Helical polyisocyanide-based macroporous organic catalysts for asymmetric Michael addition with high efficiency and stereoselectivity†

Xun-Hui Xu,[ad] Run-Tan Gao,[b] Shi-Yi Li,[b] Li Zhou, [ID] *[a] Na Liu[c] and Zong-Quan Wu [ID] *[b]

Porous materials have attracted interest due to their high specific surface area and rich functionality. Immobilizing organocatalysts onto porous polymers not only boosts enantioselectivity but also improves the reaction rates. In this work, a series of porous polymers C-poly-3_ms with rigid polyisocyanide-carrying secondary amine pendants as building blocks were successfully prepared. And the pore size and optical activity of C-poly-3_ms can be controlled by the length of the polyisocyanide blocks due to their rigid and helical backbone. C-poly-3_{150} demonstrated a preferred left-handed helix with a θ_{364} value of -8.21×10^3. The pore size and S_{BET} of C-poly-3_{150} were 17.52 nm and 7.98 m^2 g^{-1}, respectively. The porous C-poly-3_{150} catalyzes the asymmetric Michael addition reaction efficiently and generates the target products in satisfactory yield and excellent enantioselectivity. For **6ab**, an enantiomeric excess (ee) and a diastereomeric ratio (dr) up to 99% and 99/1 could be achieved, respectively. The recovered catalyst can be recycled at least 6 times in the asymmetric Michael addition reaction while maintaining activity and stereoselectivity.

Introduction

In the past few decades, porous materials have attracted considerable attention from academia and industry due to their wide range of potential applications in storage, separation, catalysis, and other fields.[1–5] A variety of new functional porous materials have been developed, such as metal–organic frameworks (MOFs), covalent organic frameworks (COFs), and porous organic polymers (POPs).[6–10] Among them, POPs have been widely studied because of their facile synthesis and diverse synthesis methods.[11–14] Generally, the pore sizes of the reported porous polymers are not uniform and cover a wider range due to the limitations of the synthetic methods.[15] Therefore, it is meaningful to develop a strategy for preparing porous polymers with controllable pore size through living polymerization.[16,17]

Among many kinds of polymers, polyisocyanides have aroused the continuous interest of researchers because of their facile available materials, convenient polymerization methods and controllable structures.[18–21] The polyisocyanide consists of a carbon backbone with carbon–carbon single bonds, and each carbon atom in the backbone carries substituent groups. Due to the steric effect of the pendants on each atom of the main chain, polyisocyanide adopts a rod-like structure and twists into a helical shape.[22,23] As one of the rigid organic polymers, the persistence length of isotactic helical polyisocyanide can be reached to *ca.* 200 nm.[24,25] Therefore, polyisocyanide is a desirable building block with sufficient rigidity to support the frameworks for the construction of porous materials.

Asymmetric organocatalysis has developed rapidly since the early 2000s, and as this method has matured, it was adopted in industry to produce chiral drugs, natural products, and bioactive molecules.[26–31] The early development of asymmetric organocatalysis used only small organic molecules as chiral catalysts, such as alkaloid derivatives, amino acid derivatives and phosphoric acid.[32–34] The subsequently developed catalysts with polymer-supported groups showed strong competitiveness.[35,36] Polymer-supported catalysts solve the problems of uneconomical and difficult product purification since this type of catalyst can be easily recovered from the reaction mixture and reused.[37,38] In the past few decades, a variety of polymer backbones such as polystyrene, polyacetylene and polymethacrylate have been developed to support catalytic groups.[39–41] Artificial helical polymers, one of the special species of polymer

† Electronic supplementary information (ESI) available. See DOI: https://doi.org/10.1039/d4sc01316f
materials, have broad applications in many fields, such as chiral separation, chiral recognition, asymmetric catalysis, liquid crystallization and circularly polarized light generation due to their helical backbone.[42–46] Among them, polyisocyanide exhibits unique advantages because of its rigid helical structure. The static helical orientation of the polyisocyanide backbone can provide an additional asymmetric environment, which exhibits synergistic effects, amplifying effects such as stereoselectivity of asymmetric reactions.[47–49]

