Antimicrobial resistance (AMR) is a growing threat to health globally, with the potential to render numerous medical procedures so dangerous as to be impractical. There is therefore an urgent need for new molecules that function through novel mechanisms of action to combat AMR. The bacterial DNA-repair and SOS-response pathways promote survival of pathogens in infection settings and also activate hypermutation and resistance mechanisms, making these pathways attractive targets for new therapeutics. Small molecules, such as **IMP-1700**, potentiate DNA damage and inhibit the SOS response in methicillin-resistant *S. aureus*; however, understanding of the structure–activity relationship (SAR) of this series is lacking. We report here the first comprehensive SAR study of the **IMP-1700** scaffold, identifying key pharmacophoric groups and delivering the most potent analogue reported to date, **OXF-077**. Furthermore, we demonstrate that as a potent inhibitor of the mutagenic SOS response, **OXF-077** suppresses the rate of ciprofloxacin resistance emergence in *S. aureus*. This work supports SOS-response inhibitors as a novel means to combat AMR, and delivers **OXF-077** as a tool molecule for future development.

Introduction

Antimicrobial resistance (AMR) is one of the most pressing challenges to global healthcare and is predicted to cause 10 million deaths per year by 2050.¹ The evolution of AMR has been accelerated by improper and overuse of antibiotics in humans and agriculture,² and there is an urgent need for development of new classes of antibiotics.³ However, even when new antibiotics have reached the market, these compounds have been rapidly compromised by the emergence of resistant strains or selection

of bacteria already harbouring resistance to related antibiotics.⁴ Any new antibiotics must therefore be safeguarded as agents-of-last-resort, leading to a limited commercial market and financially disincentivising development.⁵

One aspect of addressing the AMR challenge requires development of new molecules with novel mechanisms of action (MoA). This includes not only new antimicrobial molecules but also compounds that can be partnered with existing antibiotics to block resistance mechanisms and enhance efficacy, such as inhibitors of beta-lactamases or efflux pumps.^{6,7} An emerging target for developing antibiotic adjuvants is the bacterial DNA-repair and SOS-response pathways, which control upregulation of hypermutation, horizontal gene transfer, persister cell formation, and virulence during bacterial stress.^{8–13} DNA damage in the bacterial genome can result from the oxidative burst generated by neutrophils during infection or by treatment with antibiotics such as quinolones, which induce DNA double-stranded breaks (DSBs).

In bacteria, repair of DSBs is initiated by the enzyme complex AddAB, found mainly in Gram-positive bacteria, or RecBCD, found mainly in Gram negatives.⁹ AddAB and RecBCD are ATP-dependent helicase–nucleases that function through complex biochemical mechanisms of DNA processing,^{14–16} ultimately resulting in generation of 3' single-stranded DNA.¹⁵ Multiple

(A) Schematic of the DNA-repair and SOS-response pathways initiated by processing of a DNA double-strand break by AddAB. (B) Structure of DNA-damaging quinolone antibiotic ciprofloxacin (CFX, 1), an inhibitor of DNA gyrase and topoisomerase IV. (C) Structure of first-generation bacterial DNA-repair inhibitor ML-328 (2).²⁰ (D) Structure of MRSA DNA-repair and SOS-response inhibitor IMP-1700 (3).²¹ (E) Overview of prior structure-activity relationship (SAR) investigation of IMP-1700.²¹

copies of RecA protein bind to the single-stranded DNA to form a RecA-DNA filament (RecA*), which invades intact double-stranded DNA to continue homologous recombination.¹⁷ RecA* also binds the transcriptional repressor LexA, triggering LexA autocleavage¹⁸ and initiating expression of SOS box genes, such as error-prone DNA polymerase IV, LexA repressor protein, and DNA gyraseAB (Fig. 1A).¹⁹

