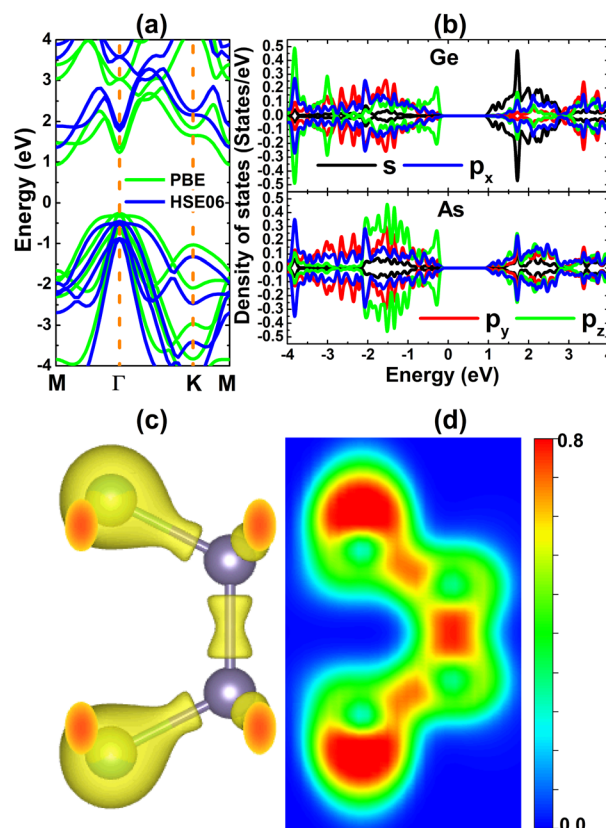

Fig. 2 (a) Electronic band structure (the Fermi level is set to 0 eV), (b) projected density of states, (c) charge distribution (iso-surface value:  $0.06 e \text{ \AA}^{-3}$ ), and (d) electron localization function of the GeAs monolayer.

covalent because significant electrons are localized in the region between Ge atoms, which may be generated by sharing electrons.

### 3.2 Effects of Ge vacancies

In this part, the effects of a single Ge vacancy ( $Va_{Ge}$  system) and a pair of Ge vacancies ( $pVa_{Ge}$  system) on the electronic and magnetic properties of the GeAs monolayer are investigated. First, the formation energies  $E_f$  of  $Va_{Ge}$  and  $pVa_{Ge}$  systems are calculated using the following formula:

$$E_f = \frac{E_{de-GeAs}^t - E_{GeAs}^t + n_{Ge}\mu_{Ge}}{n_{Ge}} \quad (1)$$

where  $E_{de-GeAs}^t$  and  $E_{GeAs}^t$  are the total energy of the defective and perfect GeAs monolayers, respectively;  $n_{Ge}$  denotes the number of Ge vacancies; and  $\mu_{Ge}$  refers to the chemical potential of the Ge atom. Results are given in Table 1. Our calculations show that additional energies of 2.80 and 2.75 eV per atom should be supplied to create a single Ge vacancy and a pair of Ge vacancies in the GeAs monolayer, respectively. Note that there is only small difference in  $E_f$  values for single and double Ge vacancies. Then, the structural stability is verified through cohesive energy  $E_c$ , which is calculated as follows:

$$E_c = \frac{E_{de-GeAs}^t - m_{Ge}E(Ge) - m_{As}E(As)}{m_{Ge} + m_{As}} \quad (2)$$

**Table 1** Formation/doping energy  $E_f/E_d$  (eV per atom), cohesive energy  $E_c$  (eV per atom), electronic band gap  $E_g$  (eV; spin-up/spin-down; M: metallic), charge transferred from the transition metal impurity  $\Delta Q$  (e), and the total magnetic moment  $M_t$  ( $\mu_B$ ) of the defective/doped GeAs monolayer

