# Insights into the optoelectronic behaviour of heteroatom doped diamond-shaped graphene quantum dots

Yassine El Haddad,<sup>ab</sup> Hala Ouarrad<sup>ab</sup> and Lalla Btissam Drissi<sup>abc</sup>

In this study we aim to manipulate the optoelectronic and photoluminescence properties of diamond-shaped graphene quantum dots (DSGQDs) in order to make them suitable for solar cells and photovoltaic devices. Using DFT and performing many-body effects studies, we investigate the impact of N, B, O, P and S heteroatom doping on DSGQDs in three different positions, namely the zigzag edge, the armchair corner and the surface, in order to identify the most appropriate and promising configurations. All the doped GQDs are found to be chemically stable making it possible to realize them experimentally. Additionally, the obtained results show that substitution with heteroatoms has a remarkable effect on the electronic energy gap, noticeably decreasing it. Doping also has a significant effect on the optical response by shifting the absorption peaks towards the visible energy range. The excitonic behaviour has revealed that these nanostructures are potential candidates for photovoltaic devices. One can deduce that doping DSGQDs with heteroatoms is useful and promising for the targeted applications.

## 1. Introduction

Since the first exfoliation of a 2D graphene monolayer in 2004,<sup>1</sup> this hexagonal lattice of carbon atoms has received a lot of attention from scientists for its excellent properties,<sup>2</sup> in particular, the charge carriers of graphene that can reach very high mobility values,<sup>3,4</sup> the high thermal and chemical stability,<sup>5</sup> the excellent optical transparency,<sup>6</sup> its absorption in a very wide energy range,<sup>7</sup> the low resistivity and the high mechanical strength.<sup>8</sup> Graphene is interesting for photonics,<sup>9</sup> microelectronics, in particular for the production of transistors,<sup>10</sup> and so on. However, it is a zero gap semi-conductor,<sup>11</sup> which reduces its application in optoelectronics.<sup>12</sup>

Many promising strategies, have been introduced to create a band gap in graphene-based materials, including the addition of a transverse electric field, surface chemical functionalization and the hybridization between atoms.<sup>13–15</sup> Another strategy consists of quantum confinement of electrons along the armchair and zigzag edges by producing 1D graphene-nanoribbons<sup>16</sup> or 0D graphene quantum dots (GQDs) which is the subject of the present work. To manufacture GQDs, two main

approaches have been adopted:<sup>17–20</sup> namely the top-down method which relies on cutting macroscale systems, such as graphite, carbon black or carbon fibers, to obtain nanoscale quantum dots; and the bottom-up approach based on organic chemistry, which aims to generate GQDs from small-scale systems to a larger one. GQDs are therefore small fragments of graphene having excellent and tunable features, namely gap energy, optical absorption, photoluminescence and quantum confinement effects.<sup>21,22</sup> These excellent properties make these zero-dimensional nanostructures more attractive for optical and optoelectrical devices used in industrial and medical fields, such as, photovoltaic devices, catalysis (electrocatalysis, photocatalysis) bio-imaging, medical diagnosis.<sup>23</sup> Several experimental and theoretical studies have shown that it is possible to control and enhance the optical and electronic properties of GQDs through the adjustment of size,<sup>24</sup> edge configuration,<sup>25</sup> shape,<sup>26</sup> chemical functionalities,<sup>27</sup> heteroatom doping<sup>28</sup> and defects<sup>29</sup> for desired and specific applications.

Interestingly, heteroatoms doping of 5 to 10 nm diameter GQDs, like nitrogen (N), has been successfully done using high-yield hydrothermal methods.<sup>30</sup> The resulting circular structures (N-GQDs) emit a strong blue emission under 365 nm UV light excitation and exhibit a high fluorescence quantum yield up to 75.2%, which is close to the conventional semiconductor QDs. Consequently, these high-yield N-GQDs seem to be promising for new avenues in the field of cell labelling, bioimaging and environmental detection.<sup>30</sup> In the same context, a hydrothermal approach has been developed for the synthesis of N-GQDs of about (1–7 nm) in diameter and a ratio atomic N/C of 5.6%,

which are characterized by bright blue photoluminescence and excellent up-conversion luminescence properties.<sup>31</sup> Otherwise, the theoretical study<sup>32</sup> on N-doping circular graphene quantum dots with a diameter ranging from 1 to 5 nm, reveals that nitrogen edge doping improves the fluorescence properties of GQDs compared to non-doped structure, and causes a blue or red shift in the absorption and emission spectra depending on the hybridization of the boundary orbitals. It was also shown that the effect of N-doping is related to the different N-doping pattern and positions, namely pyrazole, pyridazine, graphitic, pyridinic at center or edge, pyrrolic at center or edge, amido at center or edge.

