2-(Anthracene-9-yl)-4,5-diphenyl-1*H*-imidazole (ADPI) provides an intriguing molecular platform for developing organic fluorophores with diverse properties and fluorescence performances. However, derivatives of ADPI have not yet been well explored and extensive studies are warranted. To shed more light on this, we have synthesized a series of π -extended ADPIs through a concise synthetic route involving an efficient cross-condensation reaction followed by Pd-catalyzed Suzuki cross-coupling. The obtained compounds were subjected to X-ray single crystallographic analysis to understand their molecular conformational and solid-state packing properties. Furthermore, UV-Vis absorption and fluorescence spectroscopic analyses were conducted. Our experimental results have disclosed interesting solvatochromic properties of these compounds which are useful for solvent polarity-sensitive applications. The presence of an amphoteric imidazolyl group in the ADPI derivatives also renders them sensitive fluorescence responses to strong protic acids (e.g., trifluoroacetic acid) as well as fluoride anion. It transpires that the fluorescence changes are dependent on the functional groups attached to the ADPI core, suggesting a bottom-up molecular tuning approach for development of fluorophores and chemosensors with diverse functions.

1 Introduction

Imidazole is an important five-membered heterocycle that is widely present in natural products,¹ biomolecules,² pharmaceutical drugs,^{3–6} synthetic polymers,⁷ selective ligands,⁸ functional organic chromophores,^{9,10} and to just name a few. Over the past decade, planar imidazole-fused polycyclic aromatic systems, such as phenanthroimidazole^{11–15} and pyrenoidimidazole derivatives,^{16–19} have captured considerable attention in the field of organic optoelectronics primarily because of their excellent electroluminescence performances and thermal stability. Changing their fused π -motif into non-fused polyaryl-substitution results in increased steric clashing among the aryl groups and force the molecular structures to take more twisted conformations (such as that illustrated in Fig. 1). This type of variation has been found to be beneficial for

bringing about new optoelectronic performances that are very different from their planar counterparts. For example, Alreja and Kaur recently reported that 2-(anthracene-9-yl)-4,5-diphenyl-1*H*-imidazole (ADPI, see Fig. 1) shows more selective colorimetric and fluorescence sensing properties for certain transition metal ions (e.g., Cu²⁺) than an analogous fluorophore that contains a planar imidazole-fused phenanthroline.²⁰ Li *et al.* in 2014 discovered that ADPI exhibits intriguing polymorphism-dependent fluorescence and piezochromic behavior in the solid state.²¹ Pan and co-workers reported that ADPI molecules are packed in a non-parallel fashion in the crystalline state, yielding single-crystalline microwires that can act as efficient optical waveguides.²²

Besides the above-mentioned features, ADPI and its numerous analogues have also been investigated in terms of

Fig. 1 The design strategy for derivatizing the π -extended ADPI (π -ADPI) system in this work.

optical absorption/emission properties,²³ solvatofluorochromism,²⁴ electroluminescence,²⁵ and catalytic effects on Pd-catalyzed coupling reactions²⁶ over the past decade. Nonetheless, the number of ADPI derivatives so far documented in the literature is still much less than many other imidazole-based π -conjugated systems. Continued synthesis and characterizations of new variants of ADPI are therefore warranted. In this work, we designed a series of π -ADPIs that carry various aryl substituents at the *para*-positions of the ADPI's two phenyl groups (see Fig. 1). Synthetically, these π -ADPIs can be flexibly prepared through efficient transition metal-catalyzed cross-coupling reactions, especially the well-established Suzuki-Miyaura cross coupling.²⁷ Fundamentally, it is important to acquire understanding about how the aryl substituents influence the structural, electronic, and photophysical properties. Disclosure of relevant substituent–property correlations will offer useful guidance to further exploration of ADPI-based materials in optoelectronic applications. The following presents our synthesis and systematic characterizations of four π -ADPI derivatives based on single-crystal X-ray diffraction (SCXRD), NMR, UV-Vis absorption, and fluorescence analyses.

