X-Ray imaging techniques are among the most widely used modalities in medical imaging and their constant evolution has led to the emergence of new technologies. The new generation of computed tomography (CT) systems – spectral photonic counting CT (SPCCT) and X-ray luminescence optical imaging – are examples of such powerful techniques. With these new technologies the rising demand for new contrast agents has led to extensive research in the field of nanoparticles and the possibility to merge the modalities appears to be highly attractive. In this work, we propose the design of lanthanide-based nanocrystals as a multimodal contrast agent with the two aforementioned technologies, allowing SPCCT and optical imaging at the same time. We present a systematic study on the effect of the Tb³⁺ doping level and surface modification on the generation of contrast with SPCCT and the luminescence properties of GdF₃:Tb³⁺ nanocrystals (NCs), comparing different surface grafting with organic ligands and coatings with silica to make these NCs bio-compatible. A comparison of the luminescence properties of these NCs with UV revealed that the best results were obtained for the Gd_{0.9}Tb_{0.1}F₃ composition. This property was confirmed under X-ray excitation in microCT and with SPCCT. Moreover, we could demonstrate that the intensity of the luminescence and the excited state lifetime are strongly affected by the surface modification. Furthermore, whatever the chemical nature of the ligand, the contrast with SPCCT did not change. Finally, the successful proof of concept of multimodal imaging was performed *in vivo* with nude mice in the SPCCT taking advantage of the so-called color K-edge imaging method.

Introduction

The development of original and efficient nanoparticle-based contrast agents represents a significant part of the ongoing improvements in medical imaging. The constant advances in the field of nanotechnology play a major role in offering new tools for enhanced and optimized imaging with great potential for clinical applications.¹ Among the existing modalities, X-ray imaging techniques are most commonly used owing to their fast acquisition, high spatial resolution and low cost, which make them extremely relevant for use in clinics. A typical example is computed tomography (CT), which has become a widely used clinical X-ray imaging modality since its first development fifty years ago. In addition, other techniques such as X-ray micro-CT have received growing interest in life science imaging and preclinical studies on small animals thanks to their higher resolution.^{2,3} Constant developments of these X-ray imaging modalities have led to many newly emer-

ging technologies such as the recent color K-edge imaging that have been deployed in spectral photon-counting CT (SPCCT).^{4–6} This new generation of CT systems combines high resolution (250 μm), element-specific imaging and *in situ* quantification.^{7,8} One issue still remains to be addressed due to the intrinsic X-ray absorption in normal tissues that leads to relatively low imaging sensitivity. Recently, X-ray-activated luminescence has been considered as a promising approach for high sensitivity and deep-tissue imaging.^{9,10} Indeed, the combination of X-ray excitation and visible luminescence successfully combines the strengths of both techniques: deep tissue penetration, low X-ray scattering in tissue, and negligible auto-fluorescence background.¹¹

The improvement of these techniques (CT, SPCCT and X-ray activated luminescence) is strongly related to the elaboration of novel X-ray sensitive contrast agents.^{12,13} Thus, intensive research has been conducted on the development of inorganic nanoparticles to improve contrast with the new SPCCT imaging modality¹⁴ and the optimization of luminescent nanoparticles for X-ray excited optical imaging.^{9,15} Unfortunately, very few studies propose the design of nanoparticles acting as innovative contrast agents for the effective combination of both X-ray based modalities.^{16–18} Indeed the possibility to bring together CT, SPCCT and X-ray activated optical imaging with the same nanoparticle-based contrast agent offers great interest for the development of multimodal imaging with strong impact on the future of diagnostics.

Within the toolbox of available nanoparticles, compositions sometimes include elements with high toxicity such as tungsten or chromium which despite good luminescence properties have limitations for further use *in vivo*.^{17,19} Lanthanide-based rare earth sodium fluoride nanoparticles NaREF_4 are interesting systems featuring all the essential characteristics that make them ideal candidates with heavy elements, attractive optical properties with narrow emission bands and excellent photostability.^{20,21} The only weakness of these nanoparticles is their limited chemical stability in aqueous suspensions (pure water and buffers at pH 7.7 and 8.0) or under neutral physiological conditions.^{22–24}

In this context, the aim of our work was to design multimodal contrast agents suitable for X-ray based imaging technologies with high colloidal stability and biocompatibility. Recently, we demonstrated that GdF_3 nanocrystals (NCs) are efficient systems for *in vivo* imaging with SPCCT due to their X-ray attenuation properties.²⁵ Indeed, gadolinium has a K-edge value in a range of energy perfectly suited for K-edge imaging with SPCCT technology (50.2 keV).^{26,27} Furthermore, this element is already used for MRI in clinics or in nanoparticle research development.²⁸ Also, due to its very low solubility in aqueous media (less than $3 \times 10^{-5} \text{ mol L}^{-1}$), GdF_3 can be considered as one of the most stable gadolinium derivatives, making it the matrix of choice for this work.²⁹ The rational design of the targeted nanoparticles for X-ray imaging technologies requires a comprehensive understanding of the parameters inducing optimized luminescence, contrast with the scanner and biocompatibility. Hence, in order to impart

luminescence X-ray activation properties, the GdF_3 matrix was doped with various amounts of Tb^{3+} (from 0.20 moles to 0.05 moles). A systematic study using UV/Vis and X-ray irradiation identified the most relevant composition in terms of luminescence intensity and emission lifetime. For water dispersibility NCs were functionalized with various ligands and coatings including polyacrylic acid, sodium tripolyphosphate, polyethylene glycol bearing phosphonic acid function and a silica layer. Nevertheless, it is known that surface-linked molecules (*e.g.*, C–H and O–H vibrational modes of ligands) or hydroxyl groups in aqueous media can act as luminescence quenchers.^{30,31} This motivated us to study the luminescence behavior of NC surfaces modified with the typical ligands and coating, expanding the knowledge of water dispersible X-ray activated nano-contrast agent properties. Finally, the interest and feasibility to use optimal systems for multimodal imaging *in vivo* were illustrated through a proof of concept with nude mice, upon X-ray activation in the SPCCT using a clinical sequence acquisition (Scheme 1).

