Molecular functionalization of MoS<sub>2</sub> has attracted a lot of attention due to its potential to afford fine-tuned hybrid materials that benefit from the power of synthetic chemistry and molecular design. Here, we report on the on-surface reaction of maleimides on bulk and molecular beam epitaxy grown single-layer MoS<sub>2</sub>, both in ambient conditions as well as ultrahigh vacuum using scanning probe microscopy.

## Introduction

Molybdenum disulfide (MoS<sub>2</sub>) has become an interesting 2D material due to its exceptional properties and their applications in electronic and optoelectronic,<sup>1,2</sup> biosensing,<sup>3</sup> catalysis<sup>4</sup> or energy storage<sup>5</sup> among others.<sup>6–8</sup> Surface functionalization of this material with organic moieties has been targeted to improve the processability of bulk dispersions and to tune the resulting changes of the physicochemical properties.<sup>9</sup> In this context, different approaches have been reported employing molecular species through non-covalent and covalent interactions, generally in dispersions. Among them, protocols leading to a covalent bond between the modifier and the surface have gained attention due to the robustness of the functionalized material and the introduction of new functionalities made by design.<sup>10–12</sup> Some of these options rely on highly reactive species such as radicals,<sup>13–15</sup> which sometimes makes it difficult to control their high reactivity. However, other protocols are based on specific reactions between the sulphur atoms of the surface with the corresponding organic unit. The use of maleimides is included in this last group.<sup>16</sup> The reaction is based on the soft nucleophilicity of sulphur to react with a soft electrophile such as maleimide compounds

via a Michael addition. With this protocol, it is possible to obtain a highly efficient covalent attachment under very mild conditions, without transformation of the 2H-MoS<sub>2</sub> phase to the more reactive 1T-MoS<sub>2</sub> phase.<sup>17,18</sup> The use of these molecules for the functionalization of the 2H-MoS<sub>2</sub> phase has been proved useful with other transition metal dichalcogenides,<sup>16</sup> to decorate naturally occurring van der Waals heterostructures,<sup>19</sup> interconnect flakes,<sup>20</sup> and more recently for the formation of a graphene-MoS<sub>2</sub> covalent heterostructure where the electronic properties are dominated by the molecular interface.<sup>21</sup> Palma and co-workers have shown that the reaction is useful to obtain MoS<sub>2</sub>-DNA bioconjugates.<sup>22</sup> Finally, Zhao and co-workers, have demonstrated that the maleimide-MoS<sub>2</sub> reaction is useful to tailor the electronic properties of field-effect transistors by direct on-device chemistry.<sup>23</sup> Now that the versatility and potential applications of this type of functionalization have been demonstrated, it is of paramount importance to obtain a detailed understanding of the on-surface covalent functionalization of MoS<sub>2</sub> with maleimides.

Here, we investigate in detail the maleimide-MoS<sub>2</sub> chemistry for the on-surface functionalization of bulk and monolayer MoS<sub>2</sub>. The obtained organic layers are characterized using atomic force microscopy (AFM), scanning tunneling microscopy (STM), and Raman spectroscopy. The versatility of the reaction was tested at the solid–liquid interface and under ultrahigh vacuum (UHV) conditions, with two different maleimides, with and without the presence of base, allowing for structural control of the adlayer(s) covalently anchored to the MoS<sub>2</sub> surface.

## Results and discussion

Fig. 1 shows the chemical structure of the precursors used in this work. We used a molecule with a simple structure (Bn-

†Electronic supplementary information (ESI) available. See DOI: <https://doi.org/10.1039/d3nr05236b>

**Fig. 1** (a) Molecular structures for the maleimides reagents. (b) Idealised depiction of the covalently functionalised  $\text{MoS}_2$  substrate, based on experimental AFM data.

mal) and a porphyrin-derived maleimide (TPP-mal) to decorate the  $\text{MoS}_2$  surface.

