## Enhancement in the dielectric and magnetic properties of $\text{Ni}^{2+}$ – $\text{Cu}^{2+}$ co-doped $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$ hexaferrites ( $0.0 \leq x \leq 1.0$ )

M. Atif, <sup>a</sup> H. Ul Husnain, <sup>a</sup> Atta Ur Rehman, <sup>ab</sup> U. Younas, <sup>a</sup> T. Rafique, <sup>a</sup> W. Khalid, <sup>a</sup> Z. Ali <sup>a</sup> and M. Nadeem<sup>c</sup>

Herein,  $\text{Ni}^{2+}$ – $\text{Cu}^{2+}$  co-doped barium hexaferrites ( $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$ ,  $0.0 \leq x \leq 1.0$  with an interval of 0.25) were successfully synthesized using a co-precipitation method. The formation of a magnetoplumbite structure with the  $P6_3/mmc$  space group was confirmed by Rietveld refinement of the obtained X-ray diffraction patterns. Microstructural investigations revealed grains in the shape of hexagonal plates, while co-doping resulted in a variation in the grain sizes of the prepared samples. X-ray photoelectron spectroscopy was performed to determine the valence state of iron in the prepared hexaferrites. Impedance spectroscopy analysis revealed that dielectric permittivity initially decreased with an increase in the co-dopant content up to  $x = 0.5$  and then increased by two orders of magnitude for  $x = 1.0$ . Alternatively, resistive properties showed microstructural resistance values in the range  $10^5$ – $10^8$   $\Omega$ , with the highest value obtained for the sample with  $x = 0.5$ . Furthermore, magnetic measurements indicated that all the prepared samples exhibited ferrimagnetic behaviour. Saturation magnetization and magnetic anisotropy values were found to be the highest for the sample with  $x = 1.0$ , which also had the lowest coercivity among the prepared samples. Herein, the observed variations in the obtained results can be explained by the variations in grain sizes and the  $\text{Fe}^{2+}/\text{Fe}^{3+}$  ratio associated with the preferential occupation of co-dopants at octahedral sites. Based on our findings, the  $\text{BaFe}_{11}\text{Ni}_1\text{O}_{19}$  ( $x = 1.0$ ) composition appears to be the most promising choice as a microwave absorption material among the prepared samples owing to the coexistence of high dielectric permittivity ( $>10^3$  at  $10^7$  Hz) and saturation magnetization (73 emu g<sup>-1</sup>).

### 1. Introduction

Presently, hexaferrites are one of the most extensively investigated materials because of their wide range of practical application in fields such as magnetic shielding, mobile communication, electronic devices, magnetic biosensors, magnetic recording devices, and stealth technologies.<sup>1,2</sup> Generally, hexaferrites have a more complicated structure compared to spinel ferrites and orthoferrites and are a very important class of permanent magnets. Based on the chemical composition and crystalline structure of hexaferrites, they can be divided into six different types.<sup>3</sup> Among them, M-type hexaferrites ( $\text{MeO} \cdot 6\text{Fe}_2\text{O}_3$ , where Me is Ba, Sr, or Pb) are the most significant type of hexaferrites owing to their remarkable properties, which include high coercivity, high permittivity, high permeability, and high values of isotropic constants as well

as its chemical stability and high corrosion resistance.<sup>4</sup> The crystal structure of an M-type hexaferrite is composed of a combination of  $\text{R} = \text{Me}^{2+}\text{Fe}_6^{3+}\text{O}_{11}^{2-}$ ,  $\text{S} = \text{Fe}_6^{3+}\text{O}_8^{2-}$ ,  $\text{R}^*$ , and  $\text{S}^*$  blocks, where  $\text{R}^*$  and  $\text{S}^*$  are  $180^\circ$  inversion of the R and S block, respectively, along the hexagonal  $c$ -axis.<sup>3</sup> One unit cell of M-type hexaferrites is made up of two molecules, and each molecule contains five layers of oxygen atoms. There is a total of 64 ions in each unit cell, including two heavy metal divalent cations, 38 oxygen ions, and 24 ferric ions. The presence of ferric ( $\text{Fe}^{3+}$ ) ions imparts magnetism to this type of hexaferrite. In each sub-lattice of M-type hexaferrites, there are a total of 12 ferric ions occupying five distinct interstitial sites, namely 12k, 4f<sub>2</sub>, 4f<sub>1</sub>, 2a, and 2b. Six of these 12 ferric ions occupy a 12k (octahedral) site with a positive spin. On 4f<sub>2</sub> (octahedral) and 4f<sub>1</sub> (tetrahedral) sites, there are two ferric ions with spin-down. On 2a (octahedral) and 2b (trigonal bipyramidal) sites with spin-up, there is one ferric ion.<sup>3</sup> In total, eight of the twelve ferric ions have spin-up, while four have spin-down. This indicates that after balancing with four spin-down ferric ions, there are still four spin-up ferric ions.<sup>5</sup> These four spin-up ferric ions contribute to the total magnetic moment of M-type hexaferrite. Iron (Fe) is a d-block element with five unpaired electrons in its outermost

orbit, resulting in a magnetic moment of  $5 \mu_B$  for each ferric ion. Due to the presence of four spin-up ferric ions in each unit cell of hexaferrite, the net magnetic moment of each cell is  $20 \mu_B$ .<sup>6</sup>