Other types of substituent have also been investigated. Sulfur doped GQDs (S-GQDs), with a spherical shape and an average diameter of 2.46 nm, have been synthesized by the co-combustion method (TXJ method) of a liquid mixture of paraffin oil and sulfide of carbon (CS<sub>2</sub>) as a source of carbon and sulfur. These nanostructures show a blue shift of the absorption peaks compared to the non-doped GQDs, which indicates an increment in the absorption of the S-GQDs in the ultraviolet-visible region.<sup>33</sup> Besides, round-shaped sulfur-doped GQDs with a relatively uniform size of about 5.2 nm have been prepared *via* a hydrothermal process using fructose and sulfuric acid as the raw materials. They can emit a variety of colors, covering most colors in the visible light region, compared to pristine GQDs which have only two absorption peaks centred at 228 and 282 nm.<sup>34</sup> Similarly, S-GQDs with a narrow size distribution of about 3 nm and with phenolic hydroxyl decorated edges, synthesized by the top-down method from the graphite quantum dots based on sulfur-doped graphene, have shown blue-green fluorescence and improved electronic properties compared to non-doped GQDs, which renders S-GQDs potential candidates for a fluorescent probe for the detection of Fe<sup>3+</sup> ions.<sup>35</sup>

Phosphorus-doped graphene quantum dots (P-GQD), characterized by their excellent monodispersity, a spherical shape and a small and narrow size distribution mostly in the range 2 to 4 nm, have been synthesized *via* a bottom-up electrochemical approach with a high P/C ratio; showing excellent ability to scavenge free radicals and several potential uses in biotechnology and medicine.<sup>36</sup> Likewise, P-GQDs have also been prepared with different concentrations of emission wavelengths (457–632 nm) and high quantum efficiency (0.54–0.73) for application in bioimaging.<sup>37</sup> Furthermore, oxygen doping is typically studied using specifically engineered GQDs that inherently contain oxygen-rich chemical groups capable of altering the electronic characteristics of the GQDs. Indeed, O-rich groups make an important contribution in observing blue shifted absorption peaks in the photoluminescence emission of experimentally synthesized N-GQDs due to the localization of electron–hole pairs, which gives GQDs excellent hydrophilicity, unique optical performance, favourable biocompatibility and no toxicity.<sup>38</sup> Furthermore, an electrochemical method was adapted to synthesize functional GQDs characterized with a uniform size of 3–5 nm and exhibiting a green luminescence.<sup>39</sup> These structures have O-containing groups on the surface which makes them soluble in aqueous

media and suitable for functionalization and various applications such as lasing, and light emitting diodes.

Inspired by all of these experimental works exploring the effect of heteroatoms on the optoelectronic properties of GQDs, we aim to examine how heteroatoms impact the physical properties of diamond-shaped graphene quantum dots (DSGQDs), which we have previously investigated and found to exhibit strong stability alongside intriguing structural and electronic characteristics. Furthermore, DSGQDs display significant absorption and photoluminescence properties in both the visible and infrared regions of the solar spectrum, making them highly relevant for various applications. In this study, our objectives are twofold: (i) investigate the impact of heteroatom doping—employing N, B, O, P, and S heteroatoms—on the optoelectronic properties of DSGQDs. These DSGQDs possess a distinctive diamond shape characterized by zigzag edges and armchair corners connected by a seam atom. Our focus is to uncover the fundamental alterations induced by heteroatom doping in these properties. (ii) Explore the potential utilization of heteroatom-doped DSGQDs across various fields, including optoelectronics and photovoltaics. Specifically, we aim to explore their applicability in devices such as light-emitting diodes (LEDs) and solar cells. Additionally, we aim to investigate their potential in nanomedical applications, particularly in diagnostic devices and drug delivery systems, as well as their suitability for use in energy storage and conversion technologies. Based on our previous publications,<sup>51–55</sup> the shape of DSGQDs was found to have a considerable effect on the optoelectronic, excitonic and photoluminescence behaviours, especially upon functionalization. So exploiting these findings, we focus on studying the special response of DS nanostructures to the heteroatom doping process and its associated factors as a function of the type and position of five dopants, including zigzag or armchair corners, or inside the surface. Notice that the choice of these five heteroatoms is mainly for their nanomedical and safety use as proven in experimental works cited in previous sections. To do so, three different doping configurations are modelled and investigated for each heteroatom. Our findings have shown, among others, that the heteroatom doping has noticeably affected the electronic energy gap as well as the absorption character of pristine GQDs through shifting the absorption peaks towards smaller energy ranges. All these findings elect the heteroatom doping process as a useful strategy to adjust the GQDs behaviour and to tune the absorption and the photoluminescence of GQDs, making them promising for photovoltaic devices and nanomedical applications.

