Silica-coated $\text{LiYF}_4\text{:Yb}^{3+}$, Tm^{3+} upconverting nanoparticles are non-toxic and activate minor stress responses in mammalian cells†

 Kais Bietar, ^a Siwei Chu, ^a Gabrielle Mandl, ^b Emma Zhang, ^a Naim Chabaytah, ^a Renata Sabelli,^a John A. Capobianco ^{*b} and Ursula Stochaj ^{*ac}

Lanthanide-doped upconverting nanoparticles (UCNPs) are ideal candidates for use in biomedicine. The interaction of nanomaterials with biological systems determines whether they are suitable for use in living cells. In-depth knowledge of the nano–bio interactions is therefore a pre-requisite for the development of biomedical applications. The current study evaluates fundamental aspects of the NP–cell interface for square bipyramidal UCNPs containing a $\text{LiYF}_4\text{:Yb}^{3+}$, Tm^{3+} core and two different silica surface coatings. Given their importance for mammalian physiology, fibroblast and renal proximal tubule epithelial cells were selected as cellular model systems. We have assessed the toxicity of the UCNPs and measured their impact on the homeostasis of living non-malignant cells. Rigorous analyses were conducted to identify possible toxic and sub-lethal effects of the UCNPs. To this end, we examined biomarkers that reveal if UCNPs induce cell killing or stress. Quantitative measurements demonstrate that short-term exposure to the UCNPs had no profound effects on cell viability, cell size or morphology. Indicators of oxidative, endoplasmic reticulum, or nucleolar stress, and the production of molecular chaperones varied with the surface modification of the UCNPs and the cell type analyzed. These differences emphasize the importance of evaluating cells of diverse origin that are relevant to the intended use of the nanomaterials. Taken together, we established that short-term, our square bipyramidal UCNPs are not toxic to non-malignant fibroblast and proximal renal epithelial cells. Compared with established inducers of cellular stress, these UCNPs have minor effects on cellular homeostasis. Our results build the foundation to explore square bipyramidal UCNPs for future *in vivo* applications.

1. Introduction

Upconversion nanomaterials are important tools to advance the basic and applied sciences. They have become indispensable for nanomedicine, biophotonics, biosensing, and basic research.^{1,2} Among upconversion nanomaterials, lanthanide-doped upconversion nanoparticles (UCNPs) display unique excitation/emission properties.^{3,4} In particular, UCNPs do not photobleach or photoblink, have long luminescence lifetimes, as well as narrow excitation and emission bands.^{1,3–6} Due to their physical and chemical stability, fluoride-based UCNPs are ideal for biomedical applications.⁷

By tailoring the size, morphology, emission/excitation spectrum, and functionalization of the particle surface, UCNPs are optimized for specific functions. For instance, non-spherical morphologies may increase the circulation time in biological systems when compared with spherical nanoparticles (NPs).^{8,9} Non-spherical NPs can also outperform their spherical counterparts with respect to cellular uptake and retention.^{10–12} $\text{LiYF}_4\text{:Yb}^{3+}$, Tm^{3+} UCNPs are well known for their square bipyramidal morphology and strong UV and blue upconversion luminescence upon 980 nm excitation.¹³ This shape arises because the lowest energy crystal plane of the tetragonal crystal phase of LiYF_4 is the 011 plane, yielding 8 faces of equal surface energy.¹⁴ [This equal surface energy enables facile uniform coating of the NPs with a large number of different ligands or materials].^{15,16}

The use of UCNPs is currently limited by the hurdles they encounter in biological systems. Some of these obstacles can be overcome by modifying their surface coating.¹⁷ In particular, the addition of silica shells provides distinct advantages.^{18,19} Silica coating increases colloidal and chemical stability, thus

protecting against aggregation and dissolution in biological environments.¹⁸ Moreover, the coating with silica is reproducible, low cost, and ideally suited for the delivery of bioactive components.¹⁸ Silica shells that include functional groups on their surfaces can be used for the conjugation of ligands to the NP surface. NP surfaces that carry azides are especially attractive, as they are suitable for azide-alkyne click chemistry. However, the effects of these reactive groups on nano-bio interactions are largely unknown.

The first and often major barrier relevant to all *in vivo* applications of nanomaterials is cell toxicity. Furthermore, it is critically important that the sub-lethal effects elicited by UCNPs are well-defined and limited in scope. Nanomaterials can generate such sub-lethal effects by disrupting the homeostasis of healthy cells. Fibroblasts are main targets for nano-bio interactions. They are present throughout the mammalian body, where they are crucial for tissue, organ, and organismal homeostasis.²⁰ Fibroblasts respond to a wide variety of endogenous and environmental signals, including tissue damage.²¹ Accordingly, they serve as a model system to study nanodelivery.²²

Several cell types located in the kidney have emerged as targets for nanomedicine.^{23,24} Kidneys non-specifically accumulate NPs,²⁵ which makes them especially vulnerable to the adverse effects of nanomaterials. Peritubular capillaries provide the route to kidney tubules. As a result, renal epithelia become vulnerable to deleterious nano-bio interactions (reviewed in ref. 25). Despite the importance of renal tubular cells for kidney function, their response to NPs remains understudied.^{26–29}

Cultured cells are essential to assess critical aspects of nano-bio interactions in a rigorous fashion. This evaluation consists of two stages. First, initial experiments measure the acute toxicity of nanomaterials by scoring the loss of cell viability. Second, materials that pass this test are examined for their sub-lethal effects on cell physiology. To this end, appropriate biomarkers monitor the changes in cell shape and size, cytoskeletal organization, abundance or localization of relevant transcription factors, molecular chaperones (here called

chaperones), and other biomolecules that are suitable to scrutinize cellular stress responses. Fig. 1 depicts the essential cellular pathways our study examined in UCNP-treated cells.