Among the M-type hexaferrite materials, barium hexaferrite ( $\text{BaFe}_{12}\text{O}_{19}$ ) has attracted considerable interest from researchers due to its outstanding dielectric and magnetic properties, which make it useful as an electromagnetic wave absorber.<sup>7,8</sup> When electromagnetic waves interact with microwave absorbers, the energy of the incident wave is absorbed by the absorbers. At the ferromagnetic resonance frequency, this energy absorption is at its maximum. The ideal choice for a microwave absorber is a material that can both absorb high-energy waves and respond quickly to incident radiation. Typically, the absorption of an incident wave by a material depends on its dielectric permittivity ( $\epsilon'$ ), saturation magnetization ( $M_s$ ), and the magnitude of its response to an incident wave, which is defined by its coercivity ( $H_c$ ). Thus, if a material has a high  $\epsilon'$  and  $M_s$  with a low  $H_c$ , it may act as a microwave absorber. Given that  $\text{BaFe}_{12}\text{O}_{19}$  has a high values of  $\epsilon'$  and  $M_s$  but an equally strong  $H_c$ , it is inappropriate for use in microwave absorber applications. This problem can be solved by substituting transition metal cations for  $\text{Ba}^{2+}$  or  $\text{Fe}^{3+}$  ions in  $\text{BaFe}_{12}\text{O}_{19}$ , which reduces the  $H_c$  value of the material and improves its magnetic and microwave-absorbing properties.<sup>9</sup> Manglam *et al.* explored the magnetic properties of  $\text{Zn}^{2+}$ -doped  $\text{BaFe}_{12-x}\text{Zn}_x\text{O}_{19}$  hexaferrites.<sup>10</sup> They found that the maximum  $M_s$  and minimum  $H_c$  values were obtained for  $x = 0.2$ , which were described in terms of the lattice strain and super-exchange interaction, respectively. Behera *et al.* investigated the impact of  $\text{Ni}^{2+}$  doping on the magnetic and dielectric characteristics of  $\text{BaFe}_{12-x}\text{Ni}_x\text{O}_{19}$ .<sup>11</sup> According to them, the dielectric constant was found to increase with an increase in the  $\text{Ni}^{2+}$  doping content, while the values of  $M_s$  and  $H_c$  decreased with  $\text{Ni}^{2+}$  doping. Wang *et al.* reported the coexistence of remarkable improvements in the dielectric and magnetic characteristics of  $\text{Ni}^{2+}$ -doped  $\text{BaFe}_{12-x}\text{Ni}_x\text{O}_{19}$  hexaferrites due to the presence of more  $\text{Fe}^{2+}/\text{Fe}^{3+}$  pair dipoles and the preferential occupancy of  $\text{Ni}^{2+}$  ions at the  $4f_2$  sites.<sup>12</sup> Kumar *et al.* explored the effect on  $\text{Cu}^{2+}$  doping on the properties of  $\text{BaFe}_{12-x}\text{Cu}_x\text{O}_{19}$  hexaferrites.<sup>13</sup> According to them, a correlation was established between the structural parameters and magnetic/dielectric properties, and they found the maximum  $M_s$ , minimum  $H_c$ , and high dielectric constant for the  $x = 1.0$  sample. To further improve the magnetic and microwave-absorbing properties of barium hexaferrites, co-doping of  $\text{Ni}^{2+}$  with a combination of some other divalent metal ions has been reported in the literature. Widayastuti *et al.* reported that the magnetic properties of barium hexaferrite can be significantly improved by doping  $\text{Ni}^{2+}$  and  $\text{Zn}^{2+}$  ions in place of  $\text{Fe}^{3+}$ .<sup>14</sup> They found that the highest  $M_s$  (95 emu g<sup>-1</sup>) and the lowest  $H_c$  (0.12 T) were obtained for  $x = 0.6$  among the  $\text{BaFe}_{12-2x}\text{Ni}_x\text{Zn}_x\text{O}_{19}$  hexaferrites prepared at pH = 11 and sintered at 1050 °C. Moreover, Susilawati *et al.* found that the values of  $M_s$  and  $\epsilon'$  increased, while the  $H_c$  value decreased with an increase in the co-dopant contents in  $\text{BaFe}_{12-2x}\text{Ni}_x\text{Co}_x\text{O}_{19}$  hexaferrites.<sup>15</sup> However, the maximum reflection loss of  $-14.47$  dB together with an absorption coefficient of 96.43% was achieved for the  $x = 1.0$  sample. Hence, based on the above-mentioned literature,

we found that the coexistence of high dielectric and magnetic characteristics in co-doped barium hexaferrites makes these materials potential candidates as high-performance microwave absorbers.

In this work, divalent transition metals such as  $\text{Ni}^{2+}$  and  $\text{Cu}^{2+}$  were utilized as a replacement for  $\text{Fe}^{3+}$  in M-type barium hexaferrites to alter their magnetic and dielectric characteristics because of their close ionic radii and electronic configuration. Moreover, the replacement of  $\text{Fe}^{3+}$  by the lower valence of  $\text{Ni}^{2+}$ – $\text{Cu}^{2+}$  ion pair may generate extra charge carriers for conduction, leading to high dielectric permittivity in barium hexaferrites. Further, it is anticipated that the magnetic nature of this ion pair will maintain the magnetic interactions, which may enhance the magnetization and reduce the coercivity depending on their preferential occupation of the octahedral sites in M-type hexaferrites.<sup>13,16</sup> Therefore, different compositions of  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferrites with  $x = 0.0, 0.25, 0.50, 0.75$ , and 1.0 were prepared using the co-precipitation method, and then investigated for their microstructural, magnetic, and dielectric characteristics. Based on the obtained results, we found the coexistence of considerable high saturation magnetization (50–73 emu g<sup>-1</sup>) and dielectric permittivity ( $\sim 10^3$ – $10^5$  @ 10 Hz) in the prepared samples.

## 2. Experimental details

The co-precipitation method was used to synthesize  $\text{Ni}^{2+}$ -doped  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  with  $x = 0.0, 0.25, 0.50, 0.75$ , and 1.0. The precursors used for the synthesis of the above-mentioned samples were barium nitrate [ $\text{Ba}(\text{NO}_3)_2$ , Sigma-Aldrich, 99%], ferric nitrate [ $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ , Alfa-Aesar, 99%], copper nitrate [ $\text{Cu}(\text{NO}_3)_2 \cdot 2.5\text{H}_2\text{O}$ , Sigma-Aldrich, ≥98%], nickel nitrate [ $\text{Ni}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ , Sigma-Aldrich, ≥98%], potassium hydroxide [KOH, Sigma-Aldrich, 90%], and deionized water. Initially, stoichiometric quantities of nitrates were mixed in 100 mL deionized water and stirred for 15 min on a hot plate under magnetic stirring. The mixed solution of nitrates was incorporated dropwise into 100 mL solution of KOH. Subsequently, the mixture was stirred for 2 h at 80 °C on the hotplate, and then precipitates were formed. After multiple washings with deionized water, the samples were dried in an oven for 8 h at 100 °C. These dried samples were manually crushed into a fine powder using a mortar and pestle, and then annealed for 12 h at 1000 °C. The annealed powders were compressed under a compaction pressure of 5 tons per cm<sup>2</sup> using a hydraulic press to produce pellets. Finally, the pelletized samples were sintered for 6 h at 1200 °C in a furnace.