Experimental

Synthesis of NCs of various compositions

The typical procedure for the $\text{Gd}_{0.80}\text{Tb}_{0.20}\text{F}_3$ composition is as follows (quantities are then adapted for other compositions): to a solution of GdCl_3 , $6\text{H}_2\text{O}$ (3.87 g, 9.8 mmol) and TbCl_3 , $6\text{H}_2\text{O}$ (0.21 g, 1.1 mmol) dissolved in ethylene glycol, a solution of hydrofluoric acid (875 μL , aqueous solution 50% by mass) with 2-pyrrolidinone is added. The transparent mixture is placed in a Teflon insert and then heated in an autoclave at 170 °C for 1 hour. The resulting light brown product is treated with acetone to precipitate the nanoparticles. After purification steps by centrifugation–redispersion cycles in methanol the particles are finally dispersed in ultrapure water to give a transparent suspension.

Surface modification of NPs with various ligands

$\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3\text{@PEG}$. A solution of 7.7 g ($7.7 \times 10^{-3} \text{ mol}$, 0.3 eq.) of PEG phosphonic acid in water is added to 50 g of a colloidal suspension of NPs (10% w/w). The mixture is heated at 80 °C overnight under stirring and purified by dialysis. The final product is freeze dried and kept in the solid state.

$\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3\text{@PAA}$. A solution of 0.99 g ($4.95 \times 10^{-4} \text{ mol}$, 0.04 eq.) of PAA in NaOH (0.1 M) is added to 30 g of a colloidal suspension of NPs (10% w/w). The mixture is heated at 80 °C under vigorous stirring. After purification by dialysis, the final product is freeze-dried.

$\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3\text{@TPP}$. A solution of 0.38 g ($8.16 \times 10^{-4} \text{ mol}$, 0.59 eq.) of TPP in water is added to 0.3 g of NPs in water. The mixture is heated at 80 °C under stirring. After purification by dialysis, the final product is freeze-dried.

$\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3\text{@SiO}_2\text{@PEG}$. The preparation of the surface-modified nanoparticles follows 3 main steps: 1/($\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3\text{@silicate}$) 20.8 mL of a solution of sodium silicate (3% w/w) are added to 50 g of a suspension of nanoparticles (10% w/w)

Scheme 1 Conceptual advance of this work with (A). Demonstration of the spectral photon-counting scanner (conventional and color gadolinium K-edge)/luminescence imaging of optimized contrast agents, and (B). *In vivo* proof of concept for multimodal imaging.

under stirring. The mixture is heated for 1 hour at 80 °C and purified by dialysis. 2/((Gd_{0.90}Tb_{0.10}F₃@SiO₂) 1 g of the previously prepared nanoparticle is suspended in water (92 mg mL⁻¹) and added to a solution consisting of 11.7 mL water, 3150 µL ethanol and 114 µL ammoniac. A solution of tetraethyl-orthosilicate (TEOS) in ethanol (841.6 µL, 3.80 × 10⁻³ mol, in 1245 µL EtOH) is partially added in 4 steps every hour. After the last addition the mixture is stirred for 45 min at room temperature and purified by dialysis. 3/A suspension of the previously prepared Gd_{0.90}Tb_{0.10}F₃@SiO₂ in water (500 mg, 20 mL) is mixed with a solution of 1.52 mL ethanol, 154 µL ammonia and 750 mg of PEG silane (*M_w* 2000) over 24 hours under vigorous stirring. The final colloidal suspension is purified by dialysis and the particles are freeze-dried.

Analysis of particle morphology and composition

DLS and zeta potential measurements were performed on liquid suspensions of the nanoparticles, using a Malvern Instruments Nano ZS. TEM images were acquired using a JEOL 2100F and operated at 120 kV. TGA analysis was performed on a Setaram LABSYS1600. FTIR spectra were recorded on a PerkinElmer Spectrum 65 equipped with an ATR module.

Luminescence and lifetime measurements

The emission spectra of the NCs were measured with a Horiba-Jobin-Yvon Fluorolog-3 fluorimeter using a system of three monochromatic double-grid slits. The luminescence

ground state was excited by unpolarized light emitted by a 450 W continuous xenon lamp. The spectra were plotted by correcting the spectrum of the lamp and that of the detector. For the terbium(III) doped samples the entrance and exit slits were set to a 2 nm width. In all cases, the integration time used was 0.1 s. The decay in luminescence was obtained using an FL-1040P pulsed xenon lamp and half-life times were calculated by exponential fit using Origin® software.