AddAB and RecBCD are attractive targets for small-molecule intervention, as these complexes initiate the process leading to both homologous DNA repair and activation of the SOS response. Genetic studies in methicillin-resistant *S. aureus* (MRSA) show AddAB (also known as RexAB in *S. aureus*) is required for infection,²² mutagenic DNA repair²³ and antibiotic tolerance.²⁴ AddAB and RecBCD are highly conserved, with either complex present in approximately 95% of sequenced bacteria;²⁵ thus, small-molecule inhibitors may have broad spectrum activity. AddAB has two nuclease domains and one helicase, whereas RecBCD has two helicases and one nuclease. Sequence homology indicates the helicase-nuclease domains of AddA correspond to RecB, whereas AddB and RecC possess similar inactivated helicase motifs, with an addition nuclease domain in AddB.²⁵ Crystal structures of RecBCD¹⁴ and AddAB²⁶ have confirmed structural similarities, although with further important differences (discussed in detail in ref. 15). Furthermore, no closely related mammalian orthologue has been identified,²⁵ making RecBCD and AddAB attractive antibiotic targets as there may be limited effects on humans. Genetic knockouts have shown that loss of AddAB/RecBCD activity increases the efficacy of DNA-damaging quinolone antibiotics, such as ciprofloxacin (CFX, 1, Fig. 1B).^{9,21} Small-molecule

AddAB/RecBCD inhibitors may therefore increase the efficacy of DNA-damaging antibiotics, and also potentially synergise with non-DNA damaging antibiotics since almost all antibiotics have been shown to upregulate the SOS response to promote bacterial survival and resistance.²⁴ As stand-alone agents, AddAB/RecBCD inhibitors may also promote immune clearance of infections by the host immune response.²²

There have been several reports of AddAB/RecBCD inhibitors, although development has been hindered by mammalian cytotoxicity and lack of *in vivo* efficacy.⁹ ML-328 (2, Fig. 1C) was identified by high-throughput screening against *E. coli* growth in the presence of T4 *gene 2* mutant phage, whose survival is blocked by RecBCD activity.²⁰ Compound 2 inhibits purified RecBCD and AddAB with a half-maximal inhibition (IC₅₀) value of 25 μ M and 5 μ M, respectively.²⁰ A more potent inhibitor, IMP-1700 (3, Fig. 1D), was subsequently developed by substitution of the pipemidic acid substructure with a CFX substructure, based on the potential for DNA intercalation as a mechanism of inhibition, and optimisation of the aromatic thiourea substituent following the Topliss decision tree²⁷ to a 4-(trifluoromethyl) phenyl group (Fig. 1E).²¹ Compound 3 sensitizes clinical MRSA to sub-lethal concentrations of CFX (9.4 μ M) with nanomolar potency and also exhibits modest inhibition of the MRSA SOS response.²¹ However, despite the potentially therapeutically beneficial phenotypes produced by 3, the structure-activity relationship (SAR) of this series remains largely unexplored.

We therefore sought to investigate the SAR of 3 to understand key pharmacophoric requirements for DNA-damage potentiation and SOS inhibition. SAR exploration delivered 39 (OXF-077) as the new best-performing compound from this series, which both potentiates DNA damage and inhibits the evolution of quinolone resistance in *S. aureus*. This work demonstrates the potential of SOS-response inhibitors as a novel means to slow resistance emergence and provides OXF-077 as a valuable tool molecule for future development.

Results and discussion

Design and synthesis of analogues of 3

Building on the development of 3, further exploration was performed at sites where SAR understanding was limited, including the phenyl ring, thiourea linker, quinolone substructure, carboxylic acid and *N*-alkyl substituent (Fig. 1E). Synthetic routes were established to introduce variations at multiple positions within the scaffold of 3 (Schemes 1 and S1-S5†). Compound 3 was synthesised from ethyl 3-(*N,N*-dimethylamino)acrylate and 1,3,4-trifluorobenzoyl chloride, with subsequent cyclisation using cyclopropyl amine to generate the fluoroquinolone subunit 1b.²⁸ *S_NAr* with piperazine and ester hydrolysis using base afforded CFX (1), which was coupled with 4-(trifluoromethyl) phenyl isothiocyanate to give 3 in a 33% yield over five steps (Scheme 1).