	$E_f/E_d$	$E_c$	$E_g$	$\Delta Q$	$M_t$
Va <sub>Ge</sub>	2.80	−3.44	M/M	—	0.00
pVa <sub>Ge</sub>	2.75	−3.40	M/0.33	—	1.96
V <sub>Ge</sub>	1.25	−3.47	1.10/M	0.97	2.94
Cr <sub>Ge</sub>	0.78	−3.44	1.14/0.44	0.71	2.00
Mn <sub>Ge</sub>	1.44	−3.44	M/1.17	0.62	3.00
Fe <sub>Ge</sub>	1.53	−3.47	M/0.87	0.41	4.00
pV <sub>Ge</sub>	1.31	−3.45	M/1.19	0.75/0.75	4.00
pCr <sub>Ge</sub>	1.25	−3.36	0.17/0.17	0.57/0.41	0.00
pMn <sub>Ge</sub>	2.17	−3.37	M/M	0.54/0.37	0.00
pFe <sub>Ge</sub>	1.37	−3.45	0.57/0.57	0.31/0.20	0.00

where  $m_{\text{Ge}}$  and  $m_{\text{As}}$  are the numbers of Ge and As atoms in the system, respectively;  $E(\text{Ge})$  and  $E(\text{As})$  denote the energy of single Ge and As atoms, respectively. From Table 1, one can see that Va<sub>Ge</sub> and pVa<sub>Ge</sub> systems have  $E_c$  values of −3.44 and −3.40 eV per atom, respectively. Negative  $E_c$  values suggest good structural and chemical stability of the defective 2D GeAs systems. It is important to mention that the creation of Ge vacancies affects negligibly the monolayer stability as suggested by a small  $E_c$  variation (that of the perfect GeAs monolayer is −3.49 eV per atom).

It is found that the non-magnetic nature of the GeAs monolayer is preserved upon creating a single Ge vacancy, which is reflected in a zero total magnetic moment of the Va<sub>Ge</sub> system. In contrast, significant magnetization is achieved by a pair of Ge vacancies. Consequently, the pVa<sub>Ge</sub> system has a total magnetic moment of 1.96  $\mu_B$ . Spin density, which characterizes the difference in charge density between spin

**Fig. 4** Spin-polarized band structure (the Fermi level is set to 0 eV) of the GeAs monolayer with (a) a single Ge vacancy and (b) a pair of Ge vacancies.

configurations, is a useful parameter to analyze atomic contribution to the system magnetism. Fig. 3 illustrates the spin density in the pVa<sub>Ge</sub> system. From the figure, one can see that spin surfaces are centered mainly at As atoms (in both atomic sublayers) around the vacancy sites, indicating their key role in producing the pVa<sub>Ge</sub> system magnetic properties.

Fig. 4 shows the computed spin-polarized band structures of the GeAs monolayer with the presence of Ge vacancies. It can be observed clearly that the band structure of the Va<sub>Ge</sub> system is spin-symmetric, corresponding to its non-magnetic nature. Meanwhile, a pair of Ge vacancies induce significant spin polarization in the band structure. Compared with that of the perfect monolayer, one can see new middle-gap energy branches to determine the electronic nature. Specifically, a single Ge vacancy leads to the metallization of the GeAs monolayer, meanwhile the feature-rich half-metallicity is obtained by pair Ge vacancies. In the latter case, the spin-up state is metallized, meanwhile the spin-down state exhibits a semiconductor character with an energy gap of 0.33 eV. These results suggest the pVa<sub>Ge</sub> system to be a prospective 2D spintronic material, such that creating a pair of Ge vacancies can be

**Fig. 3** Spin density (iso-surface value: 0.005  $e \text{ \AA}^{-3}$ ) in the GeAs monolayer with a pair of Ge vacancies.