This paper is organised as follows, we start by detailing the computational method used for performing our calculations, then we report the findings and discuss the obtained results in the next section. We summarize with a conclusion.

## II. Computational details

We aim in this work, to determine the electronic and optical properties of our graphene-based quantum dot structures. The numerical simulation procedures that we used are the

following. First, we performed geometry optimization and ground state calculation using density functional theory (DFT) with a plane wave approach in the generalized gradient approximation (GGA) with a Perdew–Burke–Ernzerhof (PBE) exchange-correlation function,<sup>41</sup> implemented in the quantum espresso (QE) simulation package.<sup>42</sup> We used conserved norm pseudo-potentials and a set of plane wave bases with a kinetic energy cutoff of 60 Ry. In order to avoid non-physical interactions between periodic images in the study of isolated systems, a 20 Å vacuum is used in all three dimensions. To build the dielectric matrix and Green's function, we used a total of 600 bands for all structures. In all the calculations, a single gamma point is taken into account due to the zero-dimensional character of the structures considered. The considered configurations are totally optimized under stresses and forces until the components of all the forces are lower than  $10^{-3}$  eV.

In the second step of simulation, we ensure precise quasi-particle energies by utilizing the many-body perturbation theory (MBPT) within the GW approximation. This method relies on the Green's function ( $G$ ) and the projected Coulomb interaction ( $W$ ).<sup>41</sup> Our calculations are carried out using the Yambo code.<sup>44</sup> The quasiparticle (QP) corrections to the GGA eigenvalues are determined using the followed equation:

$$E_{nk}^{\text{QP}} = E_{\text{KS}}^{\text{QP}} + \langle \Psi_{nk} | \sum (E_{nk}^{\text{QP}}) - V_{xc}^{\text{KS}} | \Psi_{nk} \rangle \quad (1)$$

where  $\langle \Psi_{nk} |$  is the wave-function,  $E_{\text{KS}}^{\text{QP}}$  the Kohn–Sham (KS) energy,  $V_{xc}^{\text{KS}}$  the exchange-correlation potential and  $\sum (E_{nk}^{\text{QP}})$  is the self-energy operator.

Moreover, we studied the optical behaviour of the structures by solving the Bethe–Salpeter equation (BSE) combined with the GW method. It is generally rated GW + ESB.

We studied the excitonic properties using the Bethe–Salpeter (BSE) equation:

$$(E_{ck}^{\text{QP}} - E_{vk}^{\text{QP}}) A_{vck}^S + \sum_{k'c'v'} \langle vck | \Xi_{e-h} | v'c'k' \rangle A_{v'c'k'}^S = \Omega^S A_{vck}^S \quad (2)$$

where  $\Xi_{e-h}$  is the electron-hole interaction kernel,  $\Omega^S$  the excitation energy and  $A_{vck}^S$  is the exciton amplitudes.

Charge-transfer is calculated using Bader analysis.<sup>43</sup>

### III. Results and discussion

In this work, we study the effect of heteroatom dopants on the electronic and optical properties of graphene-based quantum dots ( $\text{C}_{30}\text{H}_{14}$ ). For this, the five dopants  $X = \text{B}, \text{N}, \text{O}, \text{S}, \text{and P}$ , are used since they are the most commonly used in literature for the intended applications mentioned above.