Substitution of the phenyl ring was previously optimised, demonstrating *para*-electron withdrawing groups (–CF₃, –NO₂) offered improved potency compared to the *ortho*- or *meta*-substituted phenyl.^{20,21} However, heteroaromatic and aliphatic substituents at this position were not investigated. Reaction of

Scheme 1 Synthesis of compounds **1** and **3**. (A) Reagents, conditions and yields: (i) ethyl 3-(*N,N*-dimethylamino)acrylate, Et₃N, toluene, 80 °C, 20 h (65%); (ii) (a) cyclopropylamine, Et₂O, EtOH, RT, 3 h; (b) K₂CO₃, DMF, 100 °C, 18 h (58%); (iii) (a) piperazine, MeCN, 80 °C, 18 h; (b) NaOH (1 M), 80 °C, 2 h (96%); (iv) 4-(trifluoromethyl)phenyl isothiocyanate, K₂CO₃, MeCN, RT, 18 h (92%). (B) Overview of structure-activity relationship (SAR) investigation in this study, with points of variation of **3** colour coded as phenyl (pink), thiourea (green), piperazine (blue), quinolone (turquoise), carboxylic acid (orange), and cyclopropyl (red). Synthetic routes to specific analogues are presented in ESI Schemes S1–S5,† colour coded as in panel (B).

CFX with either commercial isothiocyanates or amines activated with 1,1'-thiocarbonyldiimidazole afforded analogues **4–7** (Table 1 and Scheme S1†). Further analogues were prepared from reaction of **CFX** with 1,1'-thiocarbonyl compounds to generate analogues **8–10** (Table 1 and Scheme S1†).

Alteration of the thiourea linker was achieved by reaction of **CFX** with 4-(trifluoromethyl)phenyl-substituted electrophiles to form analogues **11–13** (Table 1 and Scheme S1†). Benzothiazole analogue **14** (Table 1) was generated by reaction of 4-amino-3-iodobenzotrifluoride with 1,1'-thiocarbonyldiimidazole, followed by coupling to **CFX** and cyclisation (Scheme S1†). *S*-Alkylated thiourea analogues were formed by reaction of **3** with primary alkyl bromides to afford compounds **15–17** (Table 1 and Scheme S1†).

The SAR of the piperazine group has previously been investigated, showing limited tolerance for variation.²¹ An additional piperazine analogue (**18**, Table 1) was generated by base hydrolysis of **1b**, followed by S_NAr with 4-*N*-Boc-aminopiperidine, and subsequent Boc deprotection followed by 4-(trifluoromethyl)phenyl thiourea formation (Scheme S2†).

The SAR of the quinolone substructure of **3** is unexplored; therefore quinolone analogues were prepared by S_NAr of fluoro-benzyl compounds with piperazine, followed by thiourea formation as previously described to give analogues **19–25** (Table 1, Scheme S3†). Further bicyclic aromatic heterocycles were prepared from 3,4-difluoroaniline or 2-amino-4,5-difluorobenzoic acid (Scheme S3†), and used to form quinolone analogues **26–32** (Table 1).

Alteration of the carboxylate of **3** was achieved *via* intermediate **1b** (Table 1); ethyl ester analogue **33** was generated by piperazine S_NAr and subsequent thiourea coupling (Scheme S4†). Alternatively, functionalisation of the carboxylate was achieved by hydrolysis of **1b** and amide coupling with *N*-Boc-ethanolamine, followed by S_NAr with piperazine and subsequent thiourea formation. *N*-Boc-deprotection afforded aminoethyl ester **34**,

which was rearranged under basic conditions to afford hydroxyethyl amide **35** (Table 1, Scheme S4†).

To investigate the *N*-alkyl substituent of the fluoroquinolone substructure, for which no prior SAR information was available, analogues **36–39** (Table 1) were prepared by two routes. Firstly, the fluoroquinolone substructure was prepared through a Gould–Jacobs reaction of 3,4-difluoroaniline and diethyl ethoxymethylenemalonate and subsequently alkylated to generate precursors to **36** and **37** (Scheme S5†). Secondly, intermediate **1a** was reacted with alkyl amines to afford precursors to **38** and **39** (Scheme S5†). Lastly, a urea analogue of compound **39** was synthesised using 4-(trifluoromethyl)phenyl isocyanate to afford compound **40** (Scheme S5†).

Collectively, a panel of 37 analogues of **3** were synthesised, with variation introduced at multiple positions in the scaffold.