Scintillation studies on micro-CT

Irradiation and imaging were performed using an X-RAD225Cx device (Precision X-Ray, North Branford, CT) equipped with a copper X-ray tube and a tungsten anode with an aluminum filter. The irradiated samples are placed in quartz tanks. Scintillation was detected by a camera positioned vertically to the tank at an angle of 90° to the source in order to acquire maximum luminescence.

Scintillation studies on SPCCT

SPCCT-induced luminescence measurements were performed using an experimental setup composed of an immersed optical fiber connected to a spectrometer. In addition, a home-made electronic circuit triggers the spectrometer with the X-ray emission. The cleaved end of the optical fiber (FG550UEC Thorlabs Inc.) was immersed in the nanoparticle solution and the SMA connector end was connected to the spectrometer *via* a round-to-linear bundle of fiber (PL200-2-

VIS-NIR, Ocean Insight). The bundle maximizes the light signal entering the spectrometer (Ocean Insight MayaPro2000). The spectrometer has previously been calibrated in order to give absolute spectral irradiance measurements. The luminescence measurements were triggered by a dedicated electronic circuit that detects the excitation X-ray signal emitted from the SPCCT using a stand-alone X-ray detector (Philips). The detector is composed of a basic scintillation detector attached to a photodiode encapsulated in epoxy to protect the assembly. The trigger circuit is composed of 4 electronic stages for amplifying the signal from the detector which is wired to an input pin of the Arduino Board, which is required to generate a TTL signal. The TTL signal is then fed to the triggering pin of the spectrometer. The trigger circuit allowed us to measure the light spectra both during excitation (X-ray on) and background (X-ray off). The luminescence spectrum is obtained by subtracting the background spectrum from the excitation spectrum. This suppresses any background parasitic light that could impair the luminescence emission. Finally, we applied a sliding average filtering with a window of 3 pixels to reduce the noise.

Clonogenic cell survival assay

MDA-MB-231 cells were seeded in 6 cm dishes and allowed to attach overnight. Then cells were incubated with either $\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3@\text{SiO}_2@\text{PEG}$ or $\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3@\text{PEG}$ of various concentrations between 62.5 and 1000 μM for 24 h. Then, the cells were seeded in triplicate to allow colony (>50 cells) formation for 12 days. The number of colonies was manually counted and the surviving fraction was calculated as the number of colonies divided by the number of seeded cells normalized to the plating efficiency of the untreated controls.

in vivo experiments

A nude Swiss female mouse used for the *in vivo* studies was purchased from Charles River Laboratories (7 weeks old) weighing about 30–35 g. The animal was provided with standard mouse food and water *ad libitum* and maintained under conventional housing conditions in a temperature-controlled room with a 12-hour dark–light cycle. All experiments were carried out in accordance with the European Directive 2010/63/UE, approved by the Ethics Committee (CELYNE CEEA42) and authorized by the Ministry of Higher Education, Research and Innovation (APAFIS#19829).

Results and discussion

Design and characterization of the NCs

NCs with four compositions were prepared under solvothermal conditions, following a previously described process with some modifications.³² Briefly, the desired amounts of rare earth salts of Gd^{3+} and of Tb^{3+} (with respective molar ratios 0.95/0.5; 0.90/0.10; 0.85/0.15 and 0.80/0.20) in ethylene glycol were reacted with a charge transfer complex involving F^- anions and protonated pyrrolidinone. The mixture was heated in an autoclave for 1 hour and purified by centrifugation/redispersion

steps to finally give a clear, colorless suspension of nanoparticles in water.

Powder X-ray Diffraction (PXRD) confirmed that all samples have a highly crystalline structure with a GdF_3 orthorhombic phase ($Pnma$ space group, lattice parameters: $a = 6.5710 \text{ \AA}$, $b = 6.9850 \text{ \AA}$, $c = 4.3930 \text{ \AA}$ and $\alpha = \beta = \gamma = 90^\circ$) when compared to the ICDD 00-049-1804 theoretical pattern (Fig. 1A and Fig. S1†). The composition of the prepared systems was determined by elemental analysis (Inductively Coupled Plasma – ICP) confirming that for all four compositions, the ratio between Gd^{3+} and Tb^{3+} in the inorganic core was consistent with what was expected for the synthesis (Table S2†).

The size and morphology of the nanoparticles were characterized by transmission electron microscopy (TEM) and dynamic light scattering (DLS). Whatever the composition, the NCs show slightly elongated morphologies (“bean-like”) with a $9.8 \pm 0.8 \text{ nm}$ average gyration diameter (Fig. 1B).

DLS measurements in water showed a low polydispersity of NCs and hydrodynamic diameters in the $13\text{--}18 \pm 3 \text{ nm}$ range (Table S3†). These results confirm that the amount of terbium added did not affect the size, the morphology or the crystallinity of the desired nanocrystals. Zeta potential measurements in water (pH 6) gave positive values of $48 \pm 2 \text{ mV}$, whatever the composition, confirming the high colloidal stability of these systems. The positive charge can be explained by the excess of lanthanide ions on the surface in accordance with energy dispersive X-ray spectroscopy analysis (Fig. S4†).

Fourier-transform infrared spectroscopy (ATR-FTIR) analysis shows specific bands of remaining 2-pyrrolidinone molecules on the surface of the particles as previously observed.³³ Upon coordination through the oxygen atom of the carbonyl bond, the $\text{C}=\text{O}$ stretching vibration frequency of 2-pyrrolidinone shifts from 1679 cm^{-1} to 1648 cm^{-1} . The bands of the molecule in the range $1463\text{--}1424 \text{ cm}^{-1}$ can be attributed to C–H deformations and they are shifted to 1448 cm^{-1} once on the NPs. Finally, the C–N vibration of the 2-pyrrolidinone cycle, initially observed at 1284 cm^{-1} , shifts to 1313 cm^{-1} suggesting interactions between the nitrogen atoms and lanthanides on the surface of the particles.

