A polydopamine coating enabling the stable cycling of MnO₂ cathode materials in aqueous zinc batteries†

Guoli Zhang,^a Jiaqi Zhu,^a Lu Lin,^a Yaozhi Liu,^a Shuo Li,^a Qianrui Li,^a Xiao-Xia Liu  ^{*abc} and Xiaoqi Sun  ^{*ab}

MnO₂ is a desired cathode candidate for aqueous zinc batteries. However, their cycling stability is seriously limited by active material dissolution, and pre-addition of Mn²⁺ salts in electrolytes is widely required to shift the dissolution equilibrium. Herein, we synthesize a polydopamine (PDA) coated MnO₂ composite material (MnO₂/PDA) to realize stable cycling in zinc cells without relying on pre-added Mn²⁺. The functional groups on PDA exhibit strong coordination ability with the Mn active material. It not only confines dissolved species within the cathode during discharge, but also enhances their deposition back to the cathode during charge to retrieve the active material. Thanks to this effect, the cathode achieves 81.1% capacity retention after 2000 cycles at 1 A g⁻¹ in the 1 M ZnSO₄ electrolyte, superior to 37.3% with the regular MnO₂ cathode. This work presents an effective strategy to realize the stable cycling of manganese oxide cathode materials in aqueous zinc batteries.

Introduction

Rechargeable aqueous zinc batteries have attracted great attention for their low cost, high safety and environmental friendliness.^{1–10} Zn metal is applied as the anode, providing a high capacity of 820 mA h g⁻¹/5855 mA h cm⁻³ and low redox potential.^{11–13} So far, the main cathode families studied for Zn batteries include Mn-based oxides, V-based oxides, polyanion materials and organic compounds.^{14–16} Among them, manganese oxides show great promise due to their high capacity, relatively high voltage and simple preparation.¹⁷ Various crystal structure control, morphology engineering and composite design methods have been applied to enhance the capacity and rate capability. Meanwhile, MnO₂ has been revealed to undergo complicated energy storage processes in aqueous zinc cells, including the de/intercalation of Zn²⁺ and/or H⁺, conversion reactions, and dissolution–deposition reactions.^{18,19}

One of the most important limiting factors of manganese oxide cathode materials in zinc batteries is rapid capacity fading, which is caused by active material dissolution.^{20,21} The main and most effective strategy for inhibiting dissolution and

promoting cycling stability is to shift the dissolution equilibrium by adding extra Mn²⁺ in electrolytes.^{22–25} Besides, it is proposed that the introduction of pillars, *e.g.*, polyaniline and water, in layered MnO₂ enhances its structural stability and improves capacity retention.²⁶ In addition, heteroatom doping and compositing with conductive compounds^{27,28} have been reported to improve the electrochemical stability of MnO₂. Nevertheless, the majority of MnO₂ studies still rely on pre-added Mn²⁺ salts in electrolytes to achieve reasonable cycling performance.

A possible concern for Mn²⁺ additives, on the other hand, is that they would be oxidized and deposited at the cathode during the charge process,^{29,30} functioning as extra active materials. Therefore, the tests of MnO₂ in electrolytes free of pre-added Mn²⁺ would reflect the cycling performance of the cathodes themselves. In addition to suppressing dissolution, an effective strategy to realize stable cycling would be the recycling of dissolved active material. This can be realized by promoting the deposition of dissolved Mn²⁺ back to the cathode and oxidation to MnO₂ during the charge process. In order to achieve this goal, we herein construct a polydopamine (PDA) coated MnO₂ composite material (MnO₂/PDA). Specifically, PDA contains various active sites to coordinate with the Mn active material. It not only interacts with and confines dissolved active material at the cathode during discharge, but also facilitates the back-deposition of dissolved Mn²⁺ during charge. A stable long-term cycling of the MnO₂/PDA composite material is thus realized. It retains 147 mA h g⁻¹ capacity after 2000 cycles at 1 A g⁻¹ in the ZnSO₄ electrolyte free of Mn²⁺ additives, corresponding to 81.1% capacity retention, superior to only 90 mA h g⁻¹ capacity left (37.3% retention) for the bare MnO₂ material.