#### A. Structural properties

We focus on a graphene-based quantum dot ( $\text{C}_{30}\text{H}_{14}$ ) containing a total of 44 atoms of which 30 are carbon atoms forming the core while 14 are hydrogen atoms passivating the QD edges; the bonds hanging from the edge are attached to hydrogen atoms in order to guarantee the good stability of our structure.<sup>51,52,58,59</sup> Successfully fabricated, these QDs, referred to as dibenzo[*bc,kl*]coronene, combine between zigzag edges and

armchair corners,<sup>45–48</sup> and the carbon atoms in the ring structure are  $\text{sp}^2$  hybridized leading to a planar geometry.<sup>51</sup> The GQD- $\text{C}_{30}\text{H}_{14}$  structure is considered as the most appropriate configuration to be doped among its counterparts discussed in our earlier works, notably pyrene with 16 carbon atoms ( $\text{C}_{16}\text{H}_{10}$ ) and  $\text{C}_{48}\text{H}_{18}$  QDs do not yet have a suitable synthesis route.<sup>52,53</sup> Furthermore, dibenzo coronene exhibits the most suitable features for our aimed applications.<sup>54,55,57</sup>

As illustrated in Fig. 1, each dopant  $X$  is placed in three possible positions: (i) the zigzag edge (X-ZZ) we refer to as X-EDG1, (ii) the armchair edge (X-AC) denoted also as X-EDG2 and (iii) inside the surface (X-IN) or (X-SURF).

The covalent bond lengths and the angles between the dopants and their adjacent carbon atoms, listed in Table 1, reveal that doping leads to structural distortion of the GQDs. Indeed, starting with the inside surface position (X-IN), we notice that the C–C bond with a bond length of about 1.4 Å in pure GQD increases upon doping to 1.54 Å, 1.49 Å, 1.65 Å and 1.77 Å for  $d_{\text{OC}}$ ,  $d_{\text{BC}}$ ,  $d_{\text{PC}}$  and  $d_{\text{SC}}$ , respectively. Similar enhancement of the X–C bond length is also observed for the zigzag-edge position as well as the armchair-edge position. However, we should note that the nitrogen atom keeps the value of the covalent bond (1.41 Å) close to that of the pristine structure because the atomic radius of the C and N atoms are almost equal. One can also notice that when comparing the inter-atomic distances for the same dopant, like  $d_{\text{XC}_3}$  with  $d_{\text{XC}_4}$ , the increase is more pronounced in the AC-configuration with respect to the ZZ-edge case, especially for P, O and S, while it is less significant for B and N. Therefore, we conclude that the distortion in our structures is originally induced by the length modification of the X–C bond brought by a doping process which mainly depends on the variation of the atomic radius size and the nature of the neighbour atoms.

Furthermore, the bond angles of  $\widehat{\text{CCC}}$  remain at almost  $120^\circ$  in all structures, like the pure case, whereas the situation is different for  $\widehat{\text{CXC}}$  angles. Indeed, in the IN-configurations the angle  $\widehat{\text{CXC}}$  is still close to  $120^\circ$  for B, N and P, a signature of the hexagonal lattice with  $\text{sp}^2$ -hybridization, however it becomes much lower for the O and S-adsorbent. This latter effect is also observed when the X-atom is located at the zigzag edge or at the armchair one, which indicates that the doping induces a sort of buckling around the substitution region where the  $\text{sp}^2$ -hybridization is significantly affected, as shown in Table 1, and the obtained angle values vary between  $100^\circ$  and  $103^\circ$ .

In summary, the P, S and O atoms cause significant structural modifications upon doping the pristine structure. However, the N and B atoms cause less distortion. On the other hand, it should be specified that the armchair O-doping leads to cracking of the covalent bond between the oxygen atom and the adjacent carbon atom, which can affect the electronic and optical properties of this structure.

#### B. Energetic stability

In order to evaluate the energetic stability of the studied structures, we calculated the cohesive energy values  $E_{\text{coh}}$  of the

Fig. 1 GQD structures doped with X = B, N, P, O and S heteroatoms in three positions. (a) X-EDG1 position, (b) X-EDG2 position and (c) X-SURF position.

doped structures. The cohesive energy  $E_{\text{coh}}$  values are calculated as follows:<sup>60</sup>

$$E_{\text{coh}} = \frac{E_{\text{tot}} - (E_{\text{X}} + n_{\text{C}}E_{\text{C}} + n_{\text{H}}E_{\text{H}})}{N_{\text{tot}}} \quad (3)$$

where  $E_{\text{tot}}$  the total energy of doped GQD.  $E_{\text{X}}$  is the energy of the substituent atom X = B, N, O, P and S,  $E_{\text{C}}$  is the energy of the C atom, and  $E_{\text{H}}$  is the energy of the H atom.  $n_{\text{C}}$  and  $n_{\text{H}}$  are the

number of C and H. And finally,  $N_{\text{tot}}$  is the total number of atoms.