Optical properties of the NCs

The luminescence properties of the NCs were first studied upon excitation at 273 nm in water (0.30 M in lanthanides). This wavelength corresponds to the transition between the energy levels $^8\text{S}_{7/2}$ and $^6\text{I}_J$ of Gd^{3+} (Fig. 2).³⁴

For all cases, the emission spectra observed are characteristic of Tb^{3+} and the bands centered at 488 nm, 543 nm, 582 nm and 619 nm correspond to the energy transition from $^5\text{D}_4$ to $^7\text{F}_J$ ($J = 6, 5, 4, 3$).³⁵ The maximum luminescence intensity is observed for the $\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3$ composition and other systems show lower intensities independent of Tb^{3+} amount. Furthermore, when the molar ratio of Tb^{3+} increases above 0.10 the luminescence decreases. This result can be explained by the interactions between Tb^{3+} ions in excited states. When the ions are in close vicinity within the NP matrix, phenomena such as reabsorption and non-radiative deexcitations lead to

Fig. 1 (A) PXRD of Gd_{0.95}Tb_{0.05}F₃ (red line) compared with the ICDD 00-049-1804 theoretical pattern (blue lines). (B) TEM image of NCs. HRTEM of the same sample in the inset. (C) Results of the PXRD and TEM results for all compositions.

Fig. 2 (A) Luminescence spectra of the various NC compositions after excitation at 273 nm. (B) Lifetime decay measurements after excitation at 273 nm.

the quenching of luminescence. To further confirm the optimum wavelength of excitation, spectra of the Gd_{0.90}Tb_{0.10}F₃ composition were recorded at each emission

band of Tb³⁺ (*i.e.* 488 nm, 543 nm, 582 nm, 619 nm). Whatever the Tb³⁺ band considered, the excitation spectra show an intense signal centered at 273 nm (Fig. S5†). This corresponds

to the transition of the energy level of the Gd^{3+} present in the crystalline matrix ($^8\text{S}_{7/2}$ to $^6\text{I}_J$), proving that the emission of the NCs results from an energy transfer from Gd^{3+} to Tb^{3+} .

Measurements of the luminescence decay of each composition were conducted at 543 nm with an excitation wavelength of 273 nm. The decays fit well with a monoexponential rate and the respective fluorescence lifetimes were evaluated for the different ratios of $\text{Gd}^{3+}/\text{Tb}^{3+}$ (Table 1).

Table 1 Luminescence lifetime of each composition at 543 nm with an excitation wavelength at 273 nm and a concentration of 0.3 M in water

Composition	Lifetime (ms)	Correlation coefficient
$\text{Gd}_{0.95}\text{Tb}_{0.05}\text{F}_3$	4.30 ± 0.04	0.998
$\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3$	4.84 ± 0.04	0.998
$\text{Gd}_{0.85}\text{Tb}_{0.15}\text{F}_3$	4.04 ± 0.03	0.998
$\text{Gd}_{0.80}\text{Tb}_{0.20}\text{F}_3$	3.57 ± 0.03	0.998

All lifetime values are in the 4.04–4.84 ms range except for the $\text{Gd}_{0.80}\text{Tb}_{0.20}\text{F}_3$ composition with a lifetime of 3.57 ms. The lifetime results follow the trend observed with luminescence intensity and a maximum is measured for an optimal molar amount of Tb^{3+} . Indeed, the $\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3$ composition shows both the highest luminescence lifetime (4.84 ms) and the highest intensity. As lifetime can be directly linked to photoluminescence quantum yield,³⁶ the $\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3$ NPs seem to present the most interesting optical properties, and this composition will be the candidate of choice for further studies with X-rays. To evaluate the ability of the NCs to emit light upon excitation with X-rays, a specific setup in a Micro-CT device was first used (Fig. S6†). This setup allows the irradiation of the sample with various X-ray energies and recording of the emitted light with an optical camera. For comparison, two compositions $\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3$ and $\text{Gd}_{0.80}\text{Tb}_{0.20}\text{F}_3$ were studied in suspension in water (0.5 M of lanthanides). The intensity of luminescence produced under X-ray irradiation at different energies is detailed in Fig. 3A and B.

Fig. 3 (A) Images of the tube containing the colloidal suspension of $\text{Gd}_{0.9}\text{Tb}_{0.1}\text{F}_3$ at various energies of X-ray excitation (2.5 mA, Cu filter). Red areas correspond to the ROI (luminescence and background – BKG) to determine the final intensity. (B) Evolution of luminescence intensity as a function of the X-ray energy of excitation. (C) Emission spectra of the colloidal suspension of $\text{Gd}_{0.9}\text{Tb}_{0.1}\text{F}_3$ in the spectral photocount scanner at an energy of 120 kV and 300 mAs. (D) Image of a tube containing an aqueous suspension of $\text{Gd}_{0.9}\text{Tb}_{0.1}\text{F}_3$ in water (0.5 M) subjected to X-rays in the SPCCT.