X-ray diffraction (ARL EQUINOX 3000) was performed to determine the structural phase of the prepared samples using Cu-K $\alpha$  radiation with a wavelength of  $\lambda = 1.5418$  Å. The machine was operated at a voltage of 40 kV/30 mA to observe the peaks in the  $2\theta$  range of 10° to 70°. Scanning electron microscopy (Hitachi S4800, FE-SEM) was used to study the surface morphology of the prepared samples. Energy dispersive X-ray spectroscopy (Oxford Instruments X-Max 80) was utilized to study the elemental compositional analysis of the prepared samples. To characterize the valence state of iron in the prepared hexaferrites, X-ray photoelectron spectroscopy was

performed using a SPECS PHOIBOS 100 instrument working at 1486.6 eV (Al K<sub>α</sub>). An Alpha-N Analyzer (Novocontrol, Germany) was used to investigate the dielectric properties at room temperature. The magnetic properties were measured at room temperature using a magnetic measurement system (MPMS XL-7, Quantum Design Corporation, USA).

Fig. 1 (a-e) Rietveld refinement of the XRD data for  $\text{Ni}^{2+}$ -substituted  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferrites with  $x = 0.0, 0.25, 0.5, 0.75, \text{ and } 1.0$ , and (f) representative Williamson-Hall plot between  $\beta_{hkl} \cos \theta$  versus  $4 \sin \theta$  for the  $x = 0.5$  sample.

### 3. Results and discussion

The X-ray diffraction patterns of the  $\text{Ni}^{2+}$ -doped  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferrites with  $x = 0.0, 0.25, 0.50, 0.75, \text{ and } 1.0$  are displayed in Fig. 1(a-e), respectively. As can be seen, all the produced samples exhibit XRD patterns corresponding with the

standard JCPDS File No. 00-039-1433 for the M-type hexagonal structure with the  $P6_3/mmc$  space group.<sup>17</sup> Moreover, the XRD patterns demonstrate the absence of typical impurity peaks for all the samples, confirming the phase purity of the produced samples. The FullProf software was used to perform Rietveld structural refinements on the XRD patterns of the produced samples. The peak profiles were refined using the pseudo-Voigt function and the background was fitted using a polynomial with six coefficients. The structural parameters were refined until they approached a goodness of fit ( $\chi^2$ ) value of close to 1.0. Here, the small goodness of fit values ( $\chi^2 = 1.30\text{--}1.63$ ) confirm that the structural parameters are accurate. The estimated refined values of the lattice constants ( $a, c$ ), unit-cell volume ( $V$ ), and goodness of fit ( $\chi^2$ ) are listed in Table 1. It can be seen that the estimated values of lattice parameters for the  $\text{BaFe}_{11}\text{Cu}_1\text{O}_{19}$  hexaferrites ( $x = 0.0$ ) are  $a = 5.9058$  Å and  $c = 23.270$  Å, which are consistent with the reported work.<sup>13</sup> However, these values are found to be higher than the respective values of  $a = 5.887$  Å and  $c = 23.203$  Å for the pure  $\text{BaFe}_{12}\text{O}_{19}$  sample prepared under similar conditions (not shown here).<sup>18</sup> The possible reason for the observed increase in the lattice parameters of  $x = 0.0$  is due to the replacement of  $\text{Fe}^{3+}$  with a smaller ionic radius (0.645 Å) by  $\text{Cu}^{2+}$  ions with a larger ionic radius (0.73 Å).<sup>19</sup> Moreover, with an increase in the  $\text{Ni}^{2+}$  doping content ( $x$ ) in the  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferrites, the values of the lattice parameters ( $a, c$ ) were found to decrease up to  $x = 0.5$ , and then increase with a further increase in the content of  $\text{Ni}^{2+}$  ions (*i.e.*,  $x > 0.5$ ). This variation in the lattice constants can be ascribed to the difference in the ionic radii of the dopant  $\text{Ni}^{2+}$  (0.69 Å) ions compared to  $\text{Fe}^{3+}$  (0.645 Å) and  $\text{Cu}^{2+}$  (0.73 Å), valence change of  $\text{Fe}^{3+}$  to  $\text{Fe}^{2+}$ , and the site occupancy of  $\text{Cu}^{2+}/\text{Ni}^{2+}$  ions in the hexagonal unit-cell. Here, the initial decrease in the lattice parameters of the  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  samples up to  $x = 0.5$  can be attributed to the replacement of the  $\text{Cu}^{2+}$  ions from their preferable  $4f_2$  site<sup>20</sup> by the  $\text{Ni}^{2+}$  ions at the 12k and  $4f_2$  sites.<sup>12</sup> This is because in an octahedral field, the ionic radius of  $\text{Ni}^{2+}$  (0.69 Å) is smaller than that of  $\text{Cu}^{2+}$  (0.73 Å), resulting in a decrease in the lattice parameters. However, for  $x > 0.5$ , the effect of forming oxygen vacancies to balance the charge neutrality has a greater effect on the lattice parameters than the effect of replacing  $\text{Fe}^{3+}$  ions in the lattice with  $\text{Cu}^{2+}$  and  $\text{Ni}^{2+}$ , resulting in an increase in the  $\text{Fe}^{2+}$  ions (will be discussed later in detail). The ionic radius of  $\text{Fe}^{2+}$  at the octahedral site is 0.78 Å, which is found to be larger than that of the  $\text{Cu}^{2+}/\text{Ni}^{2+}/\text{Fe}^{3+}$  ions, resulting in an increase in

the lattice constant values. Further, the observed variation in the unit-cell volume ( $V$ ) is consistent with the changes in the lattice parameters of the produced samples, as can be seen in Table 1. Alternatively, the  $c/a$  ratio of the prepared hexaferrite samples was found to be less than 3.98, indicating the presence of an M-type hexagonal structure.<sup>21</sup> Further, the Williamson–Hall method was employed to estimate the average crystallite size ( $d$ ) and lattice strain ( $\varepsilon$ ) of the  $\text{Ni}^{2+}$ -doped  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferrites with  $x = 0.0, 0.25, 0.50, 0.75$ , and  $1.0$ , which is defined as follows:<sup>22</sup>

$$\beta_{hkl} \cos \theta = \frac{k\lambda}{d} + 4\varepsilon \sin \theta \quad (1)$$