2 Results and discussion

2.1 Synthesis

2-(Anthracene-9-yl)-4,5-bis(4-bromophenyl)-1H-imidazole **3** was synthesized as a key intermediate for making diverse π -ADPIs (see Fig. 2). This imidazole intermediate was readily prepared through a one-pot condensation reaction between dione **1** and anthracene-9-carbaldehyde (**2**) in the presence of ammonium acetate and acetic acid, the reaction mechanism of which follows the multi-component Debus–Radziszewski imidazole synthesis.^{28,29} Upon refluxing at 120 °C for 12 hours, this

condensation reaction afforded intermediate **3** in a high yield of 86%. The two bromo groups in **3** provide synthetic handles for transition metal-mediated cross-coupling reactions. In our work, Suzuki–Miyaura cross-coupling reactions were respectively conducted between **3** and four areneboronic acids (**4a–d**). The reaction conditions of the Suzuki reactions involved Pd(PPh₃)₄ as the catalyst, cesium carbonate as the base, and a mixture of THF and water as the solvent. All the coupling reactions went smoothly at 70 °C and accomplished within 6 hours. The resulting cross-coupled products **5a–d** were then obtained after standard column chromatographic purification in satisfactory yields ranging from 60% to 76%. It is worth remarking that Suzuki–Miyaura cross-coupling reactions taking place on imidazole-containing substrates are often problematic (*e.g.*, low-yielding or lack of selectivity) owing to the presence of relatively acidic imidazolyl N–H group.^{30–33} In our cases here, the cross-coupling efficiency turned out to be really good, presumably due to steric effects delivered by the 9-anthryl group that is adjacent to the imidazolyl unit of **3**. Imidazole is a versatile group that can act as both hydrogen bond donor and acceptor. For the purpose of comparative analysis in our structural and photophysical studies, we also prepared compound **6** which is an *N*-methylated derivative of ADPI **3**. The synthesis of **6** was done through a substitution reaction by deprotonation of **3** with sodium hydride, followed by treatment with methyl iodide. The structures of all the prepared ADPI and π -ADPI compounds were elucidated by ¹H NMR, ¹³C NMR, infrared (IR) spectroscopic, and high resolution mass spectrometric (HR-MS) analyses. Detailed characterization data are provided in the ESI.†

2.2 X-ray single crystallographic properties

Single crystals of compounds **3**, **5b**, and **6** were successfully grown through slowly diffusing hexane into a CH₂Cl₂ solution of **3** or letting the solutions of **5b** and **6** in CH₂Cl₂/THF (1 : 2, v/v) slowly evaporate at room temperature. The crystal structures of these compounds were then elucidated by XRD analysis to understand their molecular structural and solid-state packing properties. Fig. 3A illustrates one of the molecular structures in the unit cell of the single crystal of compound **3**. The crystal structure of **3** presents a triclinic system with *P*-1 space group. As expected, the arene groups around the imidazole core in **3** all

Fig. 4 (A) ORTEP drawing (at 50% ellipsoid probability) of the molecular structure of **6** determined by single-crystal X-ray diffraction analysis. (B) Packing motif shown in the crystal structure of **6**. CCDC 2354159.

rotate significantly to avoid steric clashing. The imidazolyl group of **3** acts as both a hydrogen bond donor and a hydrogen bond acceptor, affording a network of hydrogen bonded assembly in the crystal structure as depicted by Fig. 3B. Along the hydrogen-bonded network, three similar hydrogen bonding interactions can be observed with N \cdots H distances of 2.08, 2.14, and 2.01 Å, respectively. In the meantime, the intermolecular contact is further enhanced through π -stacking of anthryl rings.

The molecular structure of compound **6** is similar to that of **3** (see Fig. 4A). The presence of an *N*-methyl group makes the anthryl unit of **6** take a nearly perpendicular orientation with respect to the central imidazole ring at a torsion angle of 84°. The other two phenyl rings are somewhat less rotated, particularly the ring at the 4-position of imidazole shows a torsion angle of 20 to 23° with respect to the imidazole plane. The solid-state packing motif of **6**, however, is very different from that of **5a**. The crystal structure of **6** is in an orthorhombic system with *Pna*2₁ space group. Because of *N*-methylation, the imidazole unit of **6** lacks the ability to form intermolecular hydrogen bonding interactions. The twisted conformation of **6** thus leads to relatively loose packing in the solid state, where the dominant intermolecular forces are C–H \cdots π stacking as shown in Fig. 4B.