Below 40 kV, no emission from the NCs is detected. For energies between 40 kV and 120 kV, the luminescence intensity increases with X-ray energy following a linear behavior until reaching a plateau after 120 kV. At that point, the inorganic matrix of GdF_3 absorbed the maximum energy it could. The two compositions follow the same profile with a slightly higher intensity observed for $\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3$ in the 90–120 kV energy range. These results seem to agree with the experiments performed with UV excitation, although intensities measured with X-rays are in the same margin of error.

Since the targeted application is the use of these systems as dual contrast agents with SPCCT, luminescence measurements were performed on $\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3$ suspension in water with the spectral scanner (Fig. 3C and D). When subjected to X-rays (120 kV, 300 mAs) a green light, specific to Tb^{3+} , is observed and imaged (Fig. 3D). The dedicated setup using an optical fiber (Fig. S7†) allows the measurement of the spectra of $\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3$ during excitation. These spectra present the four characteristic bands of Tb^{3+} luminescence centered at 488 nm, 543 nm, 582 nm and 619 nm (Fig. 3C). This result proves the ability of the NCs to generate visible light upon excitation with X-rays from a clinical scanner.

Medical imaging with the NCs

After confirming the luminescence properties of these systems with X-rays, their efficiency as contrast agents for CT imaging has been evaluated. Previous studies have shown that there is interest in using GdF_3 nanoparticles as a contrast agent for conventional CT imaging and K-edge imaging.^{25,33} The composition with optimal luminescence properties $\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3$ was therefore studied to evaluate its ability to generate con-

trast. A range of suspensions with increasing concentrations of rare earth elements (0.015 M, 0.035 M, 0.1 M, 0.17 M, 0.25 M, and 0.300 M) was placed in a dedicated phantom. The acquisition sequence was the same as generally used in conventional imaging for a patient (120 kVp and 200 mAs). Conventional and color K-edge CT imaging of the suspensions was performed in parallel to the quantification of the contrast agent concentration (Fig. 4).

With SPCCT, it is possible to conduct conventional CT imaging and gadolinium-specific color K-edge imaging of the suspensions. Both imaging techniques show an increase of the contrast with the concentration of lanthanides. The $\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3$ NCs are well suited for further use with this technology. Finally, the color K-edge imaging technique also allows us to quantify the element inducing the contrast, through a direct correlation between the measured attenuation and the gadolinium concentration. Fig. 4B shows the linear correlation existing between the gadolinium concentration measured by SPCCT and the one measured by ICP. It then becomes possible to accurately dose the quantity of the contrast agent injected *in vivo*.

Surface functionalization of the $\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3$ NCs

Surface functionalization of NCs was performed mainly following two approaches: (i) direct grafting of a ligand on the surface or (ii) the design of a core-shell system using a layer of silica (Scheme 2).

The first strategy (ligand-based) is based on the stable anchoring of organic molecules (or macromolecules) through reactive functions (phosphonates, phosphates, and carboxylic acids) on the nanoparticle surface. The nature of the chemical

Fig. 4 Imaging and quantification studies on six suspensions of $\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3$ with concentrations: 3.82 mg mL⁻¹, 7.50 mg mL⁻¹, 22.6 mg mL⁻¹, 36.8 mg mL⁻¹, 50.9 mg mL⁻¹, and 70.8 mg mL⁻¹. (A) Conventional CT imaging of a phantom containing the suspensions (up). Color K-edge imaging of the same phantom (down). The Gd concentration in the suspensions increases clockwise. (B) Correlation between the gadolinium concentrations measured by ICP and by SPCCT.

Scheme 2 General strategies for the design of surface-modified NCs and corresponding ligands.

bond formed between the nanoparticle and the molecule is coordinative, ionic or ionic-covalent, conferring stability to the final system. Numerous works related to nanoparticle applications for *in vivo* studies have shown that high biocompatibility is achieved with polyethylene glycol (PEG) ligands. Following this general idea and based on previous work,²⁵ studies have been focused on the use of phosphonic acid derived **PEG** (PPEG1000), which is known to have strong interactions with the rare earth fluoride nanoparticle surface. The choice of **TPP** (sodium tripolyphosphate) was motivated by the presence of multiple P=O and P-OH functions leading to strong anchoring on the nanoparticle surface and creating highly stable systems. Polyacrylic acid (**PAA**) is a polymer bearing several carboxylic functional groups along its structure which is expected to increase grafting stability.^{37,38} As opposed to direct grafting, the core-shell design is indeed a two-step approach where the nanoparticles are first covered by a layer of silica followed by the covalent linking of a **Si-PEG** functionalized with a silane function (C-Si-O-Si bonding).

Efficient grafting of the various ligands on Gd_{0.90}Tb_{0.10}F₃ NCs was evidenced by FTIR (Fig. S8†). For TPP and PEG modifications, the intense signal around 1060 cm⁻¹ is attributed to P-O stretching.³⁹ In the case of PAA modified NPs, the strong peak at 1680 cm⁻¹ is attributed to C=O stretching of the carboxylic acid function. Core shell systems SiO₂@PEG show the characteristic signal of Si-O-Si stretching overlapped with C-O-C stretching in the 1100 cm⁻¹ region.^{40,41} For all surface modifications involving organic moieties (SiO₂@PEG, PEG, and PAA) the presence of a signal in the 2850–2900 cm⁻¹ area (C-H stretching) is observed.