where  $\beta_{hkl}$  is the FWHM of the diffraction peak,  $\theta$  is the Bragg angle,  $k$  is a constant,  $\lambda$  is the wavelength of the X-ray, and  $d$  is the average crystallite size. Fig. 1(f) displays the plot of  $\beta_{hkl} \cos \theta$  vs.  $4 \sin \theta$  for the prepared sample with  $x = 0.5$ . According to this representative plot, the slope of the straight line provides the lattice strain ( $\varepsilon$ ) in the prepared hexaferrites, while the  $y$ -intercept provides the average crystallite size ( $d$ ). A similar procedure was also followed for the other samples (not shown here). The calculated values of  $\varepsilon$  and  $d$  for the produced samples are presented in Table 1. It was found that with an increase in the  $\text{Ni}^{2+}$  doping content, the value of  $d$  decreased from 61 nm ( $x = 0.0$ ) to 40 nm ( $x = 0.5$ ), and then increased to 56 nm ( $x = 1.0$ ). In contrast, the value of  $\varepsilon$  initially increased with an increase in the  $\text{Ni}^{2+}$  doping content up to  $x = 0.5$ , which can be attributed to the replacement of  $\text{Cu}^{2+}$  by  $\text{Ni}^{2+}$  ions with a smaller ionic radius. However, for a higher  $\text{Ni}^{2+}$  content ( $x > 0.5$ ), the observed decrease in the value of  $\varepsilon$  can be attributed to the creation of defects (oxygen vacancies) at the octahedral sites, which caused the unit-cell volume to expand slightly, and then reduced the distortion in the hexaferrite structure.

The surface morphological analysis of the  $\text{Ni}^{2+}$ -doped  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferrites with  $x = 0.0, 0.25, 0.50, 0.75$ , and  $1.0$  was studied using scanning electron microscopy (FE-SEM). Fig. 2(a–e) demonstrate the SEM micrographs of the prepared hexaferrites, respectively, which were taken from the fractured surfaces of the pelletized samples sintered for 6 h at 1200 °C. The FE-SEM images show that all samples exhibit a heterogeneous distribution of grain sizes, with the majority of grains possessing a hexagonal shape and different sizes. The ImageJ software was used to determine the average grain size ( $G$ ) and the results are listed in Table 1. The grain size was found to decrease with an increase in  $\text{Ni}^{2+}$  doping concentration up to  $x = 0.5$ , and then it increased. Here, the variation in grain size with  $\text{Ni}^{2+}$  doping in the  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferrites can be attributed to several factors, such as the difference in the ionic radius, strain, porosity, and microstructural features, which can interact and influence each other. The initial decrease in grain size with an increase in the  $\text{Ni}^{2+}$  concentration can be due to the increase in the lattice strain caused by the mismatch in ionic radius, which hinders the grain growth.<sup>10</sup> However, at higher doping concentrations ( $x > 0.5$ ), the grain size may increase due to the agglomeration of grains, relaxation of strain, and lattice expansion. Fig. 2(f) displays the result of energy dispersive X-ray spectroscopy (EDX) performed on a representative

Fig. 2 (a–e) FESEM images of  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferrites with  $x = 0.0, 0.25, 0.5, 0.75$ , and  $1.0$ , and (f) EDX spectrum of a representative sample with  $x = 0.5$ . Insets in (a–e) show the grain size distribution in the prepared samples, while the inset in (f) presents the elemental ratios of  $x = 0.5$  composition in atomic%.

$\text{BaFe}_{11}\text{Cu}_{0.5}\text{Ni}_{0.5}\text{O}_{19}$  ( $x = 0.5$ ) sample. The EDX spectrum only shows the spectral lines of Ba, Fe, Cu, Ni and O, indicating the phase purity of the material. The inset of the figure shows the atomic proportions of each element, indicating that the prepared sample has a stoichiometric ratio for each ion, which is identical to the  $\text{BaFe}_{11}\text{Cu}_{0.5}\text{Ni}_{0.5}\text{O}_{19}$  sample.

Fig. 3(a) displays a representative X-ray photoelectron spectroscopy (XPS) survey spectrum for the prepared  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferrites with  $x = 0.75$ . The spectrum exclusively

reveals peaks associated with the C, Ba, Fe, Cu, Ni, and O elements.<sup>23</sup> The C 1s peak at 284.8 eV can be attributed to contaminating carbon. The location of this peak was utilized to calibrate the binding energies of all of the other elements. All other samples exhibited comparable survey spectra (not shown here). The binding energy of each element proves that the prepared hexaferrites have a single-phase, without any additional impurity phases. Fig. 3(b) shows the high-resolution XPS spectrum of Fe 2p for the sample with  $x = 0.75$ , which was

Fig. 3 (a) XPS survey spectrum and (b) high-resolution XPS spectrum of Fe 2p for the  $x = 0.75$  sample. (c–g) Fe 2p<sub>3/2</sub> XPS spectra of the prepared BaFe<sub>11</sub>Cu<sub>1-x</sub>Ni<sub>x</sub>O<sub>19</sub> hexaferrites with  $x = 0.0\text{--}1.0$ . (h) Variation in Fe<sup>2+</sup>/Fe<sup>3+</sup> ratio with doping content.

obtained with a small energy step size. Here, the two peaks with binding energies of 712.2 eV and 725.6 eV correspond to Fe 2p<sub>3/2</sub> and Fe 2p<sub>1/2</sub> of the Fe species, respectively.<sup>16</sup> These peaks were deconvoluted into two peaks, with the first peak representing the valence state of Fe<sup>2+</sup> and the subsequent peak representing the Fe<sup>3+</sup> state. Each fitting peak in the spectrum of Fe 2p was considered to have the form of a Lorentzian–Gaussian distribution. Moreover, the relative area of the corresponding peaks can be used to determine the ratio of Fe ions with the Fe<sup>2+</sup> valence state to that with Fe<sup>3+</sup>. Fig. 3(c–g) illustrate the comparative Fe 2p<sub>3/2</sub> XPS spectra of the prepared BaFe<sub>11</sub>Cu<sub>1-x</sub>Ni<sub>x</sub>O<sub>19</sub> hexaferrites with  $x = 0.0\text{--}1.0$ . Based on the analysis, it was observed that the Fe<sup>2+</sup>/Fe<sup>3+</sup> ratio decreased as the concentration of Ni<sup>2+</sup> doping increased until  $x = 0.5$ , after which it increased significantly (see Fig. 3(h)). This behavior can be attributed to the fact that hexaferrites sintered in air often possess intrinsic oxygen vacancies and Fe<sup>2+</sup> ions,<sup>12</sup> which can be altered upon Ni<sup>2+</sup> doping. The subsequent section will provide a comprehensive analysis of the impact of Ni<sup>2+</sup> doping on the predicted Fe<sup>2+</sup>/Fe<sup>3+</sup> ratio, which is a crucial factor in determining the conduction mechanism of hexaferrites, and may consequently alter the electrical properties of the prepared samples.