Table 2 lists the values of the cohesive energy  $E_{\text{coh}}$  obtained via DFT calculations. More negative values confirm the greater stability of the investigated structures.<sup>60</sup> Indeed, all calculated cohesive energy values  $E_{\text{coh}}$  are negative, confirming the stability of all the studied systems is in good agreement the previous report.<sup>60</sup> The pristine GQD structure has a value of

**Table 2** The cohesive energy values  $E_{\text{coh}}$  of the studied systems, in eV

Structures	GQD	B-ZZ	B-AC	B-IN	N-ZZ	N-AC	N-IN	P-ZZ	P-AC	P-IN	O-ZZ	O-AC	O-IN	S-ZZ	S-AC	S-IN
$E_{\text{coh}}$	-7.270	-7.198	-7.189	-7.181	-7.244	-7.234	-7.221	-7.158	-7.144	-7.106	-7.131	-7.131	-7.098	-7.107	-7.106	-7.076

7.270 eV which decreases after doping with boron, nitrogen, oxygen, phosphorus or sulfur. This change in the cohesive energy value can be explained in terms of structural properties. The sulfur and phosphorus doped systems show the greatest decrease in cohesive energies, followed by the oxygen doped structure, as shown in Table 2. P and S doping results in structural distortions of the hexagonal ring by increasing the bond length from 1.42 to 1.8 Å, which decreases the values of the bond energies. In contrast, N and B doping results have shown a slight drop in cohesive energies compared to the pristine system, which can be attributed to the almost similar ionic radii between the B, N, and C atoms, with little change in the length of the C–N and C–B bonds.

### C. Stability indices

In order to gain insight into the chemical stability and chemical reactivity of the doped GQDs, we calculate the stability indices, namely the electrophilicity ( $\omega$ ) expressed as follows:<sup>49</sup>

$$\omega = \frac{\mu^2}{2\eta} \quad (4)$$

and the hardness ( $\eta$ ) and the chemical potential ( $\mu$ ) given in terms of the calculated frontier molecular orbital energies;  $E_{\text{HOMO}}$  and  $E_{\text{LUMO}}$ :<sup>49</sup>

$$\eta = \frac{E_{\text{LUMO}} - E_{\text{HOMO}}}{2} \quad \text{and} \quad \mu = \frac{E_{\text{LUMO}} + E_{\text{HOMO}}}{2} \quad (5)$$

As shown in Table 3, heteroatom doping brought considerable modifications to the chemical stability of the pristine GQDs. Starting with the hardness, it is noticeable that the doping mechanism decreases the hardness of the investigated structures making them slightly soft and thus more polarizable and easy to be excited. This result can be afforded to the distortion brought by the heteroatom doping in good accordance with ref. 61, where the hardness has been decreased upon

**Table 3** Global reactivity descriptors: hardness  $\eta$ , chemical potential  $\mu$  and electrophilicity  $\omega$ , as well as gap energy  $E_{\text{g}}^{\text{GGA}}$  and  $E_{\text{g}}^{\text{GW}}$  at DFT and GW level, respectively, first bright exciton binding energy  $E_{\text{b}}^{\text{x}}$ , optical gap  $E_{\text{opt}}^{\text{x}}$ , and the singlet–triplet energy splitting  $\Delta_{\text{S-T}}^{\text{x}}$ . All the energies are in eV

doping the asphaltene structure. Whereas, for the electrophilicity, we can clearly observe that the edge-doping position reduces the electrophilicity while the IN-doping position increases it which concurs well with ref. 62, showing how the doping mechanism affects the chemical potential and electrophilicity index of h-BN QDs differently depending on the doping position. Our findings can be attributed to the difference in charge transfer related to the nature of the neighbor atoms and thus, the significant frontier orbital hybridization.

#### D. HOMO–LUMO gap analysis

The HOMO–LUMO (H–L) energy gap obtained using the GGA–DFT and GW methods are listed in Table 3.