HRTEM observations of the different surface-modified systems show no modification in terms of morphology or crystallinity of the NC cores (Fig. S9†) with an average gyration diameter of 9.8 ± 0.8 nm. The NCs in suspension at pH = 7 were analyzed by DLS and zeta potential measurements (Table 2).

Table 2 Hydrodynamic diameter (Dh), zeta potential (ZP) and polydispersity index (PDI) of the various surface-modified NCs measured in water at pH = 6

	Dh (nm)	ZP (mV)	PDI
Gd _{0.90} Tb _{0.10} F ₃	13 ± 3	+48 ± 5	0.11
Gd _{0.90} Tb _{0.10} F ₃ @TPP	13 ± 3	-45 ± 5	0.10
Gd _{0.90} Tb _{0.10} F ₃ @PEG	24 ± 3	+27 ± 5	0.15
Gd _{0.90} Tb _{0.10} F ₃ @PAA	24 ± 3	-51 ± 5	0.14
Gd _{0.90} Tb _{0.10} F ₃ @SiO ₂ @PEG	32 ± 3	-25 ± 5	0.15

For all the systems considered, a clear increase of the Dh is observed after surface modification which is in agreement with the presence of the ligands on the NC surface. The small Dh (13 nm) observed for Gd_{0.90}Tb_{0.10}F₃@TPP is consistent with the grafting of small molecules as opposed to polymers such as PEG, PAA or SiO₂-PEG. The low polydispersity indexes indicate that the systems are homogeneous, without the presence of aggregates at a macroscopic scale. For all cases, the high absolute value of ZP (above 25 mV) confirms the high colloidal stability. The negative values measured for TPP, PAA, and SiO₂-PEG modifications, respectively, indicate the presence of negatively charged phosphonate, carboxylate and silanolate groups.

Finally, the quantification of the ligands was assessed using Thermogravimetric Analysis (TGA). All samples show mass loss in the 250 °C–400 °C range attributed to decomposition of the organic moieties. As expected, in the case of the inorganic ligand TPP, no loss was observed. The results obtained for the various systems are summarized in Table 3.

The analysis performed on unmodified NCs shows a mass loss of 6.4%. This result agrees with FTIR analysis (Fig. S8†) and the presence of organic molecules (2-pyrrolidinone) on the surface. In the case of Gd_{0.90}Tb_{0.10}F₃@TPP no mass loss except the one corresponding to water was observed which is

Table 3 Mass loss determined from TGA analysis and corresponding calculated amount of ligand on each NC

Composition	Total organic mass loss (%)	Calculated numbers of ligands per NCs
Gd _{0.90} Tb _{0.10} F ₃	−6.4	2.58×10^3
Gd _{0.90} Tb _{0.10} F ₃ @TPP	None	None
Gd _{0.90} Tb _{0.10} F ₃ @PEG	−40.3	2.61×10^3
Gd _{0.90} Tb _{0.10} F ₃ @PAA	−21.8	5.44×10^3
Gd _{0.90} Tb _{0.10} F ₃ @SiO ₂ @PEG	−12.8	2.68×10^2

expected since no organic molecules are attached to the surface of the NCs. For the other systems the calculated number of ligands per nanoparticles is on the same order of magnitude. In the case of Gd_{0.90}Tb_{0.10}F₃@SiO₂@PEG, the number of organic ligands per nanoparticles is lower. Indeed, the reactivity of the surface of the NPs is driven by the interactions between the alkoxysilane-derived PEG and the active sites (silanols) on the silica layer. Since the number of silanols is limited, the total amount of grafted ligands is lower than that in the case of direct grafting on Gd_{0.90}Tb_{0.10}F₃ with other macromolecules.

Effect of the ligands on the optical properties of the NCs

The influence of the various ligands or layers on the emission properties of the NCs has been studied. For a more detailed comparison, the Gd_{0.9}Tb_{0.1}F₃ nanoparticles were subjected to a surface cleaning procedure in order to remove the pyrrolidone molecules from the surface. The efficiency of this cleaning step was controlled with TEM and XRD to make sure no evolution of the size nor the crystallinity of the NCs was observed and with FTIR to verify that no organic moieties remained on the surface of the nanoparticles (Fig. S10†). The luminescence properties were recorded for all samples with the same concentration (0.06 M in lanthanides) in water and in D₂O, under UV excitation at 273 nm (Fig. 5).

For all cases, the typical luminescence spectra of Tb³⁺ are observed with ⁵D₄ to ⁷F_J (*J* = 6, 5, 4, 3) transitions. The luminescence intensities measured in water show the impact of the surface modification from clean (Gd_{0.9}Tb_{0.1}F₃) to functionalized NCs (Gd_{0.9}Tb_{0.1}F₃, Gd_{0.9}Tb_{0.1}F₃@PEG and Gd_{0.9}Tb_{0.1}F₃@SiO₂@PEG) with a decrease of the emission properties. This result can be explained by the presence of vibrators (O–H and N–H) in the molecules on the surface, acting as quenchers of the luminescence.⁴² Interestingly in the

Fig. 5 (A) Luminescence spectra of the various surface-modified Gd_{0.9}Tb_{0.1}F₃ systems in H₂O, with excitation at 273 nm. (B) Luminescence spectra of the various surface-modified Gd_{0.9}Tb_{0.1}F₃ systems in D₂O, with excitation at 273 nm. (C) Lifetime decay of the colloidal suspension of Gd_{0.9}Tb_{0.1}F₃ systems in H₂O. (D) Lifetime decay of the colloidal suspension of Gd_{0.9}Tb_{0.1}F₃ systems in D₂O.