Stress responses are controlled by multi-component networks that include chaperones and additional cellular components. In particular, the transcription factors nuclear factor erythroid 2-related factor 2 (Nrf2) and nuclear factor kappa-B (NFκB) inform on oxidative stress induced by nanomaterials.^{28,30}

Chaperones are necessary to adjust cell physiology to a wide variety of insults.^{31,32} For example, chaperone abundance may change when cells encounter UCNPs or other nanomaterials.^{28,30,33} The cellular uptake of UCNPs is generally mediated by membrane-delimited compartments.¹¹ Therefore, chaperones relevant to membrane or vesicle trafficking, such as Grp78 and Grp94, are sensitive indicators of NP-induced stress. Under conditions of severe ER stress, the transcription factor C/EBP Homologous Protein (CHOP) increases in abundance and promotes apoptosis. Crosstalk between NFκB and CHOP fine-tunes the cellular responses to ER stress.³⁴

NFκB also communicates with nucleoli, which are membrane-less compartments in the nucleus.³⁵ Nucleoli assemble ribosomal subunits and function as stress sensors.^{36–39} Impairments in cellular homeostasis affect the overall nucleolar organization and individual nucleolar proteins.^{40,41} The transcription factor p53 is closely linked to nucleolar functions and a major indicator of stress.⁴² Additional proteins are suitable to report on nucleolar stress.^{28,43–46} In particular, nucleolin, fibrillarlin and RPA194 are nucleolar proteins that respond to environmental and other insults.³⁶

Aside from cell death, a possible consequence of stress exposure is the induction of cellular senescence.⁴⁷ Senescent cells are viable and metabolically active. However, they can damage tissues, organs, and whole organisms through the secretion of a complex mixture of factors, known as the senescence-associated secretome. Hallmarks of cellular senescence include changes in cell and nuclear morphologies as well as a profound reorganization of the cytoskeleton and nuclear lamina.^{47–49} With the possible exception of cancer cells and wound healing, the induction of cellular senescence by nanomaterials will largely be an undesired outcome. Although NPs may trigger senescence in target cells, only few studies have explored this relationship.⁵⁰

The physicochemical properties of nanomaterials are crucial for their impact on mammalian cells.⁵¹ Furthermore, the consequences of nano-bio interactions are also determined by the characteristics of the participating cells. Various biological processes determine the cell type-dependent effects of NPs. Specific examples are particle uptake, subcellular trafficking, intracellular distribution, and NP-induced toxicity. Differences in proliferation, plasma membrane composition, cytoskeletal organization, endocytosis, lysosomal and metabolic activities control cell fate upon exposure to NPs.^{52–54} In addition, the numerous cell types in the human body display profound variations in size and abundance.⁵⁵ It can therefore be expected that NP-based applications can elicit a spectrum of responses that are shaped by the specific cells that interact with the NPs.

Fig. 1 Stress pathways relevant to nano-bio interactions. Key stress responses were assessed in the current study. They include the translocation of transcription factors into the nucleus, fragmentation of the nucleolus, and the accumulation of heat shock proteins in the endoplasmic reticulum (ER) or cytoplasm.

The present study was conducted to characterize the effects of square bipyramidal UCNPs on mammalian cells. We have focused on two types of silica-coated $\text{LiYF}_4:\text{Yb}^{3+}$, Tm^{3+} UCNPs, because no data are currently available on their nano-bio interactions. In particular, information on sub-lethal effects and cellular stress responses is missing. Our research aims to provide this knowledge and uncover potential UCNP-dependent changes in the physiology of fibroblasts and renal proximal tubule cells. Long-term, these data will facilitate the production of nanomaterials that are safe for the use in living organisms.

2. Materials and methods

2.1 Materials

All reagents were used without further purification. Lithium trifluoroacetate (97%, cat. AAL1680118) was purchased from Fisher Scientific (Oakville, ON). Yb_2O_3 (99.999%), Tm_2O_3 (99.999%) were purchased from Chemicals 101 Corp. (Toronto, ON). Oleic acid (90%, technical grade, no. 364525), 1-octadecene (90% technical grade, no. O806), tetraethylorthosilicate (TEOS, 98%, reagent grade, no. 131903), ammonium hydroxide (28–30% NH_3 basis, ACS reagent, no. 221228), IGEPAL® CO-520 (M_n 441, no. 238643), trifluoroacetic acid ($\geq 99.0\%$, no. 302031), were purchased from Millipore Sigma. 3-Azidopropyltriethoxysilane (AzPTES; 97%, no. SIA0777.0) was purchased from SelectLab Chemicals GmbH (Münster, Germany). 3 mm, 300 mesh copper grids coated with 10 nm thick Formvar film and stabilized with 1 nm thick evaporated carbon film were purchased from Electron Microscopy Sciences (Hatfield, PA).

The source of primary antibodies and their dilutions for different applications are listed in Table 1. Affinity-purified secondary antibodies for immunolocalization were purchased from Jackson ImmunoResearch Laboratories, Inc. (USA). The

dilution was 1:400 for Alexa 488™ or Cy3-conjugated secondary antibodies. Affinity-purified HRP-conjugated secondary antibodies (Jackson ImmunoResearch Laboratories) were diluted 1:2000 for western blotting.