Then, polyisocyanide-based porous polymers should have significant advantages in asymmetric organocatalysis. In this work, we not only establish a strategy for constructing a porous polymer framework using optically active rigid polyisocyanides as structural units but also explore the application of this framework in asymmetric Michael addition reactions. First, a four-arm polymer 4-poly-1_ms was obtained by polymerizing isocyanide monomer **1** using the four-arm catalyst 4-Pd(II) as the initiator (Scheme 1). Then, through crosslinking the chain ends of 4-poly-1_ms, the porous polymers C-poly-1_ms were generated (Scheme 1). The excellent iodine adsorption capacity and variable pore size of C-poly-1_ms have also been verified.[17] In this project, the protective *tert*-butoxycarbonyl group (BOC) was removed from the porous polymers to obtain novel porous polymers, C-poly-3_ms (Scheme 1). Previously, we proved that linear polymer poly-3_ms could serve as an organocatalyst for asymmetric Michael addition reactions with satisfactory stereoselectivity and a lower reaction rate.[50] We speculate that the porous polymer catalyst may be beneficial for not only improving the stereoselectivity but also accelerating the reaction rate. Because of the preferred left-handed helix of the polyisocyanide main chain, the resulting C-poly-3_ms also showed high optical activity. C-poly-3_ms show excellent performance in catalyzing asymmetric Michael addition reactions. Under optimized reaction conditions, the asymmetric Michael addition reaction catalyzed by C-poly-3_{150} gave the desired product in high yields (>80%) with a diastereomeric ratio (dr) of 99/1 and an enantiomeric excess (ee) of 99% for the main

product. Importantly, the dr and ee values of the catalytic product catalyzed by C-poly-3_{150} were significantly higher than those achieved under catalysis of the linear polymer poly-3_{150}. Taking advantage of its heterogeneous catalysis, C-poly-3_{150} can be facilely recovered from the reaction mixture and could catalyze the asymmetric Michael addition for at least 6 cycles while maintaining selectivity and activity.

Results and discussion

Macroporous organic catalysts C-poly-3_ms were synthesized and prepared according to the previous work reported by our group.[17] First, the polymer 4-poly-1_{20} was generated through the polymerization of monomer **1** using the four-arm initiator 4-Pd(II). Size exclusion chromatography (SEC) analysis of 4-poly-1_{20} showed a single modal and narrow elution peak. The M_n and M_w/M_n of 4-poly-1_{20} determined by SEC were 13.8 kDa and 1.19, respectively (Fig. 1a). Further, a series of polymerizations were performed at different ratios of **1** to 4-Pd(II). The generated 4-poly-1_ms showed single-peak SEC curves, and the M_w/M_n values were less than 1.24, proving that the polymerization process followed a living/controlled polymerization mechanism. Furthermore, there was a linear relationship between M_n and the feed ratio of **1** to 4-Pd(II) (Fig. 1b). Therefore, a series of 4-poly-1_ms with different M_n values and narrow M_w/M_n could be obtained by adjusting the ratio of **1** to the 4-Pd(II) catalyst (Table S1 in the ESI†). Then, the ^{1}H nuclear magnetic resonance (NMR) and Fourier transform infrared spectroscopy (FT-IR) analyses were performed to confirm the structures of the synthesized polyisocyanides. The expected resonances of the phenyl rings and the BOC pendants at 8.15–6.67 and 1.45 ppm could be clearly distinguished in the ^{1}H NMR spectrum of 4-poly-1_{20} (Fig.