The X-ray determined molecular structure of **5b** is shown in Fig. 5A. Like the other two compounds, the anthryl unit in **5b** takes a perpendicular orientation relative to the central

Fig. 5 (A) ORTEP drawing (at 50% ellipsoid probability) of the molecular structure of **5b** determined by single-crystal X-ray diffraction analysis. (B) Packing motif shown in the crystal structure of **5b**. CCDC 2354160.

imidazole ring. The two phenyl rings show torsion angles of 35–39° with respect to the imidazole unit, and 36–40° to the two benzo[*b*]thiophene units, respectively. The steric bulkiness of the arene groups surrounding the imidazole ring of **5b** hinders the formation of intermolecular hydrogen bonds among the molecules of **5b** in the crystalline state. In the crystal structure, molecules of **5b** are packed with a triclinic unit cell and *P*-1 space group. As shown in Fig. 5B, the packing motif of **5b** has no significant π -stacking involved, but C–H \cdots π interactions between benzo[*b*]thiophene units present notably.

Diffusion of methanol into a THF solution of **5b** produced solvates, the solid-state structure of which was determined by X-ray analysis. Fig. 6 shows the molecular structure of **5b** where the imidazole unit interacts with two molecules of methanol through hydrogen bonds. Compared with the molecular conformation observed in the single crystal of **5b**, the incorporation of methanol molecules in the crystal lattice causes the anthryl group to take a relatively small torsion angle of 57° with respect to the imidazole ring. It is also interesting to observe that the molecular conformation of **5b** in the solvate structure possesses a *C*₂ symmetry. As such, the solvate of **5b** shows an intimate packing motif in the solid state, forming a monoclinic *I*2/*a* system. In the crystal packing, methanol molecules filled in the space between the molecules of **5b** through hydrogen bonds

(see Fig. 6B). The imidazole unit of **5b** acts as both hydrogen donor and acceptor, showing intermolecular O \cdots H (2.04 Å) and N \cdots H (1.96 Å) interactions, respectively.

2.3 UV-Vis absorption and fluorescence spectroscopic properties

The electronic absorption properties of compounds **3**, **5a–d**, and **6** were investigated by UV-Vis absorption spectroscopic analysis. As shown in Fig. 7A, the spectra of ADPIs **3** and **6** measured in CH₂Cl₂ show three vibronic bands at 388, 368, and 348 nm in the low-energy region, which are characteristic of the $\pi \rightarrow \pi^*$ transitions at the anthryl unit. Similar absorption bands are discernible in the spectra of **5a–d** in CH₂Cl₂ (highlighted by dashed lines in Fig. 7A), but they significantly overlap with the absorption bands of the arene groups appended to the ADPI scaffold. Detailed UV-Vis absorption data are summarized in Table 1.

Fig. 7B shows the normalized fluorescence spectra of **3**, **5a–d**, and **6** measured in CH₂Cl₂. As can be seen, all the emission spectra exhibit a smooth Gaussian-type profile with different maximum emission wavelengths (λ_{em}) ranging from 469 to 522 nm (see Table 1 for details). These emission peaks are considerably redshifted than pristine anthracene, which typically shows a set of vibronic bands in the spectral region of 360–460 nm.³⁴ According to the UV-Vis analysis, the excitation light should be dominantly absorbed by the anthracene unit, promoting it to the first excited state (S_1) through vertical electronic transition.

It is interesting to note that the λ_{em} of **6** is blueshifted by 8 nm relative to **3**, although they possess the same π -frameworks except that **6** is methylated at the imidazolyl unit and **3** has a free imidazole ring. Since both of them show nearly identical low-energy absorption bands, the difference in their maximum emission wavelengths can be explained by that the anthracene and imidazole rings of **6** in the first excited state are more twisted than that of **3** due to the *N*-methyl group of **6**. For π -ADPIs **5a–d**, the maximum emission wavelengths are further redshifted; in particular, the effects of strong electron-donating diphenylamine and carbazole groups in **5c** and **5d** are more significant than the others.