case of $\text{Gd}_{0.9}\text{Tb}_{0.1}\text{F}_3\text{@TPP}$ the measured intensity is the highest. The same experiments were conducted in D_2O and the luminescence intensity is higher than that in the case of experiments performed in H_2O . This result confirms the luminescence quenching of excited Tb^{3+} by high-energy O–H vibrational modes.⁴³ The general trend remains the same with higher intensities in the case of unmodified NCs. The lowest variation is observed with $\text{Gd}_{0.9}\text{Tb}_{0.1}\text{F}_3\text{@TPP}$, suggesting that the TPP acts as a protective layer from the surroundings of the nanoparticles. Therefore, almost no variations are observed between H_2O or D_2O environments. In contrast, $\text{Gd}_{0.9}\text{Tb}_{0.1}\text{F}_3\text{@PAA}$ shows a much higher luminescence intensity in D_2O than in water. In that case, the carboxylic functions are deprotonated (confirmed by negative ZP measurements shown in Table 3) meaning that the quenching of luminescence could only come from water entrapped in the grafted polymer layer (H-bonding) near the surface of the NCs. This study was completed by measurements of the luminescence lifetime at 543 nm after excitation at 273 nm in water and in D_2O (Table 4).

Whatever the solvent, the fluorescence lifetime measured is higher for cleaned $\text{Gd}_{0.9}\text{Tb}_{0.1}\text{F}_3$, confirming the effect of water and also the impact of the O–H and N–H oscillators from the ligands. In the cases of $\text{Gd}_{0.9}\text{Tb}_{0.1}\text{F}_3\text{@PEG}$, $\text{Gd}_{0.9}\text{Tb}_{0.1}\text{F}_3\text{@SiO}_2\text{@PEG}$ and $\text{Gd}_{0.9}\text{Tb}_{0.1}\text{F}_3$, lifetimes are in the same range with an increase by roughly 0.6 ms for all the systems when shifting from water to D_2O . Whatever the solvent, the lowest fluorescence lifetime is measured with $\text{Gd}_{0.9}\text{Tb}_{0.1}\text{F}_3\text{@PAA}$ but with the highest variation from water to D_2O (0.85 ms). This confirms the previous measurements with the presence of water entrapped in the polymer layer. All the obtained results show that quenching of the luminescence has two origins: on one side, the presence of the ligands or layers on the surface of the NCs with O–H or N–H vibrators, and on the other side, the presence of water more or less attracted/adsorbed at the surface of the NCs.

Finally, the low variation measured for $\text{Gd}_{0.9}\text{Tb}_{0.1}\text{F}_3\text{@TPP}$ (0.05 ms) agrees with the observations of luminescence spectra and the protective activity of the inorganic TPP layer at the surface of the NPs. Unfortunately, despite many efforts, the stability of $\text{Gd}_{0.9}\text{Tb}_{0.1}\text{F}_3\text{@TPP}$ decreased strongly when trying to increase the concentration in water or physiological serum. Being unable to reach values above 0.1 M the composition was not evaluated further with X-ray activation.

Effect of ligands on the X-ray activated luminescence properties of the functionalized NCs

In the previous part the results showed that the various ligands grafted on the surface of the $\text{Gd}_{0.9}\text{Tb}_{0.1}\text{F}_3$ NCs played an essential role in the final optical properties of the systems when excited by UV light. The same approach was considered with the two different types of X-ray activations, microCT and SPCCT, on colloidal suspensions in water (0.5 M) (Fig. 6).

Fig. 6 shows that the luminescence intensity of the nanoparticles is lower with the presence of the ligands on their surface independent of the X-ray excitation values considered (2.5 mAs and 300 mAs) and as observed in the case of photoexcitation.

In the case of experiments conducted in micro-CT, the integrated intensity of the functionalized NCs follows the same trend as observed with UV excitation *i.e.* the intensity decreases as follows: $\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3\text{@PEG} > \text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3\text{@PAA} > \text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3\text{@SiO}_2\text{@PEG}$. This last system seems to show properties well below the other two. Interestingly slight differences are observed when measurements are conducted with SPCCT, and in that case the integrated intensities follow the order: $\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3\text{@SiO}_2\text{@PEG} > \text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3\text{@PEG} > \text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3\text{@PAA}$ with low differences. These discrepancies observed between microCT and SPCCT can be explained by the type of setup used for the measurements. Indeed, microCT experiments are very sensitive to the scattering of the nanoparticles and since $\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3\text{@SiO}_2\text{@PEG}$ has the highest Dh (Table 3) with a surrounding silica shell, it has the strongest scattering. Therefore, the overall measured luminescence intensity is impaired by this phenomenon. In the case of SPCCT experiments, the optical fiber is directly immersed within the colloidal suspensions; therefore the scattering effect is limited and the signals are less perturbed during detection. Thus, the two PEGylated systems $\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3\text{@PEG}$ and $\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3\text{@SiO}_2\text{@PEG}$ seem to be the most promising for X-ray triggered luminescence with SPCCT.