Potential of CFX antibacterial activity in MRSA

The prepared panel of analogues was tested in *S. aureus* JE2, a clinical MRSA strain of the USA300 lineage dominant in the USA, for potentiation of DNA damage induced by **CFX**. JE2 has multiple resistance elements, including a mutated DNA gyrase (Ser84Leu)^{29,30} conferring **CFX** resistance with a minimum inhibitory concentration (MIC) = 8 µg mL^{−1} (24 µM) (Fig. S1†). Determination of the half-maximal growth inhibition (IC₅₀) of **3** at varying **CFX** concentrations in JE2 indicated decreased potency of **3** at lower **CFX** concentrations (Fig. S1†), consistent with previous reports of quantitative synergy between **3** and **CFX**.²¹ Growth inhibition by analogues was measured either as single agents or in combination with the highest concentration of **CFX** at which ≥90% bacterial growth occurred (6.1 µM), a lower **CFX** concentration than used in previous reports of DNA-damage potentiation by **3** (9.4 µM).²¹ To compare the activity of compounds, the fold-change in growth IC₅₀ between

treatment with compound alone compared to compound with CFX (Δ CFX) was calculated as a proxy measure of DNA-damage potentiation. For compounds not exhibiting toxicity at the top concentration tested (10 μM), the Δ CFX value therefore represents the lower limit of fold change in growth inhibition in the presence of CFX.

In JE2, the growth IC₅₀ of 3 with CFX was 71 nM, compared to a single agent IC₅₀ of 7.6 μM (Table 1, Δ CFX = 110), in-line with previous studies with higher CFX concentration.²¹ Exchange of

the phenyl substituent to aliphatic groups (4, 5) resulted in a loss of CFX potentiation. In the development of 3, electron withdrawing phenyl ring substituents were found to increase CFX potentiation;²¹ however, analogues with an electron-withdrawing nitrile substituent (6), or heterocyclic substituents (7, 8, 10), showed a loss of CFX potentiation. *O*-Phenyl thiocarbamate 9 retained moderate potentiation of CFX (IC₅₀ = 6.0 μM, IC₅₀ + CFX = 650 nM, Δ CFX = 9.2). Collectively, this indicated the

Fig. 2 Structure–activity relationship (SAR) study of DNA-repair and SOS-response inhibitors in methicillin-resistant *S. aureus* (MRSA). (A) Schematic of MRSA JE2 SOS reporter assay; SOS response was calculated as the ratio of GFP fluorescence to OD₆₀₀. (B) SOS response inhibition (%) by analogues at 2.5 μM compared to Δ CFX of compounds (Table 1). ● = IC₅₀ values ± CFX calculated in CFX-potentiation assay; ○ = one or both IC₅₀ > 10 μM in CFX-potentiation assay. Data points are colour coded corresponding to the position of variation in the structure of 3, as in Scheme 1, Table 1 and (C). Literature compounds 2 and 3 (black) are also shown. (C) Overview of SAR conclusions from this work. (D) Dose–response analysis of SOS inhibition (%) by selected compounds. Data represent mean ± SEM (*n* = 3). (E) Dose–response analysis of growth inhibition (%) by selected compounds, in the presence (solid line) or absence (dashed line) of CFX. Data represent mean ± SEM (*n* = 3). (F) Structure of best performing compound OXF-077 (39).

optimised 4-(trifluoromethyl)phenyl substituent of **3** afforded the highest potency of all analogues tested (Table 1).

Substitution of the thiourea linkage for a urea in compound **11** exhibited no single-agent growth inhibition ($IC_{50} > 10 \mu M$), with retention of sub-micromolar CFX potentiation ($IC_{50} + CFX = 200 \text{ nM}$, $\Delta CFX \geq 50$). Exchange of the thiourea for other linkers (**12–14**) led to a decrease in CFX potentiation. In contrast to exchange of the thiourea, *S*-alkylation appeared to be more tolerated. Benzylated analogue **15** retained activity ($IC_{50} = 8.5 \mu M$, $IC_{50} + CFX = 360 \text{ nM}$, $\Delta CFX = 24$); however, *S*-acetyl analogues **16** and **17** resulted in a loss of CFX potentiation. Substitution of the piperazine linker for 4-aminopiperidine (**18**) exhibited moderate toxicity both with and without CFX ($IC_{50} 4.6 \mu M$, $IC_{50} + CFX = 1.2 \mu M$, $\Delta CFX = 3.8$).