In a previous study by Li and co-workers,²¹ the fluorescence of ADPIs was reported to exhibit solvatofluorochromic effects. In view of these properties, we also investigated the fluorescence behavior of our synthesized ADPIs and π -ADPIs in organic solvents with different degrees of polarity. Fig. 8 shows

Fig. 8 Plots of maximum emission energy (ν_{max}) versus solvent polarity index (P') for compounds **3**, **5a–d**, and **6**.

the correlations of the maximum emission energies of **3**, **5a–d**, and **6** with the polarity indexes (P') of various solvents. For all of the six ADPI derivatives, the correlation plots exhibit a general trend of decreasing emission energy (*i.e.*, redshifted λ_{em}) with increasing solvent polarity, but significant irregularities can be seen in the polarity range of 3–6; particularly, methanol and ethanol are the most notable outliers. The solvent-dependent fluorescence suggests that the emissive states of these compounds possess intramolecular charge-transfer (ICT) character. As demonstrated in the X-ray analysis of **5b**, protic solvents (methanol and ethanol) can form hydrogen bonding interactions with the imidazole C=N group and hence contribute more stabilization to the ground state. This effect in turn modifies the energy gap between the emissive state and the ground state to significantly affect the emission energy.

To better understand the solvatofluorochromic effects observed for the ADPIs and π -ADPIs, density functional theory (DFT) calculations were carried out on compound **3** and its frontier molecular orbital properties are illustrated in Fig. 9A. The highest occupied molecular orbital (HOMO) is distributed among the anthracene and imidazole units, while the lowest unoccupied molecular orbital (LUMO) is predominantly located in the anthracene unit. When an ADPI (*e.g.*, **3**) is photoexcited, the vertical electronic transition contains a character of mainly HOMO \rightarrow LUMO transition. From the FMO analysis, it is reasonable to say that the $S_0 \rightarrow S_1$ transition

Fig. 9 (A) Plots of frontier molecular orbitals (FMOs) of ADPI 3 calculated at the M06-2X/Def2-SVP level (isovalue = 0.03 a.u.). (B) Schematic illustration of the solvent effects on the energies of the ground (S_0) state and the first excited state (S_1) of an ADPI.

should result in an ICT from imidazole to anthracene. Moreover, the S_1 is more polar in nature than the S_0 due to the occurrence of ICT. As such, an aprotic dipolar solvent should provide more stabilization on the S_1 than the S_0 state to reduce the energy gap and cause redshifted λ_{em} . On the other hand, if the solvent is a hydrogen bond donor (e.g., an alcohol), the ground-state ADPI can form significant hydrogen bonding interactions similar to the case observed in the methanol-solvated X-ray structure of **5b**. These interactions, contrary to the polarity effect, stabilize the ground (S_0) state more than the first excited (S_1) state. In this case, the energy gap between S_0 and S_1 is widened and the λ_{em} is blueshifted. Overall, the observed solvatofluorochromic effects of **3**, **5a–d**, and **6** point toward a potential of utilizing these ADPI derivatives as a class of environment-sensitive fluorophores for probing different solvent properties.

2.4 Interactions of ADPI derivatives with trifluoroacetic acid

The imidazole group has an amphoteric character, allowing it to act as both an acid and a base.^{8,35} In view of this property, we subsequently investigated our synthesized ADPI derivatives in terms of their spectral responses to interactions with acids. In our experiments, a strong organic acid, trifluoroacetic acid (TFA), was used to protonate compounds **3**, **5a–d**, and **6**, respectively, in organic solution, and the detailed processes were monitored by UV-Vis, fluorescence, and NMR analysis.