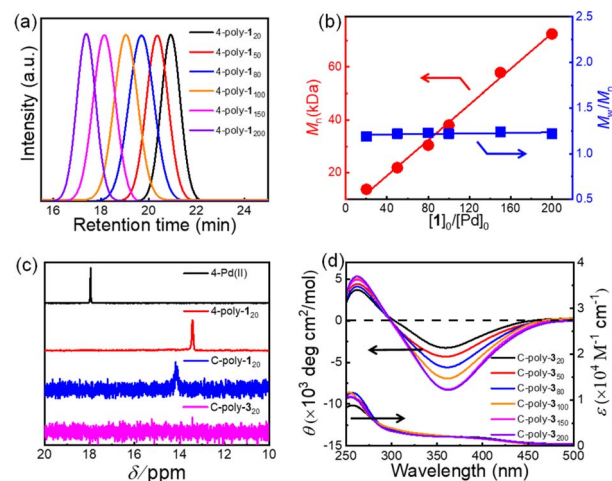

Fig. 1 (a) SEC curves for 4-poly-1_ms obtained by initiating with 4-Pd(II) with various initial feed ratios of monomer **1** to the initiator. (b) Plots of M_n and M_w/M_n values of 4-poly-1_ms as a function of the initial **1**-to-Pd(II) ratio. The values of M_n and M_w/M_n were recorded by SEC with polystyrene standards using tetrahydrofuran (THF) as eluent at 40 °C. (c) ^{31}P NMR spectra of 4-Pd(II), 4-poly-1_{20}, C-poly-1_{20} and C-poly-3_{20} recorded in CDCl$_3$ at 25 °C. (d) The CD and UV-vis spectra of film state C-poly-3_ms at 25 °C.

Scheme 1 (a) Fabrication of porous organic frameworks using polyisocyanides as frame blocks. (b) Synthesis route of compound **7**.

S1, ESI†). In the FT-IR spectrum of 4-poly-1_{20}, a characteristic vibration of the C=N bonds was observed at about 1605 cm^{-1} (Fig. S2, ESI†). The ^{31}P NMR spectrum could be used to corroborate the successful polymerization. A new characteristic signal shift in the ^{31}P NMR spectrum of 4-poly-1_{20} appeared at 13.5 ppm, accompanied by the complete disappearance of the ^{31}P NMR signal of 4-Pd(II) at 17.9 ppm (Fig. 1c). All of these results showed that the four Pd(II) units on the 4-Pd(II) catalyst had the same activity and participated in the process of the polymerization of monomer **1**. Furthermore, the optical activity of 4-poly-1_ms was investigated by circular dichroism (CD) and UV-vis spectroscopy. The isolated 4-poly-1_ms showed intense negative CD in the absorption region of the polyisocyanide backbone around 364 nm, suggesting the formation of a preferred left-handed helix, and the maximum intensity was recorded for the polymer with a degree of polymerization (DP) value close to 150 (Fig. S3, ESI†).

Subsequently, the active Pd(II) complexes on the chain ends of 4-poly-1_ms were crosslinked through the insertion of the bifunctional isocyanide monomer **2** at 55 °C in CHCl$_3$, as depicted in Scheme 1 ($[2]_0/[Pd]_0 = 1/2$). Thus, the porous polymers C-poly-1_ms were obtained in a gel state and could be precipitated in methanol, after which they were collected in high yields by centrifugation (run 1, 3, 5, 7, and 9, Table 1). The possibility of intramolecular crosslinking had been proved to be difficult to take place due to the limited length of crosslinker **2** according to density functional theory (DFT) calculations in our previous work.[17] The ^{1}H NMR and FT-IR spectra of the crosslinked polymer C-poly-1_{20} were similar to those of the 4-poly-1_{20} precursor (Fig. S2 and S4, ESI†), indicating that the chemical structures of the polyisocyanide segments were maintained. In the ^{31}P NMR spectrum of the porous polymer C-poly-1_{20}, the signal at 13.5 ppm completely disappeared, and a new resonance signal appeared at 14.1 ppm (Fig. 1c). The CD and UV-vis spectra of C-poly-1_ms film showed that C-poly-1_ms had similar properties to the precursor 4-poly-1_ms. The ellipticity of the C-poly-1_ms backbone at 364 nm (θ_{364}) increased with the increase in DP, and the θ_{364} value remained constant when DP was higher than 150 (Fig. S5, ESI†).