For the functionalization under ambient conditions, the substrates were immersed in the corresponding solution overnight (detailed information about sample preparation in the ESI†). AFM characterization of the functionalised substrates is shown in Fig. 2. Bn-succ- $\text{MoS}_2$  samples, the *N*-benzylmaleimide (Bn-mal) being converted into a succinimide upon reaction with  $\text{MoS}_2$ , show defined lines of organic material (Fig. 2a) with a coverage of around 30%. The distribution of the molecules indicates preferred adsorption on the edges, steps, and defects of the substrate. These lines can be found when a bare  $\text{MoS}_2$  surface is imaged and can be associated to steps, terraces edges and defects on the surface (ESI S1†). The higher reactivity of the edges in 2D flakes of  $\text{MoS}_2$  has been previously reported<sup>14,24</sup> However, we also observe a significant number of basal-plane attachments (ESI S2†). For TPP-succ- $\text{MoS}_2$ , full coverage is observed (Fig. 2b) which indicates a favoured adsorption on this derivative as a result of van der Waals molecule-substrate interactions.<sup>25</sup> Furthermore, partial removal of the organic film with the AFM tip reveals differences in the thickness. The thickness obtained for Bn-succ- $\text{MoS}_2$  is 0.8 nm, while the one for TPP-succ- $\text{MoS}_2$  is 1.3 nm. This result is in good agreement with the larger size of the porphyrin-derived maleimide TPP-mal molecule compared to Bn-mal, this applies only when TPP-mal is attached perpendicular to the  $\text{MoS}_2$  surface *via* the maleimide. With these data, we hypothesize that the direct connection of the maleimide to the porphyrinic core enhances its interaction with the  $\text{MoS}_2$  basal plane when compared to Bn-mal. Maximizing the number of favourable porphyrin-porphyrin interactions can also enhance the formation of such a monolayer with increased surface coverage.

However, physisorption cannot be ruled out because AFM images show the overall surface morphology but cannot dis-

**Fig. 2** AFM images ( $2\ \mu\text{m} \times 2\ \mu\text{m}$ ) for (a) Bn-succ- $\text{MoS}_2$  and (b) TPP-succ- $\text{MoS}_2$  layers on bulk  $\text{MoS}_2$ . A scratch on the surface was performed for the estimation of the thickness (see corresponding cross section). STM images ( $130\ \text{nm} \times 130\ \text{nm}$ ) for (c) Bn-succ- $\text{MoS}_2$  and (d) TPP-succ- $\text{MoS}_2$ .

tinguish between physisorbed and covalently attached molecules. To evaluate if the organic films are covalently bonded to the  $\text{MoS}_2$  surface, we used STM. STM has been widely used for the characterization of functionalization of  $\text{MoS}_2$  *via* physisorption<sup>26</sup> or chemisorption<sup>27,28</sup> of molecules. Furthermore, STM is a unique technique for the detection at the molecular level of grafted units on a surface as previously demonstrated for several materials, including  $\text{MoS}_2$ .<sup>29–31</sup> Fig. 2(c) and (d) show the STM images for Bn-succ- $\text{MoS}_2$  and TPP-succ- $\text{MoS}_2$ , respectively. Some black holes are observed which are a characteristic of natural  $\text{MoS}_2$  and relate to point defects caused by sulphur vacancies.<sup>32</sup> Grafted units on the surface appear in the STM height image as bright spots. The presence of these bright spots confirms the success in the covalent modification of the  $\text{MoS}_2$  surface. In any case the STM analysis is qualitative. This is due to the possibility of local removal of the grafted layer, *i.e.* nanoshaving, due to the STM tip interaction. However, the presence of covalent units even at low density,

where the Raman spectroscopy is not suitable for its detection, can be confirmed by STM, as shown in this work.

Another potentially useful feature of the reaction is that it can be tuned by addition of a base to introduce polymeric fragments, instead of single molecular attachments.<sup>33</sup> Fig. 3 shows the AFM results for the samples prepared by adding some drops of triethylamine ( $\text{Et}_3\text{N}$ ) to the Bn-mal or TPP-mal solution.

For Bn-succ-MoS<sub>2</sub>-Et<sub>3</sub>N, a thicker polymeric layer of 1.8 nm can be found. The holes found on the layer go down to the MoS<sub>2</sub> surface as the depth is the same as the layer thickness obtained by scratching (Fig. 2a). The surface density of these holes is not homogeneous and depends on the area analyzed, as shown in large scale images (ESI S3†). For the TPP-succ-MoS<sub>2</sub>-Et<sub>3</sub>N, the surface is completely covered by a homogeneous layer with a thickness of around 1.8 nm. Hereby, we can confirm an increase in the thickness due to the formation of a polymeric adlayer in the presence of a base. The increased amount of material deposited on the surface was previously analyzed on liquid phase exfoliated MoS<sub>2</sub> using thermogravimetric analysis (TGA) and high-angle annular-dark-field scanning transmission electron microscopy (HAADF-STEM).<sup>33</sup> However, AFM shows not only an increase in the overall thickness of the film deposited on the surface but also the formation of larger polymeric fibers in solution that can be found in some scanned areas (ESI S4†).