Fig. 10 shows the results of titration of ADPI derivatives **3** and **6** with TFA. Interaction of compound **3** with TFA caused the three characteristic anthracene absorption bands in the low-energy region (350–390 nm) to be slightly redshifted by ca. 5 nm (see Fig. 10A). In the high-energy region of the absorption spectrum, two isosbestic points can be clearly seen at 303 and 270 nm, respectively. In contrast to the moderate changes observed in the UV-Vis titration, the fluorescence profile of **3** was found to be substantially quenched by TFA titration. As shown in Fig. 10C, the fluorescence intensity of **3** at the maximum emission wavelength is quenched by nearly 93% after interacting with 8.65 mole equiv. of TFA. The fluorescence

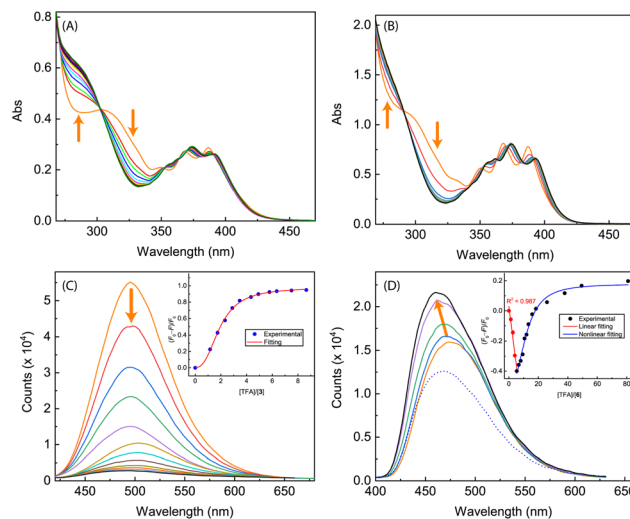

Fig. 10 UV-Vis spectra monitoring the titrations of (A) compound **3** (1.40×10^{-4} M in CH_2Cl_2) with TFA (0 to 17.8 mole equiv.) and (B) compound **6** (7.90×10^{-5} M in CH_2Cl_2) with TFA (0 to 98.1 mole equiv.). (C) Fluorescence spectra monitoring the titration of compound **3** (1.40×10^{-4} M in CH_2Cl_2) with TFA (0 to 8.65 mole equiv.). (D) Fluorescence spectra monitoring the titration of compound **6** (7.90×10^{-5} M in CH_2Cl_2) with TFA (0 to 5.34 mole equiv., solid lines; at 80.9 mole equiv., dashed line). Arrows indicate the trends of spectral changes with increasing addition of TFA. Insets in (C) and (D) are plots of $(F_0 - F)/F_0$ vs. the mole equiv. of TFA, where F_0 is the fluorescence intensity at the maximum emission wavelength before titration and F is the fluorescence intensity at the same wavelength during titration.

quenching trend can be well described by a logistic nonlinear regression model (see the inset of Fig. 10C).

The UV-Vis absorption spectrum of *N*-methylated **6** varies in a similar way to that of **3** during the TFA titration (Fig. 10B), but the fluorescence of **6** responds to TFA titration quite differently. As shown in Fig. 10D, the fluorescence intensity of **6** increases linearly with the amount of added TFA from 0 to 5.34 mole equiv., along with a noticeable blueshift of the maximum emission wavelength. Further increase in TFA addition results in a trend of fluorescence quenching that follows a non-linear

Fig. 11 ^1H NMR (300 MHz, $\text{DMSO}-d_6$) titration of **6** (5.57 mM) with TFA (0 to 2.0 mole equiv.) at room temperature. The singlet at 8.30 ppm (labelled by *) is due to residual DMF in the solution.

logistic model (see Fig. 10D). At the saturation point, the fluorescence of **6** is only quenched by *ca.* 20%, which is significantly different from the nearly quantitative quenching effect observed for ADPI **3**.

The fluorescence titration data indicates that the interactions of **6** with TFA undergo two separate stages. To better understand the protonation processes involved, ^1H NMR titration of **6** with TFA was performed in deuterated DMSO. Fig. 11 shows the NMR titration results, where characteristic signals due to certain protons on the anthracene units (labelled as Ha–Hc) are highlighted to show the trend of spectral changes. When the amount of TFA added is 0.25 mole equiv., the aromatic proton signals are complex and broad, indicating a dynamic process of proton exchange on the imidazolyl unit. At this stage, it is possible that the presence of TFA induces hydrogen bonding interactions with **6**, making the π -framework of **6** more twisted and less rotatable. The enhanced and blueshifted fluorescence observed in the early stage of fluorescence titration are consistent with this argument. When the amount of TFA is more than 0.50 mole equiv., the aromatic signals of **6** show better-resolved patterns in which the central proton (Ha) of the anthracene unit becomes significantly downfield-shifted to 9.11 ppm. The other anthryl protons are also downfield-shifted but in a less magnitude. This can be explained by that the imidazole is protonated on the C=N site, converting it into a more electron-withdrawing imidazolium ring. As a result of protonation, the excited state of **6** can be deactivated more efficiently through some non-radiative decay pathways to cause fluorescence quenching; for example, the photoinduced