Fig. 4(a) shows the behaviour of the real part of dielectric permittivity ( $\epsilon'$ ) versus applied frequency for the produced Ni<sup>2+</sup>-doped BaFe<sub>11</sub>Cu<sub>1-x</sub>Ni<sub>x</sub>O<sub>19</sub> hexaferrites with  $x = 0.0, 0.25, 0.50, 0.75$ , and  $1.0$  measured at room temperature. Typically, the dielectric polarization in pure BaFe<sub>12</sub>O<sub>19</sub> is determined by the exchange of charges between the Fe<sup>2+</sup>  $\leftrightarrow$  Fe<sup>3+</sup> ions at the octahedral site, while the Fe<sup>2+</sup>/Fe<sup>3+</sup> ratio is determined by the conversion of dominant Fe<sup>3+</sup> to Fe<sup>2+</sup> via doping, sintering, and environmental conditions.<sup>24,25</sup> As can be seen in the graph, the  $\epsilon'$  values rapidly decrease in the low-frequency region, while in the high-frequency region, they become nearly frequency independent. The Maxwell–Wagner polarisation model precisely explains this phenomenon, which is consistent with Koop's theory.<sup>26</sup> It was proposed that ferrites are composed of conducting grains (Gs) separated by resistive grain-boundaries (GBs). At low frequencies, the charge carrier moves from Gs to GBs, causing local lattice distortion due to the asymmetric charge distribution that travels along the applied field. This polarisation is referred to as space charge polarisation. However, as the frequency of the applied field increases, this slowly moving lattice distortion (space charge polarisation) cannot keep up and falls behind, resulting in a decrease in the  $\epsilon'$  values with an increase in frequency.<sup>27</sup> Moreover, the figure

Fig. 4 Variation in (a) dielectric permittivity ( $\epsilon'$ ) and (b) dielectric tangent loss ( $\tan \delta$ ) versus frequency for the  $\text{Ni}^{2+}$ -doped  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferrites with  $x = 0.0, 0.25, 0.5, 0.75$ , and  $1.0$ .

demonstrates that the obtained value of  $\epsilon'$  for the  $\text{BaFe}_{11}\text{Cu}_1\text{O}_{19}$  sample (*i.e.*,  $x = 0.0$ ) is comparably high compared to the pure  $\text{BaFe}_{12}\text{O}_{19}$  sample prepared under similar conditions (not shown here) within the available frequency domain.<sup>27</sup> Here, the observed enhancement in  $\epsilon'$  value can be attributed to the increase in electron transfer between the  $\text{Fe}^{2+} \leftrightarrow \text{Fe}^{3+}$  ions to maintain the charge neutrality at the octahedral sites. However, with the incorporation of  $\text{Ni}^{2+}$  doping content up to  $x = 0.5$ , the initial decreasing trend of  $\epsilon'$  may be due to the increase in the lattice strain ( $\epsilon$ ), which causes a distortion in the hexaferrite structure. This distortion may lead to a reduction in the concentration of intrinsic oxygen vacancies, which reduces the number of sites available for oxygen vacancies.<sup>12</sup> Consequently, the concentration of  $\text{Fe}^{2+}$  ions decreases with an increase in the  $\text{Ni}^{2+}$  doping content due to the fact that the intrinsic  $\text{Fe}^{2+}$  ions in  $\text{BaFe}_{11}\text{Cu}_1\text{O}_{19}$  may transform into  $\text{Fe}^{3+}$  ions to achieve charge balance at the octahedral sites, which weakens the exchange of charges between the  $\text{Fe}^{2+} \leftrightarrow \text{Fe}^{3+}$  ions, resulting in reduced values of  $\epsilon'$  up to  $x = 0.5$ . Hence, the possible reason for this lower value of  $\epsilon'$  is that at  $x = 0.5$ , the ratio of  $\text{Cu}^{2+}$  and  $\text{Ni}^{2+}$  ions reaches an optimum balance, where the concentration of oxygen vacancies and  $\text{Fe}^{2+}$  ions may be at their minimum in the system, resulting in a more stable lattice configuration and reduced polarization. However, a further increase in the  $\text{Ni}^{2+}$  doping content ( $x > 0.5$ ) may cause a reversal in this trend and decrease the lattice strain. This decrease in lattice strain facilitates the formation of defects, including the creation of oxygen vacancies and the reduction of  $\text{Fe}^{3+}$  to  $\text{Fe}^{2+}$ . Therefore, the formation of  $\text{Fe}^{2+}/\text{Fe}^{3+}$  pair dipoles with an increase in the  $\text{Ni}^{2+}$  doping content begins to contribute to the permittivity of the prepared samples, resulting in an increase in  $\epsilon'$  value for the  $x > 0.5$  samples. Moreover, the permittivity may also be affected by the transition of some of the  $\text{Ni}^{2+}$  ions to  $\text{Ni}^{3+}$  with an increase in the  $\text{Ni}^{2+}$  doping content.<sup>16</sup> Here, the  $\epsilon'$  value was found to be highest for the  $\text{BaFe}_{11}\text{Ni}_1\text{O}_{19}$  ( $x = 1.0$ ) sample, which is ascribed to its highest dipole density (*i.e.*,  $\text{Fe}^{2+}/\text{Fe}^{3+}$  and  $\text{Ni}^{2+}/\text{Ni}^{3+}$ ) among the prepared samples. This results in a colossal permittivity

( $\sim 10^5$ ) for the  $\text{BaFe}_{11}\text{Ni}_1\text{O}_{19}$  sample, which is two orders of magnitude higher than the permittivity of the pure  $\text{BaFe}_{12}\text{O}_{19}$  sample and also among the highest reported values to date.<sup>11,12,28</sup>

The frequency dependence of the dielectric tangent loss ( $\tan \delta$ ) for the  $\text{Ni}^{2+}$ -doped  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferrites with  $x = 0.0, 0.25, 0.50, 0.75$ , and  $1.0$  measured at room temperature is displayed in Fig. 4(b). As seen in the graph, the  $\tan \delta$  values exhibit similar behaviour to that of dielectric permittivity. At lower frequencies,  $\tan \delta$  has a higher magnitude because of the dominance of GBs, which inhibits the charge carrier hopping mechanism. Therefore, there is increased absorption, leading to greater loss. However, Gs are more conductive at higher frequencies because of the charge carrier hopping between the  $\text{Fe}^{2+}/\text{Fe}^{3+}$  and  $\text{Ni}^{2+}/\text{Ni}^{3+}$  ions at the octahedral site. Consequently,  $\tan \delta$  is reduced given that there is less absorption at higher frequencies. Moreover, a dielectric relaxation peak was observed for all the samples, which indicates that the frequency at which electrons/holes hop between different ionic states is synchronized with the frequency of the applied alternating current.<sup>29</sup> However, as the  $\text{Ni}^{2+}$  doping concentration increases, the observed peaks shifted to a lower frequency, and the peak intensity decreased slightly. This peak shifting is due to the increased relaxation time of the polarizable entities in the prepared samples, which is influenced by the presence of additional dipoles introduced by the  $\text{Ni}^{2+}$  doping content. The obtained results suggest values of  $\tan \delta < 1.0$  at higher frequencies ( $10^5$ – $10^7$  Hz). Among the prepared samples, the reduced  $\tan \delta$  value for the  $x = 1.0$  sample together with the colossal  $\epsilon'$  value makes this composition attractive for high-frequency applications.