Results and discussion

The standard MnO₂ material was obtained by a hydrothermal reaction. To achieve a PDA coating, an *in situ* self-polymerization of dopamine was further carried out. Fig. 1a compares the X-ray diffraction (XRD) patterns of MnO₂ and MnO₂/PDA. Both patterns are well fitted to the alpha-phase MnO₂ (JCPDS: 44-0141),³¹ suggesting that the coating does not affect the crystal structure of MnO₂. The morphology and microstructure of the MnO₂/PDA composite are characterized. The scanning electron microscopy (SEM) image shows a nano-rod morphology with micron-length and a diameter below 100 nm, which resembles that of the original MnO₂ (Fig. 1b and S1†). Fig. 1c shows the high-resolution transmission electron microscopy (HR-TEM) image. Well-resolved lattice fringes with a spacing of 0.51 nm are present in the inner part of the nano-rods, corresponding to the (200) plane of α -phase MnO₂. Meanwhile, an amorphous layer with a thickness below 2 nm is identified on the surface. The energy dispersive X-ray spectroscopy (EDS) elemental mapping reveals the uniformly

distributed Mn, C, and O on the nano-rods (Fig. 1d). This confirms that the amorphous PDA layer is homogeneously coated on the surface of MnO₂.

The composition of MnO₂/PDA is further studied. Fig. 1e shows the Fourier transform infrared spectroscopy (FT-IR) spectra of PDA and MnO₂/PDA. The characteristic vibrations of PDA are shown in the composite material, including that of C–N at 1382.4 cm⁻¹, C=O at 1680.6 cm⁻¹, and N–H/O–H in the range of 3000 cm⁻¹ to 3400 cm⁻¹. Interestingly, these vibrations experience a redshift in comparison to those of bare PDA. Meanwhile, the Mn–O vibration in MnO₂/PDA shows up at 633.3 cm⁻¹ in the Raman spectrum, which is blueshifted compared to that at 630.8 cm⁻¹ in bare MnO₂ (ref. 32 and 33) (Fig. 1f). These changes suggest the coordination between MnO₂ and PDA at the interface and confirm their strong interactions in the composite material.^{34,35} Fig. 1g–i and S2† show the X-ray photoelectron spectroscopy (XPS) spectra of MnO₂/PDA. The C–N peak is identified at 399.8 eV in the N 1s spectrum, and C–O and C=O components are found at 531.2 eV and 532.7 eV in the O 1s spectrum, respectively.³⁶ These species are

Fig. 1 (a) XRD patterns of MnO₂ and MnO₂/PDA. (b) SEM image, (c) HR-TEM image and (d) EDS mapping of MnO₂/PDA. (e) FT-IR of PDA and MnO₂/PDA (inset shows the chemical structure of PDA). (f) Raman spectra of MnO₂ and MnO₂/PDA. (g) N 1s, (h) O 1s, and (i) Mn 2p XPS of MnO₂/PDA.

also present in the C 1s spectrum. Besides, a third O peak is revealed at 529.7 eV in the O 1s spectrum. This corresponds to the lattice oxygen in MnO₂. In the Mn 2p spectrum, the splitting energy between the 2p_{3/2} and 2p_{1/2} peaks is 11.5 eV, which matches well with that of the typical MnO₂ material.^{37–39} Thermogravimetric analysis (TGA) is performed for the MnO₂/PDA composite. As shown in Fig. S3,† the decomposition of PDA takes place after 300 °C, and its weight percent is estimated to be 12%. The molecular weight of PDA is measured to be 1105 with a polydispersity of 3.8 by gel permeation chromatography (GPC).

The electrochemical performance of MnO₂ and MnO₂/PDA cathode materials is studied in zinc cells. The 1 M ZnSO₄ aqueous solution free of Mn²⁺ additives is applied as the electrolyte to evaluate the stability of the cathodes themselves. Galvanostatic charge and discharge is first carried out at a relatively low current density of 0.1 A g⁻¹. As shown in Fig. 2a, the MnO₂ cathode delivers a capacity of 323 mA h g⁻¹ in the first cycle, but it decays significantly in subsequent cycles. Only 222 mA h g⁻¹ capacity is left after 100 cycles. This poor cycling stability is typical for regular MnO₂ cathode materials in aqueous zinc cells, resulting from irreversible active material dissolution. In comparison, the MnO₂/PDA cathode presents much improved stability. The capacity drops slowly from 300 mA h g⁻¹ to 265 mA h g⁻¹ over 100 cycles (Fig. 2b and S4†). The rate performance is studied for the two cathodes (Fig. 2c–e). The MnO₂ cathode again experiences capacity decay at various current densities, and it is more serious at lower current densities. This is attributed to the longer time for the dissolution process at slower rates. Only 92 mA h g⁻¹ capacity is left upon the increase of current density to 2 A g⁻¹, and a poor capacity of 224 mA h g⁻¹ is recovered with the decrease of current density back to 0.1 A g⁻¹. The MnO₂/PDA cathode material, in contrast, presents stable capacity retentions at different current densities. The capacities of 278, 257, 220, 164