Fig. 13 ^1H NMR (300 MHz, $\text{DMSO}-d_6$) titration of **5a** (5.57 mM) with TFA (0 to 2.2 mole equiv.) at room temperature.

electron transfer from anthracene (donor) to imidazolium ion (acceptor).³⁶

In contrast to *N*-methylated ADPI **6**, TFA titrations of ADPI **3** and its π -extended derivatives **5a–d** all show similar fluorescence quenching behavior. As can be seen from Fig. 12, the fluorescence intensities of π -ADPIs **5a–b** and **5d** are nearly quantitatively quenched at the saturation point, which is similar to the results of ADPI **3**. Obviously, the imidazolyl N–H group in these compounds plays a key role in the acid-induced quenching effect. It is interesting to note that ^1H NMR monitoring the titration of **5a** with TFA reveals three stages of change (see Fig. 13), which is different from the one-step protonation of ADPI **3** (see Fig. S-12 in the ESI†). It is likely that the anisoyl groups attached to compound **5a** also participate in interactions with TFA and hence result in strong fluorescence quenching. In the case of **5c** where diphenylamino groups are appendages, the fluorescence is quenched by *ca.* 70% at the saturation point. The exact reason for compound **5c** to retain a relatively high level of fluorescence during TFA titration is not quite clear. However, it is tentatively proposed that protonation of the diphenylamino groups makes the structure of **5c** more twisted and sterically hindered. This effect somewhat decelerates the non-radiative decays of the excited state of **5c**.

2.5 Interactions of ADPI derivatives with fluoride anion

The performance of free imidazole as a hydrogen bond donor^{7,37} inspired us to investigate the potential of ADPIs **3** and **5a–d** as fluoride anion receptors and/or sensors, considering the strong hydrogen bond acceptor ability of fluoride anion.^{38,39} Fig. 14 shows the UV-Vis and fluorescence titration results of ADPI **3** with tetrabutylammonium fluoride (TBAF) in CH_2Cl_2 . As can be seen from the UV-Vis data (Fig. 14A), a broad long-wavelength absorption band centering at *ca.* 450 nm emerges with increasing addition of TBAF to the solution of **3**. This band can be attributed to the deprotonation of the imidazolyl N–H group by fluoride anion,³⁸ which leads to enhanced π -electron delocalization and reduced HOMO–LUMO gap. In the meantime,

Fig. 12 Fluorescence spectra monitoring the titrations of (A) compound **5a** (8.62×10^{-5} M in CH_2Cl_2) with TFA (0 to 37.1 mole equiv.), (B) compound **5b** (9.84×10^{-5} M in CH_2Cl_2) with TFA (0 to 24.5 mole equiv.), (C) compound **5c** (9.91×10^{-5} M in CH_2Cl_2) with TFA (0 to 24.3 mole equiv.), and (D) compound **5d** (8.25×10^{-5} M in CH_2Cl_2) with TFA (0 to 19.6 mole equiv.). Arrows indicate the trends of spectral changes with increasing addition of TFA. Insets are plots of $(F_0 - F)/F_0$ vs. the mole equiv. of TFA, where F_0 is the fluorescence intensity at the maximum emission wavelength before titration and F is the fluorescence intensity at the same wavelength during titration.