Fig. 5 displays the variation in AC conductivity ( $\sigma_{ac}$ ) with applied frequency for the prepared  $\text{Ni}^{2+}$ -doped  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferrites with  $x = 0.0, 0.25, 0.50, 0.75$ , and  $1.0$  measured at room temperature. Typically, the microscopic motion of charge carriers within the hexagonal ferrites can be inferred from the frequency ( $f$ ) vs. AC conductivity ( $\sigma_{ac}$ ) plot. As

Fig. 5 Frequency-dependent AC conductivity ( $\sigma_{ac}$ ) for  $\text{Ni}^{2+}$ -doped  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferrites with  $x = 0.0, 0.25, 0.5, 0.75$ , and  $1.0$ .

seen in the figure, the behaviour of  $\sigma_{ac}$  shows the opposite dependence on frequency as that of  $\epsilon'$  and  $\tan \delta$ . Here, the conductivity increases with an increase in frequency for all the samples. The values of  $\sigma_{ac}$  are small at lower frequencies and high at higher frequencies. It is well known that electron hopping between  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$  ions is the key factor that determines the conductivity of hexaferrites and this electron hopping is strongly dependent on the concentration of  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$  ions at the octahedral site.<sup>24</sup> This hopping process increases with an increase in frequency, making conductive Gs more dominant, and hence the conductivity increases. Thus, to understand the observed dispersive behaviour of the conductivity graphs, the obtained data was fitted with Jonscher's power law, as follows:<sup>30</sup>

$$\sigma_{ac}(\omega) = \sigma_0 + A\omega^n \quad (2)$$

where  $\sigma_0$  denotes the frequency-independent component of conductivity,  $A$  is a constant that defines the polarizability strength,  $\omega$  is the angular frequency, and  $n$  is the slope of the frequency-dependent curve ( $0 \leq n \leq 1$ ). Table 2 presents the values of the various fitted parameters. Further, the figure shows that the value of  $\sigma_{ac}$  initially decreases with an increase in  $\text{Ni}^{2+}$  doping content up to  $x = 0.5$ , and thereafter it begins to increase for  $x > 0.5$ . Here, the observed variation in the values of  $\sigma_{ac}$  depends on the dopant concentration ( $x$ ), which alters the  $\text{Fe}^{2+}/\text{Fe}^{3+}$  ratio in the prepared samples (as discussed earlier), resulting in a variation in the conductivity. According to the obtained results, the  $\text{BaFe}_{11}\text{Ni}_1\text{O}_{19}$  ( $x = 1.0$ ) sample has the

highest  $\sigma_{ac}$  value and lowest  $n$  value among the prepared samples. Moreover, the obtained values of  $\sigma_{ac}$  for the  $x = 1.0$  sample were found to be two orders of magnitude higher than the permittivity of the pure  $\text{BaFe}_{12}\text{O}_{19}$  sample in the available frequency range. This behavior can be due to comparatively increased  $\text{Fe}^{2+} \leftrightarrow \text{Fe}^{3+}$  and  $\text{Ni}^{2+} \leftrightarrow \text{Ni}^{3+}$  conducting networks and dense microstructures.

The Nyquist plane plots of the prepared  $\text{Ni}^{2+}$ -doped  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferrites with  $x = 0.0, 0.25, 0.50, 0.75$ , and  $1.0$  measured at room temperature are shown in Fig. 6. Typically, the Nyquist plane plot consists of one or more completely resolved or poorly resolved semi-circles, depending on the number of dielectric relaxation processes or crystallographic phases present in the produced samples. In our single-phase produced samples, we observed two poorly resolved semi-circles with dissimilar widths. These semi-circles correspond to separate dielectric relaxation processes, namely Gs and GBs. We used the ZView software to fit our experimental data with an equivalent circuit model to further analyze the Nyquist plane plots. The components of the applied circuit were ( $R_1Q_1$ ) and ( $R_2Q_2C_3$ ) linked in series, where  $R_1$  and  $R_2$  are the resistance,  $C_1$  and  $C_3$  are the capacitance, and  $Q_1$  and  $Q_2$  are the constant phase elements reflecting the capacitance variation from the optimal dielectric behavior. The following formulas were used to calculate the capacitance of each constant-phase element:<sup>31</sup>

$$C = Q^{1/n} R^{(1-n)/n} \quad (3)$$

where  $n$  denotes the degree to which the capacitance deviates from the ideal resistive ( $n = 0$ ) or capacitive ( $n = 1$ ) behavior. The values of the various derived components are listed in Table 2 according to the result of the synchronizing experimental data with fitting. According to the analysis of the fitted data, we found that lower values of  $R_1$  are obtained from the first circuit ( $R_1Q_1$ ), while the estimated capacitance values ( $C_1$ ) using  $Q_1$  (eqn (3)) are within the Gs geometrical capacitance range ( $10^{-11}\text{--}10^{-13} \text{ F cm}^{-1}$ ).<sup>32</sup> Thus, the semi-circles in the higher frequency zone are correlated with the dielectric relaxation of Gs. However, we found significantly greater values of  $R_2$  from the second circuit ( $R_2Q_2C_3$ ), while the estimated values of capacitance ( $C_2$ ) using  $Q_2$  (eqn (3)) are within the geometrical capacitance range of GBs ( $10^{-8}\text{--}10^{-10} \text{ F cm}^{-1}$ ).<sup>32</sup> Therefore, the semi-circles in the lower frequency zone are ascribed to the dielectric relaxation of GBs, but the values of  $C_3$  are linked to the presence of space charges surrounding Gs, which may create an interface that impedes charge carrier movement. Due to the

Table 2 Fitted parameters of the Jonscher power law ( $\sigma_0$ ,  $n$ ) and Nyquist plots ( $R_1$ ,  $C_1$ ,  $R_2$ ,  $C_2$ ,  $C_3$ , and  $R_T$ ) for  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferrites

Fig. 6 (a–e) Nyquist plane plots ( $Z'$  vs.  $Z''$ ) for the prepared  $\text{Ni}^{2+}$ -doped  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferites with  $x = 0.0, 0.25, 0.50, 0.75$ , and  $1.0$ . (f) Equivalent circuit model used for fitting experimental data. Arrow in (a) points to the direction of increasing frequency.

localization of these space charges, these hexaferrites produce high dielectric permittivity values.<sup>24</sup> Additionally, Table 2 includes the total resistance of the prepared sample ( $R_T = R_{\text{Gs}} + R_{\text{GBS}}$ ). It was found that initially  $R_T$  increases significantly with an increase in the  $\text{Ni}^{2+}$  doping content up to  $x = 0.5$ , and afterwards it decreases for  $x > 0.5$ . Here, the observed increase in  $R_T$  with  $x$  based on the decrease in the grain size and  $\text{Fe}^{2+}/\text{Fe}^{3+}$  ratio results in an overall decline in conductivity; thus, an increase in  $R_T$  was observed up to the  $x = 0.5$  sample. However, in the case of  $x > 0.5$ , the observed decreasing trend of  $R_T$  is due to the increase in grain size and  $\text{Fe}^{2+}/\text{Fe}^{3+}$  ratio together with the

availability of an additional hopping network ( $\text{Ni}^{2+} \leftrightarrow \text{Ni}^{3+}$ ) to facilitate the conduction mechanism, as discussed earlier.

Fig. 7(a) displays the magnetic hysteresis loops of the  $\text{Ni}^{2+}$ -doped  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferrites with  $x = 0.0, 0.25, 0.50, 0.75$ , and  $1.0$  measured at room temperature under an applied magnetic field of  $\pm 20$  kOe. The saturation magnetization ( $M_s$ ), remanence magnetization ( $M_r$ ), and coercivity ( $H_c$ ) values of all the prepared samples were obtained using these hysteresis loops. The obtained values for these parameters are listed in Table 3. As can be observed, the magnetic characteristics changed significantly with the dopant concentration in the

Fig. 7 (a) Magnetic hysteresis loops of  $\text{Ni}^{2+}$ -doped  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferrites with  $x = 0.0, 0.25, 0.50, 0.75$ , and  $1.0$ . Inset shows a representative LAS curve for the  $x = 0.5$  sample. (b) Schematic representation of the occupation of cations in M-type hexaferrites. The black, red, and green spheres represent Fe ions. The directional arrows represent the local magnetic moments of atomic positions.

$\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferrites due to the preferential occupancy of the  $\text{Cu}^{2+}$  and  $\text{Ni}^{2+}$  ions at different crystallographic sites. As shown in Fig. 7(b), the magnetic moment of  $\text{BaFe}_{12}\text{O}_{19}$ , which is typically deduced by analyzing the difference in magnetic moments between the crystallographic sites, was measured to be  $20 \mu_{\text{B}}$  (*i.e.*,  $M = M(12k + 2a + 2b) \uparrow - M(4f_1 + 4f_2) \downarrow$ ).<sup>18,33</sup> Here, the  $M_s$  value for the prepared  $\text{BaFe}_{11}\text{Cu}_1\text{O}_{19}$  sample ( $x = 0.0$ ) was found to be  $65 \text{ emu g}^{-1}$ , which is comparatively higher than that of the pure  $\text{BaFe}_{12}\text{O}_{19}$  sample (*i.e.*,  $55 \text{ emu g}^{-1}$ ) prepared under similar conditions. This observed improvement in  $M_s$  value for the  $x = 0.0$  sample can be understood based on the fact that the comparatively less magnetic  $\text{Cu}^{2+}$  ( $1 \mu_{\text{B}}$ ) ions replace the  $\text{Fe}^{3+}$  ( $5 \mu_{\text{B}}$ ) ions at their preferential  $4f_2$  spin-down site and convert more  $\text{Fe}^{3+}$  into  $\text{Fe}^{2+}$  ions at the octahedral sites due to charge compensation. Therefore, the magnetic moment on the spin-down site decreases, leading to an increase in the  $M_s$  value for the  $\text{BaFe}_{11}\text{Cu}_1\text{O}_{19}$  compared to the  $\text{BaFe}_{12}\text{O}_{19}$  sample.<sup>34</sup> However, upon the incorporation of  $\text{Ni}^{2+}$  ( $2 \mu_{\text{B}}$ ) ions in place of  $\text{Cu}^{2+}$  ( $1 \mu_{\text{B}}$ ) ions in the  $\text{BaFe}_{11}\text{Cu}_{1-x}\text{Ni}_x\text{O}_{19}$  hexaferrites, we found that the value of  $M_s$  initially decreased with an increase in the  $\text{Ni}^{2+}$  doping content up to  $x = 0.5$ , and thereafter it increased. Here, the observed initial decrease in the  $M_s$  value with an increase in  $\text{Ni}^{2+}$  content may be related to the decrease of the net magnetic moment per formula unit, indicating the preferential occupation of  $\text{Ni}^{2+}$  at the  $12k$  spin-up and  $4f_2$  spin-

down sites, while the  $\text{Cu}^{2+}$  ions occupy the  $4f_2$  spin-down site in the place of the  $\text{Fe}^{3+}$  ions (see Fig. 7(b)). Thus, the difference in magnetic moments across the sites decreases, leading to a decline in the  $M_s$  value from  $65 \text{ emu g}^{-1}$  ( $x = 0.0$ ) to  $50 \text{ emu g}^{-1}$  ( $x = 0.5$ ). However, when the  $\text{Ni}^{2+}$  doping content exceeded  $x = 0.5$ , the  $\text{Ni}^{2+}$  ions gradually occupied the  $4f_2$  spin-down sites, while the  $\text{Cu}^{2+}$  ions take up the  $4f_2$  site together with reducing more  $\text{Fe}^{3+}$  ions to  $\text{Fe}^{2+}$  ions. This leads to an increase in the difference between the sites, and thus the value of  $M_s$  increases from  $50 \text{ emu g}^{-1}$  ( $x = 0.5$ ) to  $73 \text{ emu g}^{-1}$  ( $x = 1.0$ ). Among the produced samples, the highest value of  $M_s$  was obtained for the  $\text{BaFe}_{11}\text{Ni}_1\text{O}_{19}$  sample ( $x = 1.0$ ), which is found to be higher than the reported values,<sup>12</sup> where the respective value of  $M_s$  decreases at a higher  $\text{Ni}^{2+}$  content due to the formation of a secondary phase having comparatively weak magnetic nature. Furthermore, the magnetic anisotropy ( $K_1$ ) of the prepared samples was estimated by employing the law of approach to magnetic saturation (LAS), which can be expressed as follows:<sup>35,36</sup>