2.2 Synthesis of UCNPs

$\text{LiYF}_4:25 \text{ mol}\% \text{ Yb}^{3+}$, $0.2 \text{ mol}\% \text{ Tm}^{3+}$ UCNPs were synthesized using a one-pot thermal decomposition technique.⁵⁶ The as-synthesized NPs were coated with unfunctionalized (Si-UCNP) and azide-functionalized (AzSi-UCNP) silica through a reverse microemulsion method.⁵⁷ In a 20 mL scintillation vial, 25 mg of as-synthesized (oleate-capped) NPs were dispersed in 7 mL *n*-hexanes and sonicated for 15 min. 100 μL of IGEPAL® CO-520 was added to the dispersion, and the resulting mixture was sonicated for 5 min, followed by 10 min of stirring (1000 rpm, room temperature). 200 μL of IGEPAL® CO-520 was then added and the mixture was sonicated again for 5 min, followed by 10 min of stirring (1000 rpm, room temperature). After this, 200 μL of IGEPAL® CO-520 and 80 μL of ammonium hydroxide were added to the mixture, followed by sonication for 20 min. The mixture was then stirred (1000 rpm, room temperature) and the following steps were carried out depending on the type of coating desired. For the unfunctionalized silica coated UCNPs, 20 μL of TEOS was added in 5 μL aliquots every 30 min and stirred at room temperature for 48 hours. For the azide-functionalized silica coated UCNPs, 10 μL of TEOS was added in 5 μL aliquots every 30 min. After stirring for 24 hours, 10 μL AzPTES was added in 5 μL aliquots every 30 minutes. The mixture was then stirred for 24 hours. To purify the NPs (both coatings), the dispersions were each poured into a 15 mL centrifuge tube and 10 mL of acetone was added, followed by centrifugation at $10155\times g$ for 15 min. The supernatant was discarded, and the resulting pellet was dispersed in 2 mL deionized water. 10 mL 99% ethanol were

added to precipitate the NPs. The NPs were collected by centrifugation (10 155×g, 15 min). This process was repeated three times to purify the silica coated NPs, which were stored as a pellet in ultrapure water at room temperature.

2.3 Characterization of UCNPs

Transmission electron microscopy (TEM) images were acquired with a Thermo Scientific Talos L120C electron microscope operating at an accelerating voltage of 100 kV.

Zeta potential was measured at 25 °C using a 0.5 mg mL⁻¹ dispersion of AzSi- or Si-UCNPs in distilled water (pH 7.4) or DMEM (pH 7.4) on a Malvern Zetasizer Nano ZSM using a DTS1070 disposable folded capillary cell. Zeta potential measurements were performed under identical conditions for both samples.

Attenuated total reflectance Fourier transform infrared spectroscopy (ATR-FTIR) was performed in the solid state using a Thermo Scientific Nicolet iS5 spectrometer equipped with the iD5 accessory with a laminate-diamond crystal window. Spectra were recorded with a resolution of 0.4 cm⁻¹ and 64 scans were averaged per spectrum.

Powder X-ray diffraction was performed on a Bruker AXS D2 Phaser at a step size of 0.02° over a range of 10–65° 2θ. The spectrometer was equipped with a Cu-Kα source (λ = 1.54178 Å) operating at 30 kV and 10 mA for excitation and a Bruker LYNXEYE detector operating in θ/2θ scanning geometry.

Upconversion emission spectroscopy was performed on a 1 mg mL⁻¹ dispersion of AzSi- or Si UCNPs (2 mg mL⁻¹) in phenol red-free DMEM in a 1 cm path length quartz cuvette (Thorlabs). A handheld 976 nm diode laser (SkyLaser, 1 W, 0.450 W cm⁻²) was used to excite the NPs. The emissions were collected perpendicular to the excitation source with a 600 μm optical fiber (OceanOptics Inc.) and a 330–807 nm band pass filter (Newport Inc. 10-CLVR-3) before detection with a Princeton Instruments FERGIE BRX-VR UV-NIR spectrograph fitted with a 250 grooves per mm grating blazed at 550 nm with a 50 μm entrance slit.

2.4 Cell lines, cell culture and incubation with UCNPs

Cell lines. The mammalian fibroblast cell line NIH3T3 and porcine kidney proximal tubule cells (LLC-PK1) served as model systems for this study. NIH3T3 cells were kindly provided by Dr V. Blank, McGill University. LLC-PK1 cells were originally obtained from ATCC. Both cell lines have been used extensively to investigate the interactions with nanomaterials.^{26–29}

Cell culture and treatment. Cells were cultured following published protocols.⁵⁸ Cultures were mycoplasma-free; they were regularly tested with a commercially available kit (Applied Biological Materials, abm, Richmond, BC).

Cells were grown on poly-lysine coated coverslips or cell culture dishes as described.^{28,30} In brief, one day before the treatment, cells were seeded on coverslips or dishes and incubated under standard growth conditions (37 °C, 5% CO₂). Immediately before use, aqueous UCNP stock suspensions were sonicated (3 minutes, room temperature; Daireflow bath sonicator, PS-10A), diluted in sterile water to 1 mg mL⁻¹ and

sonicated again (2 minutes, room temperature). UCNPs were then added to the growth medium to achieve the desired final concentration. Sterile water served as vehicle control. After incubation for 24 hours, the cultures reached 60–70% confluency and were processed for immunostaining or western blotting. Except for the viability assays, the final concentration of UCNPs was 100 μg mL⁻¹ throughout the study.