Fig. 14 (A) UV-Vis spectra monitoring the titration of **3** (9.51×10^{-5} M in CH_2Cl_2) with TBAF (0.00 to 50.79 mole equiv.). Inset: plot of $(A - A_0)$ against the mole equiv. of TBAF, where A_0 and A are the absorbance values measured at 450 nm before and during titration of TBAF. (B) Fluorescence spectra monitoring the titration of **3** (9.51×10^{-5} M in CH_2Cl_2) with TBAF (0.00 to 43.86 mole equiv.). Inset: plot of $(F_0 - F)/F_0$ vs. the mole equiv. of TBAF, where F_0 is the fluorescence intensity at the maximum emission wavelength before titration and F is the fluorescence intensity at the same wavelength during titration. Arrows indicate the trends of spectral changes with increasing addition of TBAF.

the high-energy absorption bands due to anthracene in the range of 340–390 nm are also observed to grow in intensity with increasing titration of TBAF. The change in UV-Vis absorbance at 450 nm follows a nonlinear model using the Hill equation⁴⁰ (see the plot in the inset of Fig. 14A).

The fluorescence titration results of **3** with TBAF are provided in Fig. 14B. During the titration, the emission intensity of **3** gradually decreases with increasing amount of TBAF, showing a straightforward fluorescence quenching effect. The trend of fluorescence quenching at the maximum emission wavelength of **3** follows a nonlinear logistic model very well, and at the saturation point of titration the fluorescence is quenched by more than 80%. Moreover, the fluorescence spectral profiles show a significant redshift as the titration progresses. At the end of titration, the maximum emission wavelength is considerably shifted to 567 nm, indicating that the corresponding emissive state has a significant degree of ICT character.^{41–43}

Fig. 15 ^1H NMR (300 MHz, $\text{DMSO}-d_6$) titration of **3** (3.61 mM) with TBAF (0 to 2.2 mole equiv.) at room temperature.

To further understand the interactions **3** with fluoride anion, ^1H NMR titration experiments were carried out and the results are illustrated in Fig. 15. It is interesting to note that when only a small amount of TBAF (0.2–0.6 mole equiv.) was added to the solution of **3**, the NMR signals appeared to be significantly broadened. This stage of NMR responses can be attributed to a rapid exchange between free ADPI **3** and its hydrogen bonded complex, $[\mathbf{3} \cdots \text{F}^-]$. When the amount of TBAF was increased to more than 0.8 mole equiv., the NMR spectral profile showed well-resolved features, indicating another stage of interaction with fluoride anion. Given the basicity of fluoride anion, it is believed that the imidazolyl unit is deprotonated at the N–H site to yield an imidazole anion. It is worth noting that in the NMR spectrum, the central anthryl proton that is labelled as Ha gives a singlet at 8.82 ppm, while the other two anthryl protons labelled as Hb and Hc appear as two pseudo doublets at 8.21 and 7.93 ppm, respectively. During the titration, these peaks are considerably shifted. The singlet Ha and the proton adjacent to it, which is labelled as Hb, are both shifted to the upfield (8.39 and 8.00 ppm, respectively). The proton (labelled as Hc) that is close to the imidazole unit, however, is considerably downfield-shifted to 8.83 ppm. It has been reported that imidazole anion has a greater degree of aromaticity than neutral imidazole ring.^{44,45} Upon fluoride titration, the anthryl proton Hc of **3** is therefore subjected to increasing deshielding effect of imidazole anion ring current, which in turn causes its resonance frequency to be substantially downfield-shifted.