**Fig. 5** Projected density of states of atoms closest to defect sites in the GeAs monolayer with (a) a single Ge vacancy and (b) a pair of Ge vacancies.

considered as an efficient approach to functionalize the GeAs monolayer for spintronic applications.<sup>59</sup>

To provide more insights into the electronic and magnetic properties of  $V_{\text{Ge}}$  and  $pV_{\text{Ge}}$  systems, PDOS spectra of As and Ge atoms closest to the defect sites are given in Fig. 5. From panel a, one can see that the metallic nature of the  $V_{\text{Ge}}$  system is derived mainly from As- $p_{x,y,z}$  states, while the Ge-s state gives rise to mainly new energy branches above the Fermi level. In the latter one, a small contribution from the As- $p_z$  state is also noted. Otherwise, the electronic and magnetic properties of the  $pV_{\text{Ge}}$  system are regulated mainly by As- $p_{x,y,z}$  states considering its high weight at the vicinity of the Fermi level in both spin channels with a strong spin polarization (see panel b).

### 3.3 Effects of doping a single transition metal atom

Herein, the effects of doping with single transition metals (TMs) at the Ge site (V –  $V_{\text{Ge}}$  system, Cr –  $\text{Cr}_{\text{Ge}}$  system, Mn –  $\text{Mn}_{\text{Ge}}$  system, and Fe –  $\text{Fe}_{\text{Ge}}$  system) on the electronic and magnetic properties of the GeAs monolayer are investigated. First, doping

energy  $E_d$  and cohesive energy  $E_c$  are calculated using the following expressions:

$$E_d = \frac{E_{\text{do-GeAs}}^t - E_{\text{GeAs}}^t + n_{\text{Ge}}\mu_{\text{Ge}} - n_{\text{TM}}\mu_{\text{TM}}}{n_{\text{TM}}} \quad (3)$$

$$E_c = \frac{E_{\text{do-GeAs}}^t - m_{\text{Ge}}E(\text{Ge}) - m_{\text{As}}E(\text{As}) - m_{\text{TM}}E(\text{TM})}{m_{\text{Ge}} + m_{\text{As}} + m_{\text{TM}}} \quad (4)$$

$E_{\text{do-GeAs}}^t$  is the total energy of the doped system. Results are given in Table 1. Results suggest that Cr doping is thermodynamically most favorable with an  $E_d$  value of 0.78 eV per atom, meanwhile the highest energy of 1.53 eV per atom should be supplied to realize the process of doping with an Fe atom. Moreover, V and Mn doping requires an additional energy of 1.25 and 1.44 eV per atom, respectively. Once formed, the doped GeAs systems may hold good structural and chemical stability, where TM impurities affect negligibly the monolayer stability with  $E_c$  values between  $-3.47$  and  $-3.44$  eV per atom (which are similar to that of the bare GeAs monolayer).

Our spin-polarized calculations assert significant magnetization of the GeAs monolayer induced by doping with transition metals. Consequently, total magnetic moments of 2.94, 2.00, 3.00, and 4.00  $\mu_B$  are obtained for V-, Cr-, Mn-, and Fe-doped systems, respectively. Herein, the local magnetic moments of V, Cr, Mn, and Fe impurities are 2.53, 3.38, 3.80, and 3.36  $\mu_B$ , respectively. Large local magnetic moments indicate the key role of TM atoms in generating the system magnetism. This feature is further confirmed by the spin density as illustrated in

Fig. 6 Spin density (iso-surface value:  $0.02 \text{ e } \text{\AA}^{-3}$ ) in (a) V-, (b) Cr-, (c) Mn-, and (d) Fe-doped GeAs monolayers.

Fig. 7 Spin-polarized band structure (the Fermi level is set to 0 eV) of (a) V-, (b) Cr-, (c) Mn-, and (d) Fe-doped GeAs monolayers.

Fig. 6. From the figure, one can see that the difference in charge density between spin states – that is the origin of magnetism – takes place mainly at impurity sites. Therefore, it can be concluded that the magnetic properties are produced mainly by transition metals.