and 134 mA h g⁻¹ are obtained at 0.2, 0.3, 0.5, 1 and 2 A g⁻¹, respectively. With the return of current density to 0.1 A g⁻¹, a high capacity of 304 mA h g⁻¹ is still retained.

Long-term cycling is carried out at 1 A g⁻¹ (Fig. 2f). The MnO₂/PDA cathode again presents better cycling performance. The capacity undergoes a short degradation period followed by a gradual increase in subsequent cycles. Considering the complicated energy storage processes of the MnO₂ active material, including one electron transfer and two electron transfer as well as irreversible dissolution of Mn²⁺ in the electrolyte, repeated cycles are required for the stabilization of these processes.⁴⁰ The capacity finally reaches 147 mA h g⁻¹ after 2000 cycles, which is 81.1% that of the initial cycle. This is superior to the MnO₂ cathode, with fast capacity decay during early cycles (Fig. S5†) and only 90 mA h g⁻¹ capacity retained after 2000 cycles. The above analysis demonstrates the largely improved electrochemical performance of the MnO₂ cathode material in aqueous zinc cells with the help of a PDA coating.

Electrochemical impedance spectroscopy (EIS) is carried out for the MnO₂ and MnO₂/PDA electrodes to study the reaction kinetics. Fig. 3a compares the Nyquist plots at 25 °C. It reveals a charge transfer resistance (*R*_{ct}) of 24 ohm for MnO₂, which largely reduces to 10 ohm for MnO₂/PDA. EIS is then performed at various temperatures. As shown in Fig. 3b and c, the semi-circles of MnO₂/PDA all exhibit smaller radii to the ones of MnO₂, suggesting the smaller charge transfer resistance of the former at different temperatures. The activation energy (*E*_a) is further calculated from the linear fits of ln(*R*_{ct}⁻¹) versus 1/*T* plots according to the Arrhenius equation (Fig. 3d). The activation energy of the MnO₂/PDA cathode is calculated to be 32.8 kJ mol⁻¹, which is lower than 40.9 kJ mol⁻¹ of the MnO₂ cathode. This suggests that the reaction kinetics of the MnO₂ material is effectively enhanced with the help of a PDA coating. This is attributed to the facilitated desolvation process of Zn²⁺ and H⁺ by PDA, which coordinates with Zn²⁺ and forms

hydrogen bonds with protons at the interface with its functional groups such as amino and hydroxyl. This ensures the excellent rate capability of the MnO_2/PDA cathode.

The energy storage mechanisms of the cathodes are studied. Fig. 4a compares the XRD patterns of the MnO_2/PDA cathode at the charged and discharged states. The charged electrode presents diffractions from MnO_2 , and extra diffractions from $\text{Zn}_4\text{SO}_4(\text{OH})_6$ show up upon discharge. Besides, SEM images show nano-rods in the charged cathode and extra flakes are formed during discharge (Fig. 4b and c), which is the typical morphology for basic zinc salts.⁴¹ This suggests proton involved

reactions during discharge, including proton intercalation and dissolution processes of MnO_2 based on the following equation: $\text{MnO}_2 + 4\text{H}^+ + 2\text{e}^- = \text{Mn}^{2+} + 2\text{H}_2\text{O}$. The consumption of protons causes a local pH increase and $\text{Zn}_4\text{SO}_4(\text{OH})_6$ precipitation. The recovery of MnO_2 upon charge confirms a reversible cathode reaction. The nano-rod morphology is still retained after long-term cycling (Fig. S6†). Similar XRD and morphology evolutions are found for the bare MnO_2 cathode (Fig. S7†).