Next, the protecting BOC groups and Pd(II)-terminals of C-poly-1_ms were removed using a mixture of trifluoroacetic acid (TFA) and dichloromethane at room temperature. After removing the BOC groups and neutralizing with ammonia solution, C-poly-3_ms with poor solubility in most common organic solvents except CH$_3$OH were obtained by precipitation in n-hexane (Scheme 1). However, the lower yield of the C-poly-3_ms may be attributed to the incomplete neutralization of the ammonium trifluoroacetate on the pendants in the interior of the polymer network structure. These resulted in a small amount of the polymer ammonium dissolving in water, leading to a slightly reduced yield. The disappearance of the *tert*-butyl resonance at 1.45 ppm in the ^{1}H NMR spectrum of C-poly-3_{20} also confirmed the removal of the BOC groups (Fig. S6, ESI†). Furthermore, it was demonstrated that the resonance signal of CH$_2$ on the crosslinker **2** appeared at 1.31 ppm, which was another piece of evidence for the successful crosslinking of 4-poly-1_{20} (Fig. S6, ESI†). Because of the newly formed N–H bond on the pendant, a new resonance signal appeared at 6.85 ppm. Furthermore, a new broad vibration band at 3417 cm^{-1} attributed to the N–H bond was observed in the FT-IR spectrum of C-poly-3_{20} (Fig. S2, ESI†). The Pd residue in C-poly-1_{20} and C-poly-3_{20} was evaluated by Inductively Coupled Plasma Mass Spectrometry (ICP-MS). The Pd residue of C-poly-1_{20} and C-poly-3_{20} was 0.8 wt% and 0.04 wt%, respectively. As expected, no obvious signals were observed in the ^{31}P NMR spectrum of the porous polymer C-poly-3_{20} (Fig. 1c). Therefore, during the TFA treatment, the Pd(II) terminal groups have been simultaneously removed. Due to the preferred left-handed helix of the main chain, the isolated porous polymer C-poly-3_{150} showed a strong negative CD in the region of 450–300 nm. The ellipticity of C-poly-3_ms also increased with the increase in DP until it reached 150 (Fig. 1d and S7, ESI†).

The uncrosslinked 4-poly-1_ms had been proved not to contain pores according to the results of XRD and BET experimental results in our previous work.[17] Then, to investigate the porosity of the porous polymers C-poly-1_ms and C-poly-3_ms, nitrogen adsorption–desorption isotherms were recorded (Fig. 2a and S8, ESI†). C-poly-3_{20} adsorbed nitrogen in the medium-pressure region, and the desorption curve lagged behind the adsorption curve, indicating the presence of numerous mesopores in C-poly-3_{20}. The adsorption curves of C-poly-3_{50}, C-poly-3_{80}, C-poly-3_{100}, and C-poly-3_{150} increased

Table 1 Results for C-poly-1_ms and C-poly-3_ms porous polymers[a]

Run	Polymer	Yield[b] (%)	$S_{BET}{}^c$ (m^2 g^{-1})	$V_{pore}{}^c$ (cm^3 g^{-1})	Pore-size[c] (nm)	$\theta_{364}{}^d$ ($\times 10^3$)