Analogues **19–32** substituting the quinolone substructure, as well as carboxylic acid analogues **33–35**, demonstrated these alterations substantially decreased CFX potentiation (Table 1). In contrast, variation of the *N*-alkyl substituent of the quinolone was more broadly tolerated. Exchange of the cyclopropyl for a benzyl group (**36**) abolished CFX potentiation, whereas 4-fluorobenzyl analogue **37** retained activity ($IC_{50} > 5.0 \mu M$, $IC_{50} + CFX = 190 \text{ nM}$, $\Delta CFX > 26$). Exchange of the cyclopropyl for ethyl (**38**) or isopropyl (**39**) resulted in low growth inhibition as single agents ($IC_{50} > 5.0 \mu M$ and $>10 \mu M$, respectively). Treatment with CFX resulted in $IC_{50} + CFX = 99 \text{ nM}$ (**38**) and 39 nM (**39**). This gives **38** $\Delta CFX = 51$, and **39** $\Delta CFX \geq 260$, which makes **39** a more potent DNA-damage potentiator than **3** in clinical MRSA (Table 1).

Thioureas can be a point of metabolic instability in small molecules;³¹ therefore, an analogue of best-performing compound **39** was prepared, substituting the thiourea for a urea (Scheme S5†). Composite analogue **40** retained DNA-damage potentiation ($IC_{50} > 10 \mu M$, $IC_{50} + CFX = 600 \text{ nM}$, $\Delta CFX > 17$), consistent with prior SAR data, although DNA-damage potentiation of **40** was reduced compared to cyclopropyl-containing urea analogue **11**.

Potentiation of CFX was also investigated in *E. coli* (K12 MG1655) containing a Ser83Leu *gyrA* mutation; however, compound **3** and the panel of analogues did not show activity (Fig. S2, and Table S1†). Cell penetration and efflux in Gram-negative bacteria present an additional challenge for small-molecule inhibitors and are common reasons for lack of activity in these species.^{32,33} Optimisation of Gram-negative activity therefore remains an important goal for future work.

Compound effects on the SOS response in MRSA

The compound panel was further assessed for inhibition of the SOS response in a JE2 cellular reporter assay, expressing GFP under control of the *recA* promoter, *precA-gfp* (Fig. 2A).²⁴ An overnight culture of JE2-*precA-gfp* was diluted 16-fold in MHB containing CFX (96 μM) to activate the SOS response, and GFP fluorescence per OD₆₀₀ unit (GFP/OD₆₀₀) measured after 6 h incubation. A higher cell seeding density and CFX concentration were used in these assays compared to growth inhibition assays to increase the SOS response signal recorded. SOS inhibition (%) was initially assessed at 2.5 μM test compound, with best performing analogues progressed to dose-response

analysis (Table 1). At 2.5 μM , **2** and **3** inhibited the SOS response by 25% and 60%, respectively. Phenyl analogues **5**, **7**, and **8** displayed <20% SOS inhibition, whereas cyclohexyl (**4**, 39%), 4-cyanophenyl (**6**, 42%), *O*-phenyl thiocarbamate (**9**, 46%), and 2-pyridone (**10**, 45%) analogues exhibited modest SOS inhibition. Thiourea analogues **12–14** showed decreased SOS inhibition; however, urea **11** (62%), thiourea benzyl adduct **15** (59%), and composite compound **40** (65%) all retained activity. Substitution of the piperazine ring for 4-aminopiperidine (**18**) retained a modest level of SOS inhibition (42%). Quinolone analogues showed decreased SOS inhibition, whereas variation of the cyclopropyl group was again more broadly tolerated. 4-Fluorobenzyl (**37**, 57%), ethyl (**38**, 66%), and isopropyl (**39**, 69%) analogues all showed similar or improved SOS inhibition compared to **3** (Table 1).

Comparison of SOS inhibition and DNA-damage potentiation (ΔCFX) indicated a statistically-significant correlation between potency in both assays (Spearman correlation $r = 0.72$, $P < 0.0001$, Fig. 2B), potentially indicative of a common mechanism or target in these effects. Matched thiourea/urea pairs (compounds **3** and **11**, and compounds **39** and **40**) showed increased activity with the more lipophilic thiourea analogues. However, comparison of lipophilicity ($cLogD_{pH 7.4}$) against SOS inhibition or CFX potentiation across the analogue panel did not show increased activity with increased $cLogD$ in either assay (Fig. S3†), suggesting lipophilicity was not a general driver of activity. Alteration of the quinolone, piperazine, and (4-trifluoromethyl)phenyl rings decreased potency in both assays, whereas analogues at the cyclopropyl and thiourea positions were tolerated and resulted in modest increases in DNA-damage potentiation and SOS inhibition. Interestingly, ethyl ester analogue **33** inhibited the SOS response (58%) but showed no growth inhibition in DNA-damage potentiation assays ($\Delta CFX = 1$). Further investigation will be required to determine if this is a result of cellular ester hydrolysis, or if the SAR for these effects is divergent. A structural map summarising the collective findings from the SAR study is presented in Fig. 2C.