For comparison with UCNP-induced stress responses, cells were treated for 1 hour with 1 mM dithiothreitol (DTT) or for 24 hours with 1 μg mL⁻¹ tunicamycin. For heat stress, cells were kept at 43 °C for 3 hours, followed by a 1 hour recovery period at 37 °C.⁵⁹

2.5 Viability assays

The procedure described in Section 2.4 was applied to grow cells in 96-well plates. Following incubation with vehicle or increasing concentrations of UCNPs, cell viability was determined with Alamar Blue (Acros), as published by us.²⁸ In brief, following treatment with UCNPs, cells were incubated with 25 μg mL⁻¹ resazurin (final concentration) under standard growth conditions. Absorbance was then measured at 570 and 600 nm with a Tecan Infinite M1000 plate reader. A minimum of three independent experiments were conducted for each UCNP concentration.

2.6 Immunofluorescence

The methods applied for immunofluorescent staining have been published earlier.²⁸ Cells grown on coverslips coated with poly-L-lysine were treated with UCNPs as described in Section 2.4. All subsequent steps were performed at room temperature. Cells were washed with PBS, fixed with 3.7% formaldehyde in PBS for 20 minutes and rinsed again with PBS. Cell membranes were permeabilized for 5 minutes (PBS, 0.1% Triton X-100, 2 mg mL⁻¹ BSA, 1 mM NaN₃), and samples were incubated for 1 hour with blocking buffer (PBS, 0.05% Tween 20, 5% bovine calf serum, 1 mM NaN₃). Primary antibodies diluted in blocking buffer were added overnight. After washing with blocking buffer (three times, 5 minutes per wash), fluorescently labelled secondary antibodies were diluted in blocking buffer and added for 2 hours. Coverslips were washed again, and DNA was stained with 4',6-diamidino-2-phenylindole (1 μg mL⁻¹ in blocking buffer, 2 minutes). Coverslips were mounted on slides and sealed. Control samples were incubated under identical conditions, but in the absence of primary antibodies. For the visualization of microtubules in fibroblasts with antibodies against α-tubulin, cells were fixed with methanol, following published protocols.³⁰ The source and dilutions of antibodies are depicted in Table 1.

2.7 Microscopy and image analysis

The imaging protocols for UCNPs have been described earlier.^{28,46} A Zeiss LSM780 confocal microscope, equipped with an IR-OPO laser was used to image UCNPs after excitation at 976 nm. To evaluate biomarkers by immunostaining, imaging was performed with a Nikon Optiphot or Nikon Eclipse microscope equipped with a 40× objective. For individual data sets, all images were acquired with identical settings. Image analysis was conducted with ImageJ for at least 30 cells per condition and for each data set. In brief,

following background correction, pixel intensities were measured for the regions of interest, and the pixel intensity/area was calculated. Bar graphs depict the results of at least three independent experiments; details are specified in the figure legends.

2.8 Western blotting

The generation of crude cell extracts, western blotting, and enhanced chemiluminescence followed published protocols.^{28,50} Cells were grown in culture dishes and treated with UCNPs as described in Section 2.4. After incubation with or without UCNPs, dishes were washed twice with PBS. Dishes were stored at -70°C . For the preparation of crude extracts, samples were suspended in 0.5-fold concentrated gel sample buffer, collected into Eppendorf tubes and incubated for 15 minutes at 95°C . Following vortexing with 0.5 mm zirconia/silica beads (3 minutes, room temperature), samples were centrifuged for 5 minutes at $15\,871\times g$. Trichloroacetic acid was added to supernatants to a final concentration of 10% (w/v), and samples were kept for 20 minutes on ice. Sediments were collected by centrifugation (2 minutes, $15\,871\times g$) and resuspended in 2-fold concentrated gel sample buffer, pH 8, supplemented with protease and phosphatase inhibitors. Aliquots of the crude extracts were separated by SDS-PAGE on gradient polyacrylamide gels. Primary antibodies and their dilutions are listed in Table 1. Raw data files for western blots are provided in the ESI.†

2.9 Statistical evaluation

Bar graphs for western blotting and image analyses represent the averages of results obtained for at least three independent experiments \pm standard error of the means (SEM). Statistical evaluation was performed with a two-tailed Student's *t*-test for the comparison of two groups. More than two groups were compared with one-way ANOVA combined with Bonferroni correction. All figures show pairwise comparisons between the vehicle control and the treated sample. Significant differences are indicated as follows: *, $p < 0.05$; **, $p < 0.01$, and ***, $p < 0.001$.

Significant differences between Si-UCNPs and AzSi-UCNPs are marked with #, $p < 0.05$; ##, $p < 0.01$.

3. Results and discussion

The current study was conducted to determine the physicochemical properties of Si-UCNPs and AzSi-UCNPs and measure

Fig. 2 Characterization of Si-UCNP and AzSi-UCNP. (a) Representative transmission electron microscopy images of UCNPs used in this study. The average thickness of the shell at the edge (magenta) and apex (green) is depicted in nm. Scale bars are 200 nm. (b) Si-UCNP and AzSi-UCNP have comparable properties related to the particle width, length, and thickness of the silica shell at the apex and side. (c) Upconversion emission spectra (2 mg mL^{-1} UCNPs in phenol red-free DMEM) of Si-UCNPs (red trace) and AzSi-UCNPs (black trace) upon excitation at 976 nm. AU, arbitrary units. Additional details on particle properties are listed in Table 2.