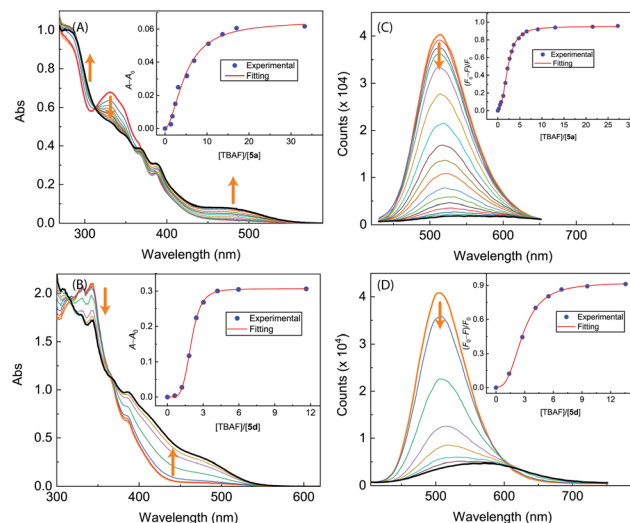

Fig. 16 UV-Vis spectra monitoring the titrations of (A) **5a** (8.62×10^{-5} M in CH_2Cl_2) with TBAF (0.00 to 33.26 mole equiv.) and (B) **5d** (8.25×10^{-5} M in CH_2Cl_2) with TBAF (0.00 to 11.63 mole equiv.). Insets: plots of $(A - A_0)$ against the mole equiv. of TBAF, where A_0 and A are the absorbance values measured at 470 nm and before and during titration of TBAF. Fluorescence spectra monitoring the titrations of (C) **5a** (8.62×10^{-5} M in CH_2Cl_2) with TBAF (0.00 to 43.86 mole equiv.) and (D) **5d** (8.25×10^{-5} M in CH_2Cl_2) with TBAF (0.00 to 11.56 mole equiv.). Insets: plot of $(F_0 - F)/F_0$ vs. the mole equiv. of TBAF, where F_0 is the fluorescence intensity at the maximum emission wavelength before titration and F is the fluorescence intensity at the same wavelength during titration. Arrows indicate the trends of spectral changes with increasing addition of TBAF.

The results of UV-Vis and fluorescence titrations of π -ADPIs **5a** and **5d** with TBAF are shown in Fig. 16. Similar to compound **3**, both **5a** and **5d** show a notable growth of a long-wavelength broad absorption band in their UV-Vis spectra, ranging from *ca.* 440 to 550 nm. The fluorescence spectra of **5a** and **5d** exhibit significant quenching in response to the titration of TBAF. For compound **5a**, the fluorescence is almost quantitatively quenched at the saturation point of titration. Compound **5d** shows fluorescence responses like those of **3**; that is, the emission peak is redshifted significantly at the end of titration (see Fig. 16D).

As can be seen from Fig. 17A and B, the UV-Vis spectra of **5b** and **5c** exhibit similar behaviors to the other ADPI derivatives during TBAF titrations. The fluorescence spectra of **5b** and **5c**, however, show very different trends at the early stage of titration. Interestingly, both compounds exhibit fluorescence enhancement when they interact with a relatively small amount of TBAF. Especially, the fluorescence of compound **5c** is increased by more than one fold when interacting with *ca.* 1.5 mole equiv. of TBAF. As the titration continues, the fluorescence behavior changes to a trend of quenching that is similar to the other ADPI derivatives. It is also interesting to comment that the maximum emission band of **5c** at the end of titration is notably blueshifted relative to that of pristine **5c**. Clearly, the electron-donating diphenylamino groups in **5c** are responsible for this unusual spectral behavior. It is possible that the electron pushing between the diphenylamino and anionic imidazole ring causes the molecular framework to be more twisted and less π -conjugated.

3 Conclusions

We herein report a systematic study of a series of ADPI derivatives that contain π -extended units and appendage groups with different electronic effects. These compounds can be readily accessed through concise synthetic routes with satisfactory to good yields. X-ray single crystallographic analysis shows that the ADPI compounds take twisted molecular conformations and are packed in very different motifs depending on the appendage groups attached. All of these compounds show significant solvatofluorochromic effects that can be potentially useful as molecular probes for solvent polarity. The amphoteric properties of the imidazole unit in these compounds allow them to interact with strong protic acids (*e.g.*, TFA) and hard anionic species (*e.g.*, fluoride anion). Significant UV-Vis and fluorescence responses to TFA and fluoride anion have been thoroughly examined and analyzed. Our results point to the applicability of π -ADPIs in achieving colorimetric and fluorescence sensing of various acidic and/or anionic species. Moreover, the observations of some ADPI derivatives showing unexpected fluorescence enhancement in response to TFA or TBAF titrations indicate that the appendage groups in these compounds play an important role in dictating their photo-physical properties. It is therefore anticipated that preparation of more arene-appended π -ADPIs would allow diversely behaving fluorophores to be attained, which may be further applied to form sensor arrays for rapid and accurate detection of chemical species of interest. Studies along this direction are underway.