Fig. 7 shows the spin-polarized band structures of the doped GeAs systems, where strong spin polarization is observed in all cases. It is undoubted that the magnetism with unbalanced spin-dependent charge density is reflected in the spin-polarized profile. Note that the electronic nature of the doped GeAs systems is determined by new middle-gap energy branches that appear in the vicinity of the Fermi level as a consequence of doping. Specifically, the half-metallicity is induced by doping

with V, Mn, and Fe atoms. In these cases, one spin state is metallized, meanwhile the other exhibits the semiconductor character with energy gaps of 1.10, 1.17, and 0.87 eV, respectively. Moreover, the Cr-doped system can be classified as a diluted magnetic semiconductor material with spin-up and spin-down band gaps of 1.14 and 0.44 eV, respectively. Because of their metallic nature with the lowly electronegative character, TM impurities act as charge losers when they are substitutionally incorporated into the host GeAs monolayer. This process is further quantified by the Bader charge analysis, which indicates the transfer of 0.97, 0.71, 0.62, and 0.41  $e$  from V, Cr, Mn, and Fe dopants to the host monolayer, respectively.

The contribution of TM impurities to form the band structure is further analyzed by their PDOS spectra displayed in Fig. 8. Focusing on the region around the Fermi level, the main contribution from the TM-3d orbital can be noted. The spin metallic character of the V-, Mn-, and Fe systems is derived mainly from V- $d_{yz}$ , Mn- $d_{yz}$ , and Fe- $d_{yz}$  states, respectively. Importantly, the spin polarization suggests also that magnetic properties are produced mainly by the 3d electrons of transition metal impurities.

### 3.4 Effects of doping a pair of transition metal atoms

Now, the effects of doping with a pair of TMs (pTM<sub>Ge</sub> system) on the electronic and magnetic properties of the GeAs monolayer are investigated. First, the spin alignment between TM dopants is determined using the criterion of the lowest energy. Herein, parallel and antiparallel orientations are considered, as illustrated in Fig. 9. It is found that the ferromagnetism with a total

Fig. 8 Projected density of states of transition metals in (a) V-, (b) Cr-, (c) Mn-, and (d) Fe-doped GeAs monolayers.

Fig. 9 Spin density (iso-surface value:  $0.02 \text{ e } \text{\AA}^{-3}$ ; positive spin value: red surface; negative spin value: green surface) in (a) pV-, (b) pCr-, (c) pMn-, and (d) pFe-doped GeAs monolayers.

Fig. 10 Spin-polarized band structure (the Fermi level is set to 0 eV) of (a) pV-, (b) pCr-, (c) pMn-, and (d) pFe-doped GeAs monolayers.

magnetic moment of  $4.00 \mu_B$  is energetically favorable in the V-doped system with an energy of 608.3 meV smaller than that of the antiferromagnetism. In contrast, the antiferromagnetic state with zero total magnetic moment is more stable than the ferromagnetic state in the Cr-, Mn-, and Fe-doped GeAs monolayer. In these cases, the differences in energy are 1423.7, 1146.6, and 513.1 meV, respectively. From now on, only the stable states are investigated. Applying eqn (3),  $E_d$  values of 1.31, 1.25, 2.17, and 1.37 eV per atom are obtained for a pair of V, Cr, Mn, and Fe atoms, respectively. Except for the cases of Fe

impurities, a higher doping level may require more energy to realize the doping process. Once formed, all pV-, pCr-, pMn-, and pFe-doped systems are structurally and chemically stable considering their negative  $E_c$  values of  $-3.45$ ,  $-3.36$ ,  $-3.37$ , and  $-3.45$  eV per atom, respectively, which have been calculated using eqn (4).