significantly in the high-pressure region ($P/P_0 = 0.8$–1.0), indicating mainly macroporous structures in these porous polymers. The Brunauer–Emmett–Teller (BET) specific surface area (S_{BET}) and pore volume (V_{pore}) of C-poly-3_{20} were 41.20 m^2 g^{-1} and 0.12 mL g^{-1}, respectively, calculated by a nonlocal density functional theory (DFT) approach (run 2, Table 1 and Fig. S9a, ESI†). The S_{BET} values decreased to 27.97 m^2 g^{-1} for C-poly-3_{50}, 19.17 m^2 g^{-1} for C-poly-3_{80}, 10.26 m^2 g^{-1} for C-poly-3_{100}, and 7.98 m^2 g^{-1} for C-poly-3_{150}, as the length of polyisocyanide blocks increased (run 4, 6, 8, and 10, Table 1 and Fig. S9a, ESI†). Furthermore, a relationship between the pore size and the length of the polyisocyanide arms was observed. For instance, the pore size of C-poly-3_{20} was 5.62 nm and increased to 10.68, 12.74, 15.42, and 17.52 nm for C-poly-3_{50}, C-poly-3_{80}, C-poly-3_{100}, and C-poly-3_{150} with narrow distributions, respectively (run 2, 4, 6, 8, and 10, Table 1, Fig. 2b and S9b, ESI†). However, the pore size of C-poly-3_{150} deviated slightly from the linear relationship, which may be attributed to the chain interpenetration between the longer polymer chains, which has an influence on the defect of the frameworks of the porous polymer.[51,52] Compared to the porous polymer C-poly-1_ms, the pore diameter, S_{BET}, and V_{pore} of C-poly-3_ms increased correspondingly (Table 1). This result may be attributed to the removal of the large BOC groups. The powder X-ray diffraction (PXRD) pattern of the porous polymers C-poly-3_ms exhibited an extensive diffraction at 2θ of 19° and a sharp diffraction in the 2θ range of 3°–6° (Fig. S10, ESI†). The 2θ value of C-poly-3_ms decreased apparently with increasing main chain length of the polyisocyanides (Fig. S11, ESI†). These results not only supported that ordered porous polymers formed through the connection of rigid polyisocyanide chain ends but also explained that the pore size was determined by the length of polyisocyanide blocks.

Scanning electron microscopy (SEM) was used to observe the loose and porous morphology of porous polymers. As depicted

Fig. 3 SEM images of the porous polymers of C-poly-3_{20} (a), C-poly-3_{50} (b), C-poly-3_{100} (c), and C-poly-3_{150} (d).

in Fig. 3, C-poly-3_ms had different morphologies with different lengths of polyisocyanide arms. In Fig. 3a, a rough surface was observed for C-poly-3_{20} with relatively short polyisocyanide arms. With the increase in the length of the polyisocyanide arms, the surfaces of C-poly-3_{50} and C-poly-3_{100} gradually transformed into flat surfaces (Fig. 3b and c). According to the SEM image, C-poly-3_{150} with longer polyisocyanide arms had a sponge-like morphology (Fig. 3d). These observations suggested that the morphologies of these porous polymers were controlled by the length of the polyisocyanide arms.

Chiral secondary amines are excellent catalysts that are widely used in asymmetric Michael addition reactions for constructing the skeleton of natural products and drugs.[53–55] With the optical porous polymers C-poly-3_ms bearing abundant secondary amine pendants in hand, we attempted to screen their catalytic abilities in asymmetric organocatalysis. Inspired by the previous work on the asymmetric catalytic ability of linear polymer catalyst poly-3_{150} in the asymmetric Michael addition,[50] we decided to investigate the capacity of C-poly-3_{150} in the asymmetric Michael addition between cyclohexanone (**5a**) and *trans*-nitrostyrene (**4a**). The reaction was conducted in dichloromethane at 25 °C with a catalyst loading of 30%. The reaction produced the expected compound **6aa** in 86% yield. The dr and ee values of the target product were 91/9 and 93%, respectively, as determined by high performance liquid chromatography (HPLC) (run 8, Table 2). In addition, the same Michael addition reaction was conducted under identical conditions with the linear polymer catalysts poly-3_{150} and 4-poly-3_{150}. The dr and ee values of the product catalyzed by poly-3_{150} were 82/18 and 75%, which were much lower than those obtained with the porous polymer catalyst C-poly-3_{150} (run 2 and 8, Table 2). However the dr and ee values catalyzed by 4-poly-3_{150} were almost the same as those of 4-poly-3_{150} (run 3 and 8, Table 2). Furthermore, an analogue compound **7** with a similar structure to the repeating unit of C-poly-3_{150} was then generated (Scheme 1b and Fig. S12, ESI†) and employed in the same reaction with identical 30% loading. As anticipated, the expected product could be isolated in 75% yield. The dr value of the product was 79/21, and the ee of the main product was 43% (run 1, Table 2).