The cycling stability of MnO_2 materials is highly dependent on the active material dissolution/deposition phenomenon. To be more specific, the reduction of MnO_2 during discharge would form Mn^{2+} , which easily dissolves in the electrolyte and causes active material loss. Nevertheless, if they can be reversibly deposited back to the cathode during charge, the active material can be effectively recycled. Meanwhile, this $\text{MnO}_2/\text{Mn}^{2+}$ reaction is associated with two-electron transfers and adds capacity to the cathode. The above processes are evaluated for the two cathode materials by measuring the Mn concentration changes in the electrolytes at different states by using inductively coupled plasma (ICP, Fig. 4d). With the bare MnO_2 cathode, the Mn concentrations in the electrolyte at the discharged and charged states are 148 mM and 48 mM, respectively. Notably, the Mn in the electrolyte at the charged state corresponds to the active material not able to deposit back,⁴⁰ and this irreversible loss of active material results in the fast capacity decay of MnO_2 in zinc cells. With the MnO_2/PDA cathode, on the other hand, lower Mn concentrations are obtained at both states, *i.e.*, 108 mM and 6.5 mM, respectively. This suggests that PDA suppresses Mn^{2+} dissolution during discharge to some extent. Importantly, the low Mn concentration at the charged state demonstrates the reversible oxidation of dissolved Mn^{2+} and its re-deposition as MnO_2 at the cathode. In order to further confirm the positive effect of PDA on Mn^{2+}

deposition, cells are assembled with cathodes of carbon cloth or carbon cloth coated with PDA (no MnO₂ material) in the electrolyte 1 M ZnSO₄ + 0.1 M MnSO₄. A constant voltage hold at 2 V is carried out to allow the oxidation of Mn²⁺ in the electrolyte and the deposition of MnO₂ at the cathode. As shown in Fig. S8,† the current response of the carbon cloth electrode decays rapidly and drops below 0.7 mA cm⁻² after only 30 s. In comparison, the current density of the PDA electrode decays much slower, and it takes 1360 s to drop below 0.7 mA cm⁻². The results verify the largely enhanced deposition reaction with the help of PDA. This recycles dissolved active material back to the cathode.

The functioning mechanism of PDA is studied. As discussed earlier in Fig. 1e and f, PDA and MnO₂ exhibit strong coordination interactions. The FT-IR spectra of the MnO₂/PDA cathode at different states show the preservation of PDA vibration peaks (Fig. S9†), suggesting stable interactions during the electrochemical process. We further test the zeta potential of PDA, MnO₂ and MnO₂/PDA (Fig. 4e). The MnO₂ material itself shows a positive zeta potential of around 2 mV, whereas PDA exhibits a negative potential of -23.0 mV. The MnO₂/PDA composite also exhibits a negative value of -17.4 mV. This suggests a negatively charged surface with a PDA component, which provides electrostatic attraction for the dissolved Mn²⁺ cations. Fig. 4f and S10† compare the FT-IR spectra of a PDA suspension in water and MnSO₄ solution. Although many vibrations from PDA are overlapped with those of water, the C–N vibration is identified and shows a redshift in MnSO₄. This is attributed to the coordination between PDA and Mn²⁺, confirming their effective interactions. Therefore, although Mn²⁺ are still formed during the discharge process of the MnO₂/PDA cathode, these cations are linked with PDA species and gather around the cathode, resulting in a lower Mn concentration in the bulk electrolyte at the discharged state. Importantly, this strong interaction promotes the re-deposition of Mn²⁺ back to the cathode during the charge process. This retrieves the active material and ensures the stable long-term cycling of the MnO₂/PDA composite material.

Conclusions

In summary, we present a PDA coating strategy to promote the cycling stability of the MnO₂ cathode material in aqueous zinc batteries without relying on pre-added Mn²⁺ salts in electrolytes. FT-IR and Raman results confirm the coordination between nitrogen and oxygen sites on PDA with Mn components, and ICP reveals reduced Mn concentrations in the electrolyte at both discharged and charged states with the MnO₂/PDA composite cathode in comparison to bare MnO₂. This suggests that the strong interactions of PDA with Mn active material effectively confine the latter at the cathode and help the deposition of any dissolved species back to the cathode during the charge process. Therefore, the active material is well maintained for cathode reactions during the electrochemical process, which ensures a stable cycling performance. In aqueous zinc cells with the ZnSO₄ electrolyte, the MnO₂/PDA composite cathode retains 147 mA h g⁻¹ capacity after 2000

cycles at 1 A g⁻¹. This is superior to the bare MnO₂ material, with only 90 mA h g⁻¹ capacity left without the effects from PDA. Our work demonstrates an effective way to promote the cycling performance of manganese oxide electrode materials in aqueous zinc batteries. It could also be applied to other materials with dissolution problems.