The GGA–DFT data reveal that O-, B-, N-, P- and S-dopants either on the edges or inside the surface, significantly affect the band gap of the pristine GQDs in good agreement with our previous work demonstrating how the energy gap is sensitive to substituents<sup>51</sup> and the functionalization of diamond-shaped quantum dots (DSQDs).<sup>53,54</sup> More precisely, with respect to the pure nanostructure, dopants result in a reduction of the corresponding H–L gap for the ZZ-, AC- and IN-configurations, in good accordance with ref. 40, showing that N and S impurities remarkably reduce the energy gap of the hexagonal-shaped graphene quantum dots. Furthermore, the IN-doping exhibits the most pronounced decrease in the H–L energy gap of the pure nanostructure for most heteroatoms, except dopants causing significant structural distortion, which disrupts the carbon  $sp^2$  hybridization in the skeleton due to the higher electronegativity or larger size of impurities, and results in a pronounced reduction of the energy gap as explained for the case of nitrogen doping in carbon dots.<sup>63</sup> Consequently, the variation of the HOMO or LUMO energy gap is attributed to the hybridization of the frontier molecular orbitals as well as the geometry deformation which mainly depends on the type and the position of heteroatoms, in accordance with the results on doping heteroatoms and covalent bonding with specific groups in hexagonal GQDs.<sup>64</sup>

On the other hand, a significant enhancement brought by the quasiparticle corrections is observed in the GW-energy gap with respect to the GGA-results. This behaviour is attributed to the heteroatoms acting like an electron donor or acceptor which increases the screening and impacts the electron–electron interactions.<sup>53,54</sup> Our finding are in good agreement with the many-body study of functionalized hexagonal GQDs.<sup>56</sup>

Next, Fig. 2 displays the charge density distributions associated with the HOMO and LUMO energy levels obtained using the GGA method. Interestingly, most of the investigated structures exhibit an edge-localized charge density similar to the pristine structure. However, there is a wide difference in the atomic contribution depending on the dopant type and its position. Starting with analysing the zigzag-doping case, we can see that for all the structures, a considerable contribution to either the HOMO or the LUMO levels originates from the dopant X. We should note that, for N, P, and O dopants, the contribution to the HOMO originates from carbon atoms in subsite A of the hexagonal structure, while the contribution to

the LUMO comes from the the neighboring carbon atoms. This explains the reduction in both HOMO and LUMO energies and thus the decrease in the H–L energy gap values. Whereas GQDs doped with the B atom, which is a donor atom, and which provides a significant contribution from the dopant to both HOMO and LUMO levels, increases the corresponding energies as listed in Table 3, explaining the slight rise in H–L energy gap value with respect to the pristine structure. The same behaviour has been noticed for the S doped structure, even though only the HOMO energy is increased which explains the reduction of the energy gap similar to the case of N, P and O atoms. On the other hand, armchair-edge doping has shown a different impact on the charge density of the pristine structure, depending on the dopant type and the position. We notice that only a few carbon atoms contribute to the HOMO level which increased its energy, while the LUMO energy has shown a small change compared with the HOMO energy, resulting in decreasing the GGA(H–L) energy gap.

In the case of inside the surface (IN or INace) doping, the distribution of charge density for a B doped structure is quite similar to that of the pristine structure, which results in small variation in the H–L gap originating from the absence of the armchair corner contribution. For the N and P doped structure, the contribution to the LUMO level, coming mostly from the dopant and the INace atoms, widely alters the  $E_{\text{LUMO}}$  resulting in a slight increment in the LUMO energy. The HOMO energy undergoes a significant increment since the contribution to the HOMO originates mainly from the zigzag edges characterized with edge states, which results in a quick reduction of the H–L(GGA) gap. The opposite is true for O and S doping, the contribution to the HOMO comes from the dopant and the surface atoms, while the charge density of the LUMO is mostly localized at the zigzag edges, showing a slight decrement in  $E_{\text{LUMO}}$  and an increment in  $E_{\text{HOMO}}$ , which explains the diminution in the H–L(GGA) energy gap. To sum up these findings, we can deduce that heteroatom doping, gathered by varying the type and the position of the dopant, considerably alters the electronic properties of the pristine DSGQD and this originates mainly from the competition between the strong frontier molecular orbitals hybridization and also the distortion effects.

#### E. Charge transfer and magnetic behaviour

**1. Charge transfer.** Table 4 shows the charge transfer between different atoms and their neighboring carbon atoms, calculated using Bader analysis.

We observe that B, P, and S donate electrons to nearby carbon atoms, while N and O atoms take electrons from their neighboring carbon atoms. This behaviour is mainly attributed to the Pauling electronegativities which are highest for oxygen O(3.44), then nitrogen N(3.04), followed by carbon C(2.55), sulfur S(2.58), boron B(2.04), and phosphorus P(2.19). Besides, the atoms shared between heteroatoms and carbon atoms suggest that B, N, and O atoms form polar covalent bonds with carbon neighbors, whereas P and S atoms create nonpolar covalent bonds with carbon atoms.