$$M(H) = M_s \left( 1 - \frac{b}{H^2} \right) \quad (4)$$

where  $M_s$  denotes the saturation magnetization,  $H$  denotes the magnetic field, and  $b$  denotes the anisotropy parameter. In the case of M-type hexagonal symmetry,  $b$  can be computed using the following expression:

$$b = \frac{4K_1^2}{15M_s^2} \quad (5)$$

The inset of the figure shows the fitting of the high-field region (*i.e.*,  $H \gg H_c$ ) of the representative hysteresis loop of the  $x = 0.5$  sample. According to the values of the fitting parameters ( $M_s$  and  $b$ ), the values of  $K_1$  for the prepared samples were calculated. As shown in Table 3, the value of  $K_1$  initially decreased, and then increased with an increase in the  $\text{Ni}^{2+}$  doping content, reaching a minimal value at  $x = 0.5$ . In M-type hexaferrites, the  $12k$ ,  $4f_2$ , and  $2b$  sites are known as major

contributors to the magnetic anisotropy.<sup>37</sup> Therefore, the initial decrease observed in the  $K_1$  value is attributed to the competition between the Ni<sup>2+</sup> and Cu<sup>2+</sup> ions to occupy the 12k, 4f<sub>2</sub> and 4f<sub>2</sub> sites in place of Fe<sup>3+</sup> ions, respectively, thereby weakening the magnetic anisotropy. However, the observed increase in  $K_1$  for  $x > 0.5$  can be explained by the probable occupation of the Ni<sup>2+</sup> and Cu<sup>2+</sup> ions at the 4f<sub>2</sub> site, which transfer more Fe<sup>3+</sup> ions from the octahedral to tetrahedral sites, thus increasing the magnetic anisotropy. Moreover, the variation in coercivity ( $H_c$ ) with an increase in the Ni<sup>2+</sup> doping content can be related to the changes in magnetic anisotropy ( $K_1$ ) and grain size ( $G$ ) of the prepared hexaferrites (see Table 1). Here, we found that  $H_c$  has a positive relationship with  $K_1$  and inverse dependance on  $G$ .<sup>38,39</sup>

Table 4 shows a comparison of the magnetic and dielectric characteristics of the prepared BaFe<sub>11</sub>Cu<sub>1-x</sub>Ni<sub>x</sub>O<sub>19</sub> hexaferrites ( $x = 0.0$  and  $1.0$ ) with the reported relevant compositions measured at room temperature. The comparison reveals that the fabricated sample BaFe<sub>11</sub>Ni<sub>1</sub>O<sub>19</sub> ( $x = 1.0$ ) exhibits comparatively high values of saturation magnetization ( $M_s$ ) and dielectric permittivity ( $\epsilon'$ ) together with a low dielectric tangent loss ( $\tan \delta$ ). This is probably because of the influence of the Ni<sup>2+</sup> ions occupying the 4f<sub>2</sub> sites and the increased dipole density (Fe<sup>2+</sup>/Fe<sup>3+</sup>). Therefore, the coexistence of high magnetic saturation and dielectric permittivity in the BaFe<sub>11</sub>Ni<sub>1</sub>O<sub>19</sub> material presents potential for its utilization in microwave-absorbing devices. This highlights its application in new technologies and helps advance materials that are designed to effectively attenuate electromagnetic waves.

## 4. Conclusions

In this study, we investigated the effect of Ni<sup>2+</sup>–Cu<sup>2+</sup> co-doping on the structural, dielectric, and magnetic characteristics of barium hexaferrites. The co-precipitation technique was employed to prepare Ni<sup>2+</sup>–Cu<sup>2+</sup> co-doped BaFe<sub>11</sub>Cu<sub>1-x</sub>Ni<sub>x</sub>O<sub>19</sub> hexaferrites with  $x = 0.0, 0.25, 0.50, 0.75$ , and  $1.0$ . All the prepared samples showed the development of a single-phase

hexagonal structure, according to the Rietveld refinement of their XRD patterns. The structural analysis revealed that doping of Ni<sup>2+</sup> and Cu<sup>2+</sup> changed the values of the lattice parameters ( $a, c$ ), unit-cell volume, lattice strain, and crystallite size, which were explained in terms of the difference in the ionic radii and occupation at the different crystallographic sites. The FE-SEM analysis showed that the grains are hexagonal in shape, while EDX confirmed the stoichiometry of the produced samples. The XPS analysis confirmed the formation of Fe<sup>2+</sup> ions; however, the ratio of Fe<sup>2+</sup>/Fe<sup>3+</sup> changed with an increase in the Ni<sup>2+</sup> doping content. Dielectric measurements displayed a decreasing trend in the frequency-dependent dielectric behavior, in accordance with Maxwell–Wagner interfacial polarization. Alternatively, the impedance analysis showed a considerable variation in the resistive properties of the prepared samples with an increase in the Ni<sup>2+</sup>–Cu<sup>2+</sup> doping content. The observed variation in the dielectric and resistive properties were attributed to the changes in the grain size and electron–hole transfer between the charge carriers. The magnetic measurements showed that the Ni<sup>2+</sup>–Cu<sup>2+</sup> co-doping caused a noticeable variation in the values of  $M_s$  and  $H_c$  measured at room temperature. This was attributed to the preferential occupation of the Ni<sup>2+</sup> ions at the different crystallographic sites, which may have a more significant impact on the overall magnetic moment. Based on the obtained results, we found that the sample with  $x = 1.0$  had the highest dielectric permittivity ( $>10^3$  at  $10^7$  Hz) and magnetization (73 emu g<sup>-1</sup>) together with a lowest dielectric tangent loss (0.2) and material resistance ( $1.5 \times 10^5$  Ω). This makes the BaFe<sub>11</sub>Ni<sub>1</sub>O<sub>19</sub> composition a promising choice as a microwave absorption material, which requires high dielectric permittivity and magnetization together with a reduced dielectric tangent loss. Currently, experiments are being conducted to measure the electromagnetic interference (EMI) shielding efficacy of this material. In the future, we are planning to disperse BaFe<sub>11</sub>Ni<sub>1</sub>O<sub>19</sub> in a conductive matrix to develop a light-weight, flexible, and efficient composite material for microwave absorbing applications.