To clarify the interaction of the molecules with the MoS<sub>2</sub> surface, we have performed the functionalization of the

surface using maleimides under ultra-high vacuum (UHV) conditions. Under these conditions we have information of the crystallographic perfection and cleanliness of the MoS<sub>2</sub> surface at the atomic level with the added advantage of an exquisite control in the number of molecules deposited (ESI S5†). Exposing a clean MoS<sub>2</sub> surface to a pressure of  $2.1 \times 10^{-7}$  Torr for 36 minutes, corresponds to the deposition of approximately 60 Bn-maleimides for every exposed sulfur atom on the surface of the MoS<sub>2</sub> islands. Fig. 4 shows two STM images measured after the exposition. After the exposition to the Bn-maleimides, the surface appears covered with objects that present the same contrast at both positive and negative voltages. In contrast, defects present in the MoS<sub>2</sub> films as they grown display a contrast inversion in the tunneling images when going from positive to negative. The molecules have decorated the edges of the islands, the linear defects (mirror twin boundaries, MTB) and a few of them appear adsorbed in the middle of the islands.

Quantitative information about the strength in the interaction between adsorbed molecules and the surface cannot be obtained from STM imaging alone, but single molecule manipulation in UHV at cryogenic temperatures allow us to distinguish between physisorbed and chemisorbed molecules. Fig. 5(a) shows a single molecule adsorbed in the middle of a MoS<sub>2</sub> single layer island. There are also molecules adsorbed on the step edges and MTBs present on the island.

Fig. 5(b)–(g) shows a series of images taken during the manipulation process. For high positive bias voltages, the images show the molecule as a bright spot on the terraces as shown in Fig. 4(a) and (b). During the acquisition of these images the electrons are tunneling from the STM tip to the LUMO of the molecule and the images represent the spatial distribution of the unoccupied frontier molecular orbital. For bias smaller than +1.0 V the molecule does not appear well defined anymore because the bias voltage is lower than the energy of the LUMO and most of the electrons are tunneling directly to the substrate and the tip pushes the molecule when acquiring the images. This process creates at the position of the molecule a small bump with straight horizontal edges, as

**Fig. 3** AFM images ( $2 \mu\text{m} \times 2 \mu\text{m}$ ) for (a) Bn-succ-MoS<sub>2</sub>-Et<sub>3</sub>N and (b) TPP-succ-MoS<sub>2</sub>-Et<sub>3</sub>N layers on bulk MoS<sub>2</sub> in the presence of Et<sub>3</sub>N. A scratch on the surface was performed for the estimation of the thickness (see corresponding cross section).

**Fig. 4** STM images ( $100 \text{ nm} \times 100 \text{ nm}$ ) measured in the same area of the sample with negative bias voltage ( $V_b = -1.0$  V,  $I_t = 3$  pA) (a) and positive bias voltage ( $V_b = +1.8$  V,  $I_t = 3$  pA) (b) after exposing the MoS<sub>2</sub> film to a partial pressure of maleimides of  $2.1 \times 10^{-7}$  Torr during 36 minutes.

**Fig. 5** (a) STM image (50 nm  $\times$  50 nm,  $V_b = +1.8$  V,  $I_t = 3$  pA) of a MoS<sub>2</sub> single layer with a maleimide adsorbed in the middle of a terrace (encircled in green) (b)–(g) STM images (7.5 nm  $\times$  7.5 nm,  $I_t = 50$  pA) sequence of single molecule manipulation reducing the bias voltage. (b)  $V_b = +1.8$  V, (c)  $V_b = +1.0$  V, (d)  $V_b = +0.9$  V, (e)  $V_b = +0.25$  V, (f)  $V_b = +0.05$  V, (g)  $V_b = +0.01$  V.

can be seen in Fig. 5(d). Further reducing the bias voltage to +0.25 V produce images where the position of the molecule is indicated by few horizontal stripes, the molecule is invisible for the tunneling electrons and the only hint of its presence is the noisy signal at the molecule's position, caused by the physical interaction between the STM tip and the molecule protruding from the surface. Further reducing the bias voltage to +5 mV forces the tip closer to the surface to keep the current constant and as a result, the atomic structure of the MoS<sub>2</sub> film begins to be resolved. While the position of the molecule is still marked with some noisy signal, see Fig. 5(f). At lower voltages (+1 mV) the atomic structure of the MoS<sub>2</sub> layer is better resolved and in the position of the molecule the sulfur atom below the molecule presents a different contrast to