Fig. 2 The HOMO and LUMO electronic charge density distribution of (a) pristine, and (b–f) doped DSGQDs with X = B, N, P, O or S.

Table 4 Bader charge transfer of dopant X = B, N, P, O or S, (+ve) denotes electron loss while (–ve) denotes electron gain

Structures	B-ZZ	B-AC	B-IN	N-ZZ	N-AC	N-IN	P-ZZ	P-AC	P-IN	O-ZZ	O-AC	O-IN	S-ZZ	S-AC	S-IN
X	+2.99	+2.99	+2.99	–0.35	–0.41	–0.81	+3.40	+3.56	+4.99	–1.42	–1.55	–0.83	+0.36	+0.46	+1.94

**2. Magnetic behaviour.** In this paragraph, we report the results obtained upon performing spin-polarization employing DFT calculations, in order to examine the effect of heteroatom doping on the non-magnetic pristine GQD. Interestingly, and depending on the calculated magnetic moments, we can divide

our doped systems into two categories: non-magnetic doped GQDs and magnetic doped GQDs. Specifically, O and S doped GQDs remain non-magnetic, however B, N and P atoms induce the non-magnetic phase of GQD into magnetic nanomaterials. This result is mainly explained by the introduction of localized

states within the electronic structure of the GQDs. These localized states can lead to the formation of unpaired electrons, resulting in a net magnetic moment and conferring magnetic properties to the pristine GQDs, paving the way for utilizing these magnetic nanomaterials in spintronic applications.

## F. Absorption profile and excitonic effects

In what follows, we investigate the impact of heteroatom doping on the optical profile of DSGQDs through the determination of the absorption spectra in the absence and the presence of the electron-hole interactions. The inclusion of excitonic effects has drastically modified the peak position and the intensity of the first bright exciton making GW + RPA results negligible. For this reason, Fig. 3 only plots the optical absorption spectra at the GW + BSE level for the X-direction light polarization. The optical response for light polarized along the Y-direction have shown anisotropic behaviour upon doping. Compared to the optical behaviour of the pristine GQD, Fig. 3 shows that the ZZ-, AC-, IN-dopants shift the absorption curves towards lower energies. Interestingly, the O-AC and O-IN structures show the greatest influence on absorption spectra compared to other structures, their absorption curves are the most redshifted. On the other hand, the absorption spectrum of the B-IN-GQD structure is the least affected compared to the other doped structures, followed by the B-ZZ-GQD structure and then the P-ZZ-GQD structure. We should note that the doping process helps enhance the intensity peaks compared to the pristine structure, especially when doping with O, B and S heteroatoms. As a direct consequence of the absorption redshift caused by

dopants, the first exciton is manifested by the presence of an absorption peak located at an energy lower than that of the pristine structure. Table 3 shows how the difference in type and position of the dopant allows a series of GQDs with different absorptions in the visible and infrared region of the solar spectrum. Indeed, the majority of the exciton binding energy  $E_b^x$  values range in the interval [2.07, 2.7] eV which prove that our structures are promising candidates for photovoltaic applications. The structures, exhibiting significant GW-gap and thus an optical gap in the visible-infrared region of the solar spectrum, may be potential candidates for different applications, especially for bioimaging.

To predict the type of photophysical process and the effect of the doping mechanism on the luminescent behaviour of our doped GQDs, Table 3 reports the singlet-triplet energy splitting  $\Delta_{S-T}$ . Compared to pristine GQDs, the heteroatoms B, N, P, O and S lower the singlet-triplet energy splitting values compared to the non-doped GQD nanostructure. Indeed, the calculated values vary from 1.46 eV for B-IN, down to the lowest value of 0.19 eV obtained for the O-AC configuration. Furthermore, thermally activated delayed fluorescence (TADF) characterizes N-ZZ and O-AC structures, exhibiting the lowest splitting values (less than 0.37 eV).<sup>50</sup> It follows that fluorescence occurs in QDs with splitting energy values between 0.5 and 1 eV, except for the P-ZZ structure characterized by triplet-triplet annihilation processes, whereas S-ZZ, B-ZZ and B-IN structures exhibit a singlet fission process in agreement with the findings in ref. 50, regarding the control of singlet-triplet splitting for organic exciton manipulation. Our results are similar to other GQDs structures of the same size characterized by TADF, such as