Table 2 Summary of UCNP physicochemical properties

Parameter	Si-UCNP	AzSi-UCNP
Host matrix		LiYF_4
Sensitizer		25 mol% Yb^{3+}
Activator		0.2 mol% Tm^{3+}
Morphology		Square bipyramidal
Coating	Unfunctionalized silica	Azide-functionalized silica
Core size; length [nm]	98.3 ± 6.5	98.3 ± 6.5
Core size; width [nm]	52.3 ± 4.3	52.3 ± 4.3
Size + shell, length [nm]	109.5 ± 7.0	111.2 ± 6.8
Size + shell, width [nm]	71.6 ± 4.8	73.0 ± 5.9
Shell thickness at edge [nm]	10.2 ± 1.1	10.4 ± 1.4
Shell thickness at apex [nm]	5.4 ± 1.0	5.5 ± 0.9
Zeta potential in water, 0.5 mg mL^{-1} Ln-UCNP [mV]	-11.5 ± 2.3	-16.3 ± 0.4
Zeta potential in DMEM, 0.5 mg mL^{-1} [mV]	-4.1 ± 0.1	-9.0 ± 0.5

their impact on mammalian cell physiology. The potential effects of the azide group on the NP surface is of particular interest, as it can be used to covalently attach therapeutic or other molecules to the NP surface.

3.1 Physicochemical properties of UCNPs

Transmission electron microscopy shows the square bipyramidal morphology of UCNPs with an average core length of 98.3 ± 6.5 nm (Table 2, Fig. 2). Powder X-ray diffraction confirmed the expected tetragonal crystal phase of the UCNPs (Fig. S1a†). ATR-FTIR confirms the presence of the pendant azide groups on AzSi-UCNPs (2100 cm^{-1} , N–N stretch) and the silica coating on both AzSi- and Si-UCNPs as evidenced by the bands centered at 1000 cm^{-1} (Si–O stretch; Fig. S1b†).

The zeta potentials of Si-UCNP and AzSi-UCNP in distilled water at physiological pH were -11.5 ± 2.3 mV and $-16.3 \pm$

0.4 mV, respectively. This agrees with our previously reported values and the intrinsic negative charge of silica.^{60,61} Azide-functionalized silica produces a more negative surface charge due to the negative charge on the terminal nitrogen atoms in the azide groups.⁶² In cell culture medium (DMEM), the surface charges of both NPs were reduced to -4.1 ± 0.1 mV for Si-UCNPs and -9.0 ± 0.5 mV for AzSi-UCNPs. This can be attributed to the electrostatic coordination of cations present in DMEM to the surface of the NPs. Following illumination with infrared light at 976 nm, UCNPs emit light at different wavelengths (Fig. 2c). This property was used to visualize the uptake of UCNPs by mammalian cells (see below).

3.2 Effect of UCNPs on cell viability

For simplicity, we refer to Si-UCNP or AzSi-UCNP collectively as “UCNPs” throughout the text. If results differ for Si-UCNP or AzSi-

Fig. 3 Effects of UCNPs on the viability of NIH3T3 fibroblasts and LLC-PK1 cells. Cells were incubated for 24 hours with increasing concentrations of UCNPs as specified in the figure. The left side depicts results for NIH3T3 fibroblasts; the right side shows data for LLC-PK1 cells. Western blots assessed the possible loss of PARP1 in UCNPs-treated cells. The molecular mass of marker proteins is shown in kD at the right margin of the blots. Bar graphs represent averages \pm SEM for at least three independent experiments. Results were normalized to control samples incubated with vehicle. Graphs show the ratio of PARP1/actin. (Black circles represent individual data points). Statistical evaluation was performed with one-way ANOVA and Bonferroni *post hoc* correction; **, $p < 0.01$. AU, arbitrary units.

UCNP, they are described separately. A first set of experiments determined whether UCNP alter the viability of NIH3T3 or LLC-PK1 cells. To this end, chromogenic assays monitored the performance of mitochondria. After a 24 hour incubation period with a wide range of concentrations (final concentration 0 to 100 $\mu\text{g mL}^{-1}$), no significant changes in cell viability were detected (Fig. 3). When the incubation period was extended to 3 or 5 days, the viability was significantly reduced with high UCNP concentrations for NIH3T3 fibroblasts, but not for LLC-PK1 cells (Fig. S2†).

Independent evidence for the lack of cell death after 24 hour incubation with UCNP was obtained by western blot analyses of PARP1. Apoptosis is associated with PARP1 cleavage,⁶³ which leads to a loss of full-length PARP1. However, UCNP did not profoundly alter PARP1 abundance in fibroblasts or renal proximal tubule cells (Fig. 3). On the other hand, PARP1 abundance was significantly reduced with other stressors (Fig. S3†).

Taken together, data in Fig. 3 demonstrate that 24 hour treatment with Si-UCNPs and AzSi-UCNPs has no or negligible toxicity in cell lines of different origins. As many NPs are rapidly cleared in living organisms,⁶⁴ subsequent experiments were conducted for a 24 hour incubation period.