The best performing SOS inhibitors at each variation position that exhibited no single-agent growth inhibition (**11**, **33**, **39** and **40**) were further analysed in dose-response, alongside literature compounds **2** and **3**. SOS inhibition reached a maximum upper plateau of ~60% compared to no-CFX activation control; the inability to achieve complete SOS inhibition may result from partial pathway inhibition, SOS activation *via* additional pathways, or background GFP expression. Literature compounds **2** and **3** exhibited $IC_{50} > 10 \mu M$ and = 730 nM, respectively (Fig. 2D). Ethyl ester analogue **33** had $IC_{50} = 470 \text{ nM}$, although a decrease in SOS inhibition was observed above 5 μM (Fig. S4†), potentially due to limited solubility. Collectively, dose-response analysis of the selected compounds was in good agreement with CFX potentiation dose-responses (Fig. 2E).

Isopropyl analogue **39** was the most potent compound, with SOS inhibition $IC_{50} = 290 \text{ nM}$. Urea analogue **11** possessed $IC_{50} = 3.3 \mu M$, and the composite urea and isopropyl analogue **40** exhibited $IC_{50} = 900 \text{ nM}$. Across both assays, compound **39** was

the best-performing CFX potentiator and SOS inhibitor, which we here term **OXF-077** (Fig. 2F).

A recent report assessing single agent toxicity of **2** and **3** in *E. coli* using genetic methods suggests these compounds act through inhibition of DNA gyrase or topoisomerase IV, potentially resulting from the presence of quinolone substructures.³⁴ Cleavage of the thiourea bond of this series under assay conditions could release the quinolone subunit and result in inhibition of gyrase/topoisomerase IV. Aqueous stability of **2**, **3**, **11**, **OXF-077** and **40** was therefore assessed in PBS, using HPLC to measure release of the corresponding quinolone subunits (Fig. S5†). Release of pipemidic acid from **2** increased over time; however, only 5% fragmentation was observed after 48 h at 37 °C. Analogues of **3** showed <2% quinolone release over 48 h, with **OXF-077** displaying improved stability compared to **3** (Fig. S5†), indicating these compounds are not readily degraded in aqueous solution at 37 °C over the timeframe of biological assays. Release of quinolone subunits in intact cells, potentially as the result of enzymatic degradation, is an alternative route to generate quinolone-like phenotypes. Activation of the SOS response by **2**, **3**, **11**, **33**, **OXF-077**, **40** and **CFX** as single agents was therefore assessed in the SOS reporter assay. Analogues of **3** did not activate the SOS response at concentrations ≤10 μM (Fig. S4†), consistent with their lack of cytotoxicity as single agents ≤10 μM (Table 1). In contrast, DNA gyrase/topoisomerase IV inhibitor **CFX** activated the SOS response as a single agent (Fig. S4†) and did not inhibit the SOS response when already activated (Fig. 2C). Collectively, these data suggest the best performing compounds may act *via* a distinct mechanism of action in DNA-damage potentiation and SOS inhibition to canonical DNA gyrase/topoisomerase IV inhibitors. Toxicity of **2** and **3** to bacteria as single agents, rather than when used in combination with a DNA-damaging antibiotic, may be indicative of binding to ‘off-targets’ at high concentrations. In this regard, engagement of DNA gyrase/topoisomerase IV by this compound series may be possible if sufficiently high concentrations are used; however, this does not preclude binding of other biologically relevant targets, such as DNA-damage repair enzymes, at lower concentrations where compounds will act more selectively. Single-agent toxicity and a lack of **CFX** potentiation, for example as observed for compound **14** or **18**, may be indicative of molecules acting through gyrase/topoisomerase IV inhibition. Robust determination of the target(s) and mechanism(s) of action of this series therefore remain key unanswered questions for future investigation.