Table 2 Optimization of the reaction conditions for the asymmetric Michael addition reaction[a]

[a] Unless otherwise denoted, all reactions were carried out with **4a** (0.20 mmol), **5a** (0.80 mmol) in a specific solvent (1.0 mL). [b] The dr and ee values were determined by HPLC analysis using a chiral stationary phase. [c] Isolated yields.

Following the reaction with C-poly-3_{150}, a series of porous polymers C-poly-3_ms with different pore sizes were used in the asymmetric Michael addition reaction between cyclohexanone and *trans*-nitrostyrene under the same experimental conditions. The results are summarized in Table 2. After carefully analyzing the ee values in Table 2, it was found that the ee values of the isolated products were quite different and seemed to correlate with the pore size of C-poly-3_ms. For example, the ee values of the major Michael addition product **6aa** catalyzed by C-poly-3_{20}, C-poly-3_{50}, C-poly-3_{80}, and C-poly-3_{100} were 53%, 60%, 68%, and 75%, respectively (run 4–7, Table 2 and Fig. 4a). As shown in Fig. 4a, the dr and ee values of **6aa** increased gradually with the increase in DP of the porous polymer catalysts until DP reached 150 (run 4–8, Table 2 and Fig. 4a). Despite the further increase in the DP of the catalyst, no apparent increase in these values was noted. The ee and dr values of **6aa** obtained under C-poly-3_{200} catalysis were similar to those synthesized with C-poly-3_{150} (run 8–9, Table 2 and Fig. 4a). The correlation between stereoselectivity and pore sizes may be attributed to the M_n-dependent helicity of the polyisocyanide blocks of the porous polymers.[49,50] Furthermore, the different DP of porous polymers C-poly-3_ms had little effect on the yield (Fig. S13, ESI†).

The asymmetric Michael addition reaction catalyzed by the porous polymers C-poly-3_ms was investigated in more detail. First, the solvents including tetrahydrofuran (THF), toluene, methyl alcohol (CH_3OH), water, and brine were screened. Using THF and toluene as solvents resulted in lower dr and ee values

of the product (run 10 and 12, Table 2). Strong polar solvents such as CH_3OH, water, and brine may be beneficial for enhancing the stereoselectivity of the reaction (run 11, 13–14, Table 2), and polar solvents may facilitate the proton transfer and imide hydrolysis of the intermediate according to the

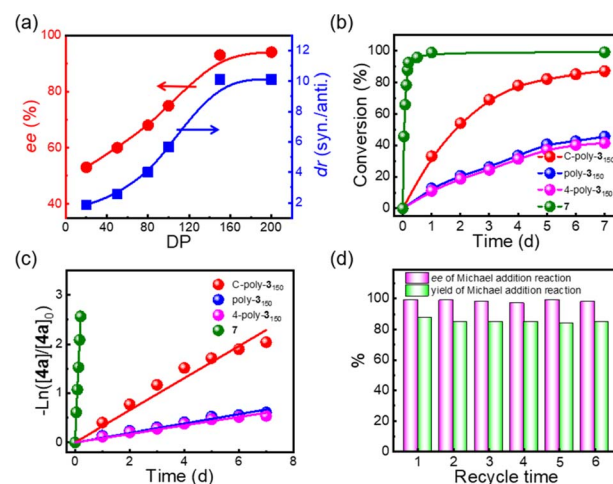

Fig. 4 (a) Plots of ee and dr values of the product **6aa** *vs.* DP of the C-poly-3_ms. The plots of time-dependent conversions of **4a** (b) and −ln([**4a**]/[**4a**]$_0$) (c) *vs.* reaction time using C-poly-3_{150}, poly-3_{150} 4-poly-3_{150}, and **7** as catalysts, respectively. (d) Yield and ee values of the reaction of **4a** (0.20 mmol) and **5a** (0.80 mmol) in brine (1.0 mL) at −10 °C catalyzed by recycled C-poly-3_{150} (with 10% loading).
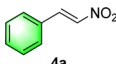