3.3 Cellular uptake of UCNP

The lack of cellular toxicity of Si-UCNPs and AzSi-UCNPs may be explained by their failure to interact with cells. To address this point, we conducted imaging experiments that simultaneously detect UCNP and the protein ZO-1. ZO-1 is a peripheral membrane protein that is concentrated at cell–cell junctions.⁶⁵ In fibroblasts, a pool of ZO-1 is also present in intracellular locations.⁶⁶ ZO-1 was used to delimit LLC-PK1 and NIH3T3 cells, because the selected antibody is suitable for immunostaining in different cell lines. While the staining patterns for ZO-1 may differ in epithelial and non-epithelial cells,⁶⁷ the method clearly demarcated renal proximal epithelial cells and fibroblasts. The presence of ZO-1 in the nucleus is consistent with previous reports, which suggest a role for zonula occludens proteins, including ZO-1, in cell nuclei.^{68,69}

As shown in Fig. 4, Si-UCNPs and AzSi-UCNPs associated with NIH3T3 and LLC-PK1 cells. Notably, the Si-UCNPs and AzSi-UCNPs exhibit luminescence upon 976 nm excitation, enabling direct identification of UCNP within the cells. The cyan signals observed in Fig. 4 are attributed to the $^1\text{G}_4 \rightarrow ^3\text{H}_6$ transition of Tm^{3+} . A portion of the internalized UCNP formed agglomerates that were composed of multiple UCNP and thus are easily detectable by confocal microscopy. These agglomerates predominantly resided in the cytoplasm of cells. No signals were seen in the channel used to detect UCNP when cells were incubated with medium only (Fig. S4†). Collectively, results in Fig. 4 demonstrate UCNP uptake by fibroblasts and renal proximal tubule cells. At the same time, the particles had only minimal effects on cell viability, emphasizing that UCNP internalization does not trigger rapid cell death (Fig. 3).

3.4 Effects of UCNP on nuclear lamins and cytoplasmic microtubules

The nuclear envelope maintains cellular homeostasis by separating the nucleoplasm from the cytoplasm. Proteins of the nuclear

Fig. 4 UCNP uptake by fibroblasts and renal proximal tubule cells. NIH3T3 fibroblasts and LLC-PK1 cells were incubated for 24 hours with 100 $\mu\text{g mL}^{-1}$ Si-UCNPs or AzSi-UCNPs. After fixation, cell borders were demarcated with antibodies against ZO-1. Images were acquired as described earlier.⁴⁶ Scale bar is 20 μm .

envelope, especially nuclear lamins, preserve the shape and integrity of the nucleus.⁷⁰ Changes in the distribution and abundance of lamin A and B are linked to stress and senescence.⁷¹ The nuclear envelope is connected to filament systems in the cytoplasm. This connection supports the communication between the nucleoskeleton and cytoplasmic microtubules.⁷⁰ Together, nuclear and cytoplasmic filament systems regulate cell shape and size. Relevant to the potential impact of nanomaterials, cell and nuclear size increase in senescent cells.⁴⁸ By contrast, cell shrinkage and pyknotic nuclei are key features of apoptotic cells.^{72,73}

Common to both NIH3T3 and LLC-PK1 cells, UCNP diminished the abundance of full-length lamin B, and this effect was more pronounced for AzSi-UCNPs (Fig. 5b). Interestingly, the immunolocalization studies did not fully recapitulate these differences. It is possible that proteolytic products of lamin B contributed to the pixel intensities measured in Fig. 5a.

The UCNP-dependent loss of full-length lamin B may suggest that senescence was triggered in a subpopulation of cells. However, UCNP did not affect the size or morphology of cells or nuclei (Fig. S5† and 5a). As well, there was no significant change in the ratio of nuclear area/cytoplasmic area (Fig. S5†). Furthermore, our experiments did not uncover cell shrinkage or the accumulation of cells with pyknotic nuclei. These results support the idea that a 24 hour UCNP treatment did not cause cellular senescence or apoptosis at detectable levels.

Fig. 5 Effects of UCNP treatments on nuclear lamins and on α -tubulin. NIH3T3 or LLC-PK1 cells were incubated for 24 hours with vehicle, $100 \mu\text{g mL}^{-1}$ Si-UCNP or AzSi-UCNPs. (a) The distribution of lamin A, lamin B or α -tubulin was monitored by immunolocalization. Images were acquired and the pixel intensities in the whole cell and in the nucleus were quantified for three independent experiments (see Materials and methods for details). All scale bars are $20 \mu\text{m}$. (b) The abundance of lamin A, lamin B and α -tubulin was measured for at least three independent experiments. Results were normalized to vehicle controls. Graphs depict the ratio of the protein of interest/actin. (a and b) One-way ANOVA combined with Bonferroni *post hoc* correction identified significant differences between the vehicle control and individual treatment groups; *, $p < 0.05$; **, $p < 0.01$; ***, $p < 0.001$. Significant differences between Si-UCNPs and AzSi-UCNPs are marked with #, $p < 0.05$; ##, $p < 0.01$. AU, arbitrary units.

3.5 Impact of UCNP treatments on Nrf2 and NF κ B; GAPDH, biomarkers of oxidative stress

Nrf2 and NF κ B are among the first cellular responders to oxidant exposure.^{74,75} Both transcription factors accumulate in the nucleus when cells are stressed.⁷⁶ As part of the cellular

antioxidant defense reaction, Nrf2 also increases in abundance.⁷⁷ GAPDH is a marker of oxidative stress;⁷⁸ GAPDH levels diminish when cells enter senescence.⁴⁸ On the other hand, proapoptotic conditions upregulate GAPDH, at least in cancer cells.⁷⁹

Fig. 6 evaluates the effects of UCNPs on Nrf2, NFκB and GAPDH in NIH3T3 and LLC-PK1 cells. Nrf2 was in the nucleus and cytoplasm of fibroblasts, but mostly nuclear in renal proximal tubule cells. Quantification of the fluorescence intensities in the whole cell, nucleus, and cytoplasm revealed that UCNPs did not induce significant changes in the nucleocytoplasmic distribution of Nrf2 or NFκB (Fig. 6a). Moreover, no significant differences were revealed for the abundance of Nrf2 or NFκB (Fig. 6b). Si-UCNPs reduced the levels of GAPDH in NIH3T3 cells, but had no impact on LLC-PK1 cells.