The computed spin-polarized band structures of the GeAs monolayer doped with a pair of transition metals are displayed in Fig. 10. Note that the ferromagnetism of the pV-doped system corresponds to its spin-polarized band structure that indicates the half-metallic nature. Herein, new middle-gap states appear to metallize the spin-down state, meanwhile the semiconductor spin-down state has an energy gap of 1.19 eV. In contrast, the band structures of pCr-, pMn-, and pFe-doped systems are spin-symmetric. A pair of Mn impurities leads to the emergence of the antiferromagnetic metallic nature, meanwhile the antiferromagnetic semiconductor behavior is induced in the GeAs monolayer by doping with a pair of Cr and Fe atoms, respectively. In the latter cases, energy gaps of 0.17 and 0.57 eV are obtained, respectively. Further, our Bader charge analysis indicates that each V atom transfers a charge quantity of  $0.75 e$  to the host monolayer. In the antiferromagnetic systems, the atoms with a positive spin value transfer a larger amount of charge to the host monolayer than those with a negative spin value. Specifically, the host GeAs monolayer attracts charge quantities of  $0.57/0.41$ ,  $0.54/0.37$ , and  $0.31/0.20 e$  from Cr(+)/Cr(-), Mn(+)/Mn(-), and Fe(+)/Fe(-) atoms, respectively.

Now, PDOS spectra of a pair of TM impurities are given in Fig. 11 to investigate in more detail the origin of electronic and magnetic properties. Due to the structural symmetry, PDOS spectra of V atoms are identical, meanwhile those of Cr-Mn-Fe atoms are asymmetric. Note that the metallic spin-up state of the pV-doped system is derived mainly from V- $d_{xy} - d_{xz} - d_x^2$  states. Similarly, Mn- $d_{xy} + d_x^2$  and Mn- $d_{xz} + d_{yz}$  states metallize the spin-up and spin-down states of the GeAs monolayer. Importantly, the strong spin polarization demonstrates the key role of TMs-3d electrons in generating the system magnetism.

## 4. Conclusions

To conclude, a systematic study has been carried out to clarify the effects of Ge vacancies and doping with transition metals on the electronic and magnetic properties of the GeAs monolayer. Theoretical calculations confirm the good dynamical, thermal, and mechanical stability of the GeAs monolayer. Ge–As bonds exhibit a mix of covalent (generated by the electronic hybridization between Ge- $p_z$  and As- $p_z$  states) and ionic (generated by the charge transfer from the Ge atom to the As atom) characters, while the Ge–Ge bond is predominantly covalent. The monolayer is significantly magnetized by creating a pair of Ge vacancies, where magnetic properties are produced mainly by the  $p_{x,y,z}$  states of As atoms around the defect sites. Meanwhile, the non-magnetic nature is preserved upon creating a single Ge vacancy, where As- $p_{x,y,z}$  states induce the metallic behavior. Significant magnetism is also achieved by doping with transition metals, which is produced mainly by TMs-3d electrons. Moreover, the 3d orbital develops new middle-gap states to control either the half-metallicity or diluted magnetic semiconductor nature, which is desirable for spintronic applications. Further investigations indicate the ferromagnetic half-metallicity induced by doping with a pair of V atoms. Meanwhile antiferromagnetic metallic/semiconductor characters are obtained in the pMn-/pCr(pFe)-doped GeAs monolayer. Because of the structural symmetry, a zero total magnetic moment is obtained in the antiferromagnetic systems, meanwhile that of the pV-doped system is  $4.00 \mu_B$  contributed equally by V atoms. Our work may pave solid ways to achieve proper magnetization of the non-magnetic GeAs monolayer, from which new half-metallic or diluted magnetic semiconductor materials are obtained towards spintronic applications.

## Data availability

Data related to this study are available upon reasonable request.

## Conflicts of interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

## Acknowledgements

Calculations were performed in the DGCTIC-UNAM Supercomputing Center (projects LANCAD-UNAM-DGTIC-368). D. M. Hoat expresses his gratitude for all the valuable support from Duy Tan University, which is going to celebrate its 30th anniversary of establishment (Nov. 11, 1994–Nov. 11, 2024) towards "Integral, Sustainable and Stable Development".