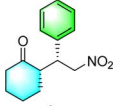

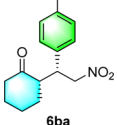

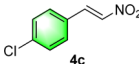

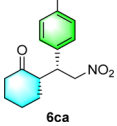

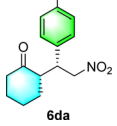

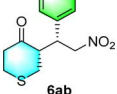

reported mechanism catalyzed by the pyrrolidine-based catalyst.[56,57] The dr values of the product reached 93/7 and 90/10, respectively, using CH_3OH and brine as solvents, while they had the same ee value of 95%. However, a yield of 89% was achieved in brine, which was much higher than the product yield in CH_3OH (run 11 and 14, Table 2). Hence, brine was chosen as the best reaction medium for the asymmetric Michael addition reaction. Interestingly, the ee and dr values of the desired product improved to 99% and 92/8 without apparent loss of catalyst efficiency when lowering the reaction temperature from room temperature to −10 °C (run 16, Table 2). Importantly, reducing the loading of C-poly-3_{150} from 30 mol% to 10 mol% did not have any negative effect on the yield or the ee and dr values of the product (run 16 and 18, Table 2). Therefore, the optimal conditions comprised a C-poly-3_{150} loading of 10 mol%, brine as the solvent, and a reaction temperature of −10 °C.

As commonly known, porous polymers have a higher specific surface area and inherent porosity than linear polymers. In order to confirm that the porous polymer catalysts maintained a higher specific surface, the time-domain NMR was used to investigate the wetted surface area of C-poly-3_ms in water. It could be observed that the spin–spin relaxation time (T_2) increased with the increased DP of C-poly-3_ms. The wetted surfaces could be calculated to 129.89 $m^2 g^{-1}$, 102.72 $m^2 g^{-1 -1}$ and 58.21 $m^2 g^{-1}$ of C-poly-3_{20}, C-poly-3_{80} and C-poly-3_{150}, respectively (Fig. S14, ESI†).[58,59] In our previous studies, the linear polymer poly-3_{150} has also been explored to catalyze asymmetric Michael addition reactions with satisfactory ee values and longer reaction time.[50] Compared to the linear polymer poly-3_{150}, the porous polymer C-poly-3_{150} may have higher catalytic efficiency. Therefore, the difference in kinetics of the test reaction catalyzed by C-poly-3_{150} and poly-3_{150} was assessed by HPLC (Fig. S15, ESI†). According to Fig. 4b, the trans-nitrostyrene conversion catalyzed by C-poly-3_{150} was about twice that observed under poly-3_{150} catalysis within 7 d. However the conversion of substrate 4a was over 90% within 5 h when catalyzed by compound 7 (Fig. 4b and S15d, ESI†). Furthermore, the reaction rate constants of the Michael addition reaction catalyzed by compound 7, poly-3_{150}, 4-poly-3_{150} and C-poly-3_{150} were $5.21 \times 10^{-1} h^{-1}$, $3.66 \times 10^{-3} h^{-1}$, $3.27 \times 10^{-3} h^{-1}$ and $1.36 \times 10^{-2} h^{-1}$, respectively (Fig. 4c). These

Table 3 Substrate scope for Michael addition reactions catalyzed by C-poly-3_{150}[a]

Run	4	5	6	Yield[b] (%)	syn/anti[c]	ee[c] (%)
1	4a	5a	6aa	84	92/8	99
2	4b (MeO)	5a	6ba	83	90/10	99
3	4c (Cl)	5a	6ca	86	97/3	99
4	4d (F)	5a	6da	86	94/6	99
5	4a	5b	6ab	80	99/1	99