As reference for the responses triggered by UCNPs, we conducted control experiments with established stressors. As such, cells were exposed to heat, DTT or tunicamycin and the abundance of Nrf2 was quantified (Fig. S6†). Heat stress induces the production of heat shock proteins, especially members of the hsp70 family.⁸⁰ DTT causes reductive stress, while tunicamycin interferes with protein glycosylation in the endoplasmic reticulum (ER). Both agents trigger an unfolded protein response (UPR) in the ER.⁸¹

Notably, several forms of stress elevated the levels of Nrf2 in fibroblasts and LLC-PK1 cells, and DTT induced the accumulation of NFκB in nuclei of renal proximal tubule cells (Fig. S7†). As well, tunicamycin significantly diminished GAPDH abundance in NIH3T3 cells; the tunicamycin-dependent loss exceeded the changes observed for Si-UCNPs (Fig. S6†). GAPDH levels in LLC-PK1 cells were not altered by the incubation with UCNPs or tunicamycin (Fig. 6 and S6†). These data highlight that cells of different origins vary in their responses to UCNPs.

Taken together, the results for key transcription factors and GAPDH support the idea that Si-UCNPs or AzSi-UCNPs elicited only minor stress or pro-inflammatory responses. By contrast, established stressors triggered marked changes in both fibroblasts and renal proximal tubule cells.

3.6 Evaluation of nucleolar stress in UCNP-treated cells

Nucleoli produce ribosomal subunits, serve as stress sensors, control apoptosis and cellular senescence. The transcription factor p53 is closely linked to nucleolar function and cellular

Fig. 6 Impact of UCNPs on markers of oxidative stress and inflammation. Biomarker distribution and abundance were quantified for UCNP-treated cells as in Fig. 5. (a) Immunolocalization of Nrf2 and NFκB. Scale bar is 20 μm. (b) Western blot analyses for Nrf2, NFκB, and GAPDH. Graphs represent the ratio of the protein of interest/actin. (a and b) Statistical evaluation was conducted as described for Fig. 5; *, $p < 0.05$; **, $p < 0.01$. Significant differences between Si-UCNPs and AzSi-UCNPs are marked with #, $p < 0.05$. AU, arbitrary units.

Fig. 7 Effect of UCNPs on nucleolar proteins and p53. Immunofluorescence, western blotting and statistical evaluation were conducted as described for Fig. 5. (a) Immunolocalization of RPA194, fibrillarin, and nucleolin. Scale bar is 20 μm . (b) Western blot analyses of p53, RPA194, fibrillarin, and nucleolin. Graphs show the ratio of the protein of interest/actin. Statistically significant differences are marked with *, $p < 0.05$; ***, $p < 0.001$. Significant differences between Si-UCNPs and AzSi-UCNPs are marked with #, $p < 0.05$. AU, arbitrary units.

senescence; p53 provides a stress marker that is stabilized when nucleolar functions derail.^{42,82}

Nucleolar activities are determined by the proper organization into nucleolar subcompartments.⁴¹ To examine this aspect of cellular homeostasis, we evaluated three biomarkers that report on the spatial organization of nucleoli, RPA194,

nucleolin, and fibrillarin. RPA194 is a subunit of RNA polymerase I, which transcribes ribosomal RNA genes; nucleolin participates in rDNA transcription, rRNA maturation, and ribosome assembly; fibrillarin acts as rRNA 2'-O-methyltransferase.^{36,83}

The subcellular localization of RPA194, nucleolin, and fibrillarin did not profoundly alter when cells were incubated with UCNPs (Fig. 7a). By contrast, other conditions, such as pharmacological agents, cause significant changes in the distribution of nucleolar proteins in NIH3T3 and LLC-PK1 cells.^{84,85}

While UCNPs did not trigger a re-organization of nucleoli, they modified the abundance of nucleolin. Interestingly, UCNPs reduced nucleolin abundance in fibroblasts, but had the opposite effect in LLC-PK1 cells (Fig. 7b). By contrast, the levels of p53 did not significantly increase upon UCNP treatment. (The apparent molecular mass of “p53” detected in LLC-PK1 cells was >75kD. The same apparent molecular mass was observed for two different antibodies against p53, which were generated in different species). Collectively, our data support the hypothesis that UCNPs did not compromise the organization of nucleoli.

3.7 UCNPs modulate selected components of the stress and proteostasis network

Several signaling pathways and chaperones ensure that cells adjust to environmental and other insults, including the exposure to nanomaterials. Our earlier work demonstrated that certain NPs alter the abundance of the chaperone hsp70.⁴⁶

Therefore, upregulation of heat shock proteins is a potential outcome of nano–bio interactions. Like heat shock proteins, the AAA⁺ ATPase valosin-containing protein (VCP) functions as a pillar of the proteostasis network. VCP dismantles protein aggregates and thereby maintains cell health under normal and stress conditions.⁸⁶ Control experiments were conducted with DTT, tunicamycin or heat shock to compare the severity of changes elicited by UCNPs and established stressors (Fig. S6†).