**Fig. 6** STM images (50 nm  $\times$  50 nm,  $V_b = +1.8$  V,  $I_t = 3$  pA) before (a) and after (b) single molecule manipulation. The molecules removed from the domain boundary (encircled in green) appear in the terraces or at the step edges.

the rest of the sulfur atoms in the STM images, see Fig. 5(g). Adjusting the bias voltage back to +1.0 V we observe the molecule adsorbed on the same surface location shown in Fig. 5(a). This is a clear indication of the bonding between the maleimides and MoS<sub>2</sub> surface.

In contrast, the molecules attached to the MTBs are easily manipulated by scanning the area with high bias voltages, an indication that the interaction with the substrate is different compared with the molecules in the middle of the terraces suggesting that the molecules are physisorbed on the 1D defects (see ESI† for details). Fig. 6(b) shows the MTB after manipulation of the molecules. Once the molecules of the MTB have been removed, the structure of the MTB in the STM images looks similar than prior to exposure to maleimides. This behavior contrast with what occurred with the molecules adsorbed in the center of the terraces (see Fig. 5).

Finally, Raman spectroscopy of the bare and functionalized substrates was performed to establish changes in the electronic structure of the material. These results are included in the ESI S6.† The characteristic active modes of 2H-MoS<sub>2</sub> at 383 cm<sup>-1</sup> and 408 cm<sup>-1</sup> were observed; after the reaction, the decrease of (2LA(M)) mode in the 450–460 cm<sup>-1</sup> region, typically used as an indication of functionalization<sup>17</sup> does not show a significant difference, mainly due to the type of substrate used in this work (natural MoS<sub>2</sub>) and the low density of grafted moieties. This different reactivity of surface-based systems compared to exfoliated materials is expected due to the lower number of defects or reactive sites.

## Conclusions

Solid supported MoS<sub>2</sub> functionalization using thiol–ene chemistry has been investigated. STM and AFM at the solid–liquid interface revealed the formation of a covalently bound polymeric adlayer on the MoS<sub>2</sub> surface. The addition of a Lewis base to the maleimide solutions lead to an increase in the thickness, measured by scratching with the AFM tip. In order to study the interaction of single molecules with the MoS<sub>2</sub> surface we took advantage of the precise control achievable in

UHV and we deposited a small number of molecules on the surface compared to the experiments carried out in solution. Molecules adsorbed on different sites of the surface (terraces, edges of the islands and linear defects) have been visualized. Quantitative information about the strength of the molecule-substrate interaction has been obtained by single molecule manipulation. Molecules adsorbed in the center of the terraces cannot be displaced from their adsorption site using the STM. Tuning the tunneling conditions to observe the electronic states of the surface sulfur atoms, shows a strong modification in its electronic structure of the sulfur atom below the adsorbed maleimide, confirming the covalent interaction previously observed by STM at the liquid-solid interface. However, molecules adsorbed on 1D surface-defects are easily removed and the MoS<sub>2</sub> lattice is fully recovered, an indication of physisorption. These results reveal that the molecule-substrate interaction is stronger on the basal plane and that the defects percentage on the surface will undoubtedly influence the nature of the molecule-MoS<sub>2</sub> interactions. The applicability of thiol-ene chemistry on solid-supported MoS<sub>2</sub> has been validated and provides a tool for the functionalization of surfaces focused on the development of, for instance, molecular electronic applications.

## Author contributions

M.C.R.G., M.V.S., A.L.V.P., E.M.P. and S.D.F. conceived and designed the experiments. M.V.S. and A.N. prepared the maleimide compounds. M.C.R.G. and R.S. carried out the surface characterization of samples prepared under ambient conditions. I.M.I., C.R., and C.G.A. performed the analysis of samples in UHV. M.G. and F.C. supervised the UHV experiments. M.C.R.G., A.L.V.P., E.M.P. and S.D.F. supervised research and directed data analysis. M.C.R.G., A.L.V.P., E.M.P. and S.D.F. wrote the manuscript, with contributions from all authors. All authors have given approval to the final version of the manuscript.