OXF-077 effect on antibiotic potency and resistance evolution

A range of antibiotics induce the SOS response in *S. aureus*, with *addB* transposon insertion mutants showing increased antibiotic sensitivity,²⁴ putatively through production of ROS during antibiotic treatment. However, potentiation of other antibiotic classes by **3** has not been investigated. **OXF-077**, **2** and **3** (5.0 μM) were therefore tested for MIC reduction of **CFX**, ampicillin, cefazolin, vancomycin, gentamicin, and linezolid in JE2 MRSA (Table 2). This revealed **3** reduced the MIC of **CFX** and gentamicin 2-fold. **OXF-077** reduced gentamicin MIC 4-fold, as

Table 2 Potentiation of antibiotic activity by analogues of **3**. Minimum inhibitory concentration (MIC) of antibiotics assessed against JE2 MRSA in the presence of either DMSO vehicle or analogues **2**, **3**, and **OXF-077** (**39**) (5.0 μM, *n* = 3)

Antibiotic	MIC	MIC-fold reduction		
	μg mL ⁻¹ (μM)	2	3	OXF-077
CFX	8 (24)	1	2	2
Ampicillin	1 (2.9)	2	1	1
Cefazoline	1 (2.2)	2	1	1
Vancomycin	1 (0.7)	2	1	2
Gentamicin	1 (2.1)	2	2	4
Linezolid	2 (5.9)	1	1	1

well as reducing **CFX** and vancomycin MIC 2-fold. The decreases in antibiotic MIC are not as substantial as the decrease in **OXF-077** IC₅₀ with sub-lethal **CFX**; however, these values are in-line with quantitate drug-synergy measurements showing a 2.8-fold dose-reduction index of **3** with **CFX**²¹ and 4-fold reduction of **CFX** MIC in *addB* transposon insertion mutants.²⁴

The SOS response initiates expression of error-prone DNA polymerases which increase mutation rates and thus promote the evolution of antibiotic resistance.¹⁹ The effect of **OXF-077** on **CFX**-resistance evolution was therefore investigated by serial passage of a **CFX**-susceptible strain of methicillin-sensitive *S. aureus* (MSSA), SH1000.²¹ SH1000 has 32-fold higher **CFX** susceptibility compared to the clinical JE2 isolate, with **CFX** MIC = 0.25 μg mL⁻¹ (0.75 μM, Fig. S1†). Briefly, a **CFX** titration was used to determine MSSA **CFX** susceptibility with either **OXF-077** (5.0 μM) or DMSO vehicle after overnight growth. Culture from the highest concentration of **CFX** at which ≥90% bacterial growth occurred was then used to inoculate the next **CFX**-susceptibility determination passage with either **OXF-077** (5.0 μM) or DMSO vehicle; this process was repeated for 14 consecutive passages (Fig. 3A). MSSA passaged with either **CFX** + **OXF-077** or **CFX** + DMSO both showed a ~5-fold decrease

Fig. 3 Inhibition of **CFX** resistance evolution with **OXF-077**. (A) Serial passage of MSSA with **CFX** in the presence of **OXF-077** (5.0 μM) or DMSO vehicle, showing **OXF-077** inhibited the rate of **CFX** resistance evolution. Data represent mean ± SEM (*n* = 3). (B) **CFX** MIC of strains resulting from the serial passage experiment shown in panel (A), measured using the Clinical and Laboratory Standards Institute (CLSI) method M07-A11.³⁵ Either **OXF-077** (5.0 μM) or DMSO was added as a co-treatment to investigate the effect of **OXF-077** on cells once **CFX** resistance had evolved (*n* = 3). Blue dotted line indicates the EUCAST clinical breakpoint for **CFX** (2 μg mL⁻¹).

in CFX susceptibility over the first five passages. After this initial decrease, the CFX susceptibility of cells passaged with CFX + OXF-077 remained at 3.0 μM . In contrast, MSSA passaged with CFX + DMSO continued to become progressively less susceptible and, after 14 passages, CFX susceptibility was 80 μM , a ~ 50 -fold decrease in susceptibility. The ~ 5 -fold decrease in CFX susceptibility observed over passages 1–5 with CFX + OXF-077 may reflect upregulation of non-mutational resistance mechanisms, such as efflux pumps. DNA sequencing of strains passaged with OXF-077 may provide further mechanistic insight into the target of this series and resistance mechanisms. The effect of OXF-077 (5.0 μM) or DMSO alone on CFX susceptibility was also determined by serial passage without CFX, which indicated CFX susceptibility remained constant for both conditions over 14 passages (Fig. S6†).