Consistent with a stress response, UCNPs stimulated the phosphorylation of eIF2 α in fibroblasts (Fig. 8). Nevertheless, the changes were minor when compared to heat shock (Fig. S6†). UCNPs also increased the abundance of hsp70 in NIH3T3 cells, but to a lesser extent than heat stress.⁵⁹ Notably, UCNPs had only marginal effects on the proteostasis network in renal proximal tubule cells. By contrast, conventional types of stress, such as tunicamycin, markedly increased the ER chaperones Grp78 and Grp94 (Fig. S6†). A striking difference between UCNPs and conventional forms of stress was also observed for the transcription factor CHOP (Fig. S6†). While CHOP levels were low in control and UCNP-treated samples, DTT markedly increased its abundance. As CHOP promotes apoptosis when ER stress is severe, the data confirm that cell viability was not compromised after 24 hours of UCNP incubation. Moreover, no significant changes were observed for the

Fig. 8 UCNP-mediated changes to the proteostasis network. Key components of the proteostasis network were analyzed in NIH3T3 and LLC-PK1 cells. Western blotting and statistical evaluation were carried out as described for Fig. 5b. Except for p-/t-eIF2 α , all graphs represent the ratio of the protein of interest/actin. Comparison with vehicle controls revealed significant differences for UCNP-treated samples; *, $p < 0.05$; ***, $p < 0.001$. Significant differences between Si-UCNPs and AzSi-UCNPs are marked with #, $p < 0.05$; ##, $p < 0.01$. AU, arbitrary units. The cartoon depicts essential elements of the proteostasis network.

Table 3 Effects of Si-UCNPs or AzSi-UCNPs on the abundance of protein biomarkers. Results are summarized for 24 hours UCNP treatments. The changes in protein levels relative to the vehicle controls are depicted. ↔, no or minor change, abundance ≤ 20% reduced or increased compared to control; ↓, reduction to 60–79%; ↓↓, reduction to less than 60%; ↑, increase to 121–140%; ↑↑, increase to more than 140%

Protein	NIH3T3 cells		LLC-PK1 cells	
	Si-UCNPs	AzSi-UCNPs	Si-UCNPs	AzSi-UCNPs

abundance of VCP. These results further emphasize the low toxicity of UCNPs detected by other assays (Fig. 3).

4. Conclusions

The current study was conducted to provide a better understanding of the biological effects elicited by Si-UCNPs and AzSi-UCNPs. These are mandatory steps to assess their safety in biological environments. To achieve this, we performed a rigorous evaluation of cell viability and a panel of stress biomarkers in fibroblasts and renal proximal tubule cells. Our insights are promising for the future development of UCNP-based applications. Neither Si-UCNPs nor AzSi-UCNPs caused immediate toxicity in cell types that are known targets of NPs. Under the experimental conditions examined, the overall impact of UCNPs on cellular homeostasis was mild (summarized in Table 3). These results are especially striking, as the azide surface modification of AzSi-UCNPs did not diminish cell viability after a 24 hour incubation period.

Notably, we demonstrate that the response to UCNPs varies remarkably among non-malignant cells. Cell type-specific differences are the simplest explanation for these diverse responses. Such cell type-dependent reactions to nanomaterials are consistent with published observations.^{52–54} In our study, UCNPs elicited less pronounced changes to the proteostasis network in renal proximal tubule cells than in fibroblasts. The kidney is frequently exposed to stressful conditions, even in healthy organisms.⁸⁷ This may limit the effects of exogenous stressors on kidney cells. Thus, the high abundance of

molecular chaperones, such as Grp94,⁸⁸ in renal proximal tubule cells may protect against UCNP-mediated stress in LLC-PK1 cells, but could require an upregulation in fibroblasts.

Our study generated additional support for the hypothesis that NPs cause cell type-specific changes in cell physiology. While we did not uncover a marked re-organization of the microtubule cytoskeleton, AzSi-UCNPs led to a significant increase in α-tubulin in renal proximal tubule cells, but not in fibroblasts. This outcome is consistent with the distinct NP-induced effects on the cytoskeleton of epithelial cells and fibroblasts.⁵⁴

We also observed a striking difference for the UCNP-dependent changes in nucleolin levels. Nucleolin levels were reduced by UCNPs in fibroblasts, but increased in LLC-PK1 cells. Nucleolin is a multitasking protein that binds RNA, serves as histone chaperone, contributes to the processing of ribosomal RNA, and plays a role in chromatin remodeling.³⁷ This nucleolar protein is highly abundant, both in human fibroblasts and renal proximal tubule cells.⁸⁸ At present, it is unclear why UCNPs have opposite effects on nucleolin abundance in NIH3T3 and LLC-PK1 cells. Future experiments will have to address this topic.

Despite the differences described above, a partial loss of the nuclear envelope protein lamin B was a common denominator for the effects of Si-UCNPs and AzSi-UCNPs in fibroblasts and renal proximal tubule cells (Table 3). The molecular mechanisms underlying the diminished lamin B abundance are presently not known. B-type lamins are linked to DNA replication, DNA repair, chromatin organization, nuclear stiffness, and cellular senescence.⁸⁹ Thus, lamin B should be included in future studies that investigate nano-bio interactions. Our results also emphasize the importance of testing cells of different origins to define the UCNP-dependent changes in cellular homeostasis that are directly pertinent to their biological applications.