Functionalized NCs as contrast agents with the CT scanner and SPCCT

To prove that functionalized NCs can be used as a contrast agent for scanner imaging, a conventional CT scanner and color K-edge imaging have been used with SPCCT. A phantom containing suspensions of functionalized NCs in an

Table 4 Luminescence lifetime of each composition at 543 nm with an excitation wavelength of 273 nm and a concentration of 0.06 M in water and in D_2O

Composition	Lifetime (ms)	Lifetime (ms)	Correlation coefficient
$\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3$	4.84 ± 0.03	5.56 ± 0.03	0.997
$\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3$ cleaned	5.16 ± 0.03	5.82 ± 0.03	0.997
$\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3\text{@TPP}$	5.05 ± 0.04	5.10 ± 0.04	0.997

$\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3\text{@PAA}$	3.65 ± 0.03	4.50 ± 0.03	0.997
$\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3\text{@SiO}_2\text{@PEG}$	4.59 ± 0.03	5.11 ± 0.03	0.997

Fig. 6 (A) Integrated luminescence intensities of various systems studied under X-ray excitation with microCT (2.5 mAs, 120 kV). (B) Integrated luminescence intensities of the same systems under X-ray excitation of SPCCT (300 mAs, 120 kV).

Eppendorf tube (0.5 M in water) was irradiated under 100 mAs, 120 keV using X-rays of SPCCT (Fig. 7).

Comparison with a water sample confirms that functionalized NCs exhibit properties generating high contrast in conventional SPCCT imaging. Color K-edge observations only show the signal of gadolinium and confirm that these samples are suitable for this technique of imaging (high contrast). The contrast being the same for all samples with K-edge imaging, we can also confirm that the concentration in gadolinium in the different suspensions is the same. Finally, whatever the ligand or coating, the contrast was the same proving that the surface modification did not impair the NCs.

Cytotoxicity of the NCs

Prior to *in vivo* studies, clonogenic cell survival assay was performed to assess the cytotoxicity of $Gd_{0.90}Tb_{0.10}F_3@SiO_2@PEG$ and $Gd_{0.90}Tb_{0.10}F_3@PEG$ in three independent experiments

(Fig. S11†). The results indicated that the investigated NCs did not induce a significant decrease in clonogenic cell survival up to 1 mM.

Proof of concept of *in vivo* dual imaging with SPCCT

To assess the ability of the NCs to be used as X-ray based multimodal contrast agents *in vivo*, a study was carried out on a nude and healthy mouse with an acquisition sequence in the SPCCT. A suspension of $Gd_{0.90}Tb_{0.10}F_3@PEG$ (50 μ L, 1 M in physiological serum) was injected subcutaneously near the caudal thigh muscles of the anesthetized animal. Conventional CT and color gadolinium specific K-edge as well as luminescence imaging were then achieved with the SPCCT (Fig. 8).

While conventional CT imaging provides a nonspecific imaging of the contrast agent (Fig. 8A), color K-edge imaging enables a specific and quantitative imaging of its biodistribu-

Fig. 7 (A) Conventional SPCCT imaging of a phantom containing colloidal suspensions of normal, PEG modified, PAA modified and $SiO_2@PEG$ modified NCs in water (0.5 M). (B) Same phantom with color gadolinium K-edge imaging using SPCCT.

Fig. 8 Multimodal *in vivo* SPCCT imaging of the mouse 20 min after injection of $\text{Gd}_{0.90}\text{Tb}_{0.10}\text{F}_3$ at different sub-cutaneous sites at different volumes and concentrations. The area of interest (injection of the 1 M suspension) is delimited by the red box. (A) Conventional CT imaging of the whole animal. (B) Color gadolinium specific K-edge imaging. (C) Fusion of conventional and color K-edge imaging. (D) Luminescence imaging during acquisition with SPCCT.

tion (Fig. 8B). Fusion of conventional and color K-edge imaging enables a comprehensive imaging of the contrast agent biodistribution (Fig. 8C). Monitoring was carried out over a period of 1 hour in order to follow the distribution of the nanoparticles. The systems remain localized and no diffusion in the surrounding tissues was observed. Finally, 24 hours after injection, the mouse showed no sign of infection. The detection of the luminescence of NCs *in vivo* was conducted during a new acquisition sequence of the SPCCT, on the same animal, using the previously used parameters (120 KeV – 300 mAs). Observations were made with a camera during the X-ray irradiation (Fig. 8D). A clear and intense green luminescence at the injection site of the 1 M suspension is observed. The signal is strong enough to be detected through the skin of the animal with the naked eye. The impact of the X-ray dose delivered for optimized imaging and the influence of the concentration of the particles are currently being studied and will be the subject of an upcoming paper.

Conclusions

In summary, we have successfully developed highly efficient X-ray activated nanoprobe for multimodal imaging. The nanocrystals consist of a GdF_3 matrix doped with various ratios of Tb^{3+} . After finding the optimal composition of the original NCs with a systematic luminescence study, we were able to effectively evaluate the contrast capability in CT and SPCCT with gadolinium specific color K-edge imaging. The influence of surface modification on the luminescence properties was evaluated. Various strategies were considered using encapsulation with a silica layer and direct grafting of molecules such as PEG, PAA or TPP derivatives. As the contrast with conventional CT and color K-edge imaging using SPCCT did not change, the luminescence intensity of these NCs in water was reduced compared to that of the original NCs. This was attributed to the quenching caused by surface ligands and water molecules. Our results suggest that the surface modified NCs are promising contrast agents for multimodal medical imaging with X-ray optical imaging, as well as for CT and SPCCT. The proof of concept performed on a nude mouse with SPCCT confirmed that the luminescence could be observed through the skin of the animal, together with strong contrast in CT and SPCCT.