To assess the clinical relevance of suppressed CFX resistance evolution, the CFX MICs of isolates resulting from the serial passage were measured using the Clinical and Laboratory Standards Institute (CLSI) method M07-A11³⁵ (Fig. 3B). Isolates arising from serial passage with CFX + DMSO had a CFX MIC of 4 or 8 $\mu\text{g mL}^{-1}$, which is above the CFX clinical breakpoint for *S. aureus* of 2 $\mu\text{g mL}^{-1}$ as defined by the European Committee on Antimicrobial Susceptibility Testing (EUCAST).³⁶ In contrast, isolates resulting from serial passage with CFX + OXF-077 had a CFX MIC of 1 $\mu\text{g mL}^{-1}$, remaining below the EUCAST clinical breakpoint even after serial passage with the antibiotic.³⁶ The CFX MIC of isolates from the serial passage were also determined with OXF-077 co-treatment using the CLSI method (Fig. 3B). Isolates from serial passage with either CFX + OXF-077 or CFX + DMSO had a CFX MIC of 0.25 $\mu\text{g mL}^{-1}$ when co-treated with OXF-077, indicating that OXF-077 reduced the CFX tolerance to below the EUCAST clinical breakpoint.³⁶ The CFX MIC of these isolates when co-treated with OXF-077 was also equal to the CFX MIC of isolates that had been serially passaged with OXF-077 or DMSO alone and had not been exposed to CFX (Fig. S6†).

Collectively, these data therefore indicate that not only can OXF-077 slow the evolution of resistance against CFX, but also that OXF-077 can re-sensitize bacteria that have already acquired resistance to CFX, reducing the MIC to the level of bacteria that have not been exposed to the antibiotic. The previously noted potential for this series to engage DNA gyrase/topoisomerase IV at higher concentrations raises the interesting possibility of optimising compounds that could simultaneously induce DNA damage and also inhibit DNA repair and the SOS response. Such compounds may show decreased rates of resistance emergence compared to traditional quinolone antibiotics.

Conclusions

AMR is one of the most serious public health threats and presents multifaceted challenges to development of new treatments, including technical difficulties and financial barriers.¹ One aspect of addressing this challenge is the development of new molecules with novel mechanisms of action. Bacterial DNA repair inhibitors may act as antibiotic adjuvants to potentiate the efficacy of failing

DNA damaging antibiotics, such as CFX, or slow emergence of resistance to new antibiotics which activate the SOS response.^{9,20,21} IMP-1700 (3) was previously optimised as a potentiator of DNA-damage in MRSA; however, SAR information was limited.²¹

We report here the first comprehensive exploration of the scaffold of 3 with variation at multiple structural positions, identifying the thiourea and *N*-alkyl groups as sites tolerating modification. We further demonstrate a statistically significant correlation between DNA-damage potentiation and SOS-response inhibition across the series, suggesting a common mechanism in these effects. Compounds in this series have been proposed to inhibit AddAB in *S. aureus*,²⁰ a component of both the DNA damage repair and SOS pathways, although the cellular target(s) remain to be robustly determined. The best-performing compound in this series, OXF-077, reduced the rate of CFX resistance evolution in *S. aureus* and re-sensitized *S. aureus* to a concentration of CFX below the clinical breakpoint once resistance had emerged. OXF-077 (39) is therefore a valuable tool molecule for further development, guided by the SAR presented here, to explore the potential of bacterial DNA-repair and SOS inhibitors in combatting the global challenge of AMR.

Data availability

Synthetic procedures, compound characterisation, biological methods and supplementary data can be found in the ESI.†

Author contributions

J. D. B., T. H., A. M. T., O. T., G. L. M., V. R., L. J. M., E. K. T., and K. G. synthesised compounds. J. D. B., A. M. T., A. Y. S., and Y. Z. performed testing. A. M. E., G. R. S., T. R. W., and T. L.-H. were responsible for funding acquisition. A. M. E., C. J. G.-H., G. R. S., P. M. R., T. R. W., and T. L.-H. supervised the research. J. D. B., A. M. T., and T. L.-H. wrote the manuscript with input from all authors.