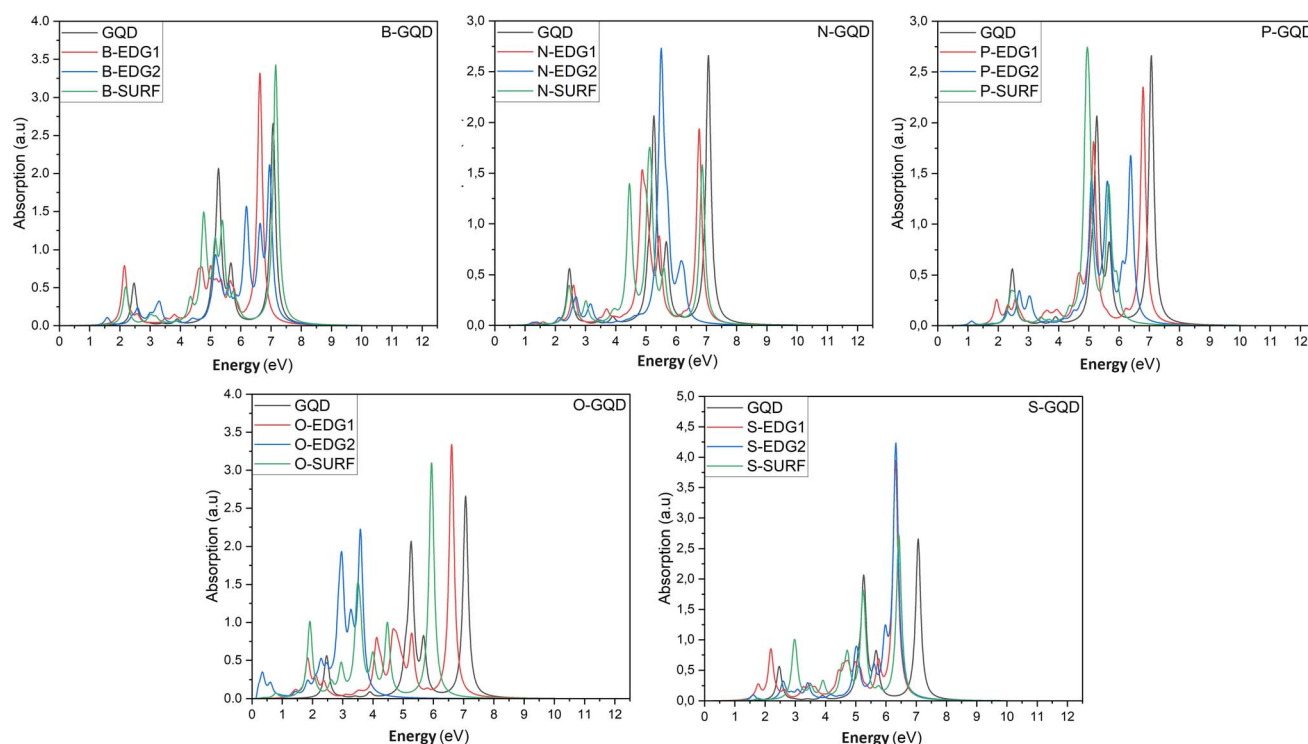

Fig. 3 The optical absorption spectra of pristine and heteroatom doping structures with X = B, N, O, P or S, at the GW + BSE level.

molecular structures of SiCQDs edge-functionalized with H, OH and COOH, and edge-functionalized SiQD structures with H and OH.<sup>51,52,54,55</sup>

## IV. Conclusion

In summary, we have adapted a heteroatom-doping mechanism to manipulate the structural, electronic, optical, excitonic and photoluminescence properties of DSQDs. The obtained results show that the type and the position of the dopant, influences the binding environment of the GQD with respect to the pristine nanostructures. Interestingly, the INace doping improved the responsiveness of DSGQDs, especially upon using N, P and O dopants, making them more responsive and less hard. The optoelectronic behaviour of the pristine structure is considerably decreased with doping, depending on the nature and the location of the heteroatom dopant due to the frontier orbitals hybridization. With respect to pure QD, the absorption curves are shifted towards lower energies and the binding energy of the first exciton is significantly increased for most edge-doped structures, except for the B heteroatom which exhibits anomalies. Whereas, for surface-doped structures, the binding energy shows an increase only for the S-dopant. Finally, the singlet-triplet energy splitting, which strongly depends on the doping atom type and site, greatly reduces the intersystem conversion from the singlet state to the triplet state and consequently enhances the fluorescence process. These results seem to be very useful and promising for applications in photovoltaic and optoelectronic devices.