[a] Reaction conditions: 4 (0.20 mmol), 5 (0.80 mmol), and C-poly-3_{150} (10% loading). The reaction was carried out in brine (1.0 mL) at 0 °C. [b] Isolated yields. [c] The dr and ee values were determined by HPLC analysis using a chiral stationary phase.

results quantitatively confirmed that the reaction rate of the asymmetric Michael addition could be accelerated when using porous polymers instead of linear polymers as the catalyst. That's probable because the mesoporous and macroporous structures facilitated the diffusion of organic substrates during the reaction process.[60,61] In addition, C-poly-3_{150} could be easily recovered by precipitation and centrifugation after the completion of the reaction due to its poor solubility in brine. Then, the recovered C-poly-3_{150} could be recycled and successfully used in further reactions. The yield and ee values of the isolated product **6aa** were plotted over the recycle times, as displayed in Fig. 4d. C-poly-3_{150} was recycled and used at least six times without significant loss in activity and stereoselectivity (Fig. 4d and Table S2, ESI†).

After the establishment of the optimal conditions for the asymmetric Michael addition reaction catalyzed by C-poly-3_{150}, the scope of substrates with different substituents was screened. As summarized in Table 3, the optimized reaction conditions were applied to different substituted *trans*-nitrostyrenes and cycloketones. When using substrate **4b** with an electron-donating OMe group, the products **6ba** were isolated with 99% ee despite a slight decrease in the dr value (90/10) (run 2, Table 3). The reaction of substrates **4c** and **4d** with halogen substituents such as Cl and F proceeded smoothly with ee values of 99% and dr values exceeding 94 : 6 (run 3 and 4, Table 3). Notably, the product **6ab** of the reaction between **4a** and tetrahydro-4*H*-thiopyran-4-one (**5b**) was generated with both higher dr and ee values of 99/1 and 99%, respectively (run 5, Table 3). It could be demonstrated that all the stereoselectivity of the main products listed in Table 3 could be up to *ca.* 99%. Among these products, the stereoselectivity of **6aa**, **6ba** and **6ca** catalyzed by C-poly-3_{150} was improved apparently compared with those catalyzed by linear polymer catalysts in previous work.[50]

Conclusions

In summary, a series of novel porous polymer catalysts C-poly-3_ms with secondary amine pendants were designed and synthesized using a four-arm Pd(II) catalyst. The pore size of the porous polymers can be controlled by adjusting the DP of the polyisocyanide blocks. Among the C-poly-3_ms compounds, C-poly-3_{150} had a higher optical activity with a θ_{364} value of -8.21×10^3, indicating that its main chain adopted a preferred left-handed helix. The S_{BET} and pore size of the C-poly-3_{150} were 7.98 m^2 g^{-1} and 17.52 nm, respectively. Compared to the linear polymer poly-3_{150}, the porous polymer C-poly-3_{150} exhibited excellent activity and selectivity in organocatalyzed asymmetric Michael addition reactions. Under the optimized reaction conditions, various Michael addition reaction products were synthesized in high yields and with satisfactory stereoselectivity. The ee and dr values of **6ab** could reach 99% and 99/1, respectively. The recovered catalyst can be recycled at least six times in the asymmetric Michael addition reaction while maintaining activity and stereoselectivity. In the future, we will focus on the studies for constructing POP polymers with uniform aperture distribution through a reversible cross-

linking method. We believe that this study not only develops a novel porous polymer organocatalyst for asymmetric Michael addition reactions, but also provides a direction for the future design of novel topological polymer-supported chiral organocatalysts.

Data availability

All experimental procedures, characterisation data, SEC spectra, CD and UV-vis spectra, NMR spectra, and HPLC spectra can be found in the ESI.†

Author contributions

X.-H. Xu performed the synthesis of polymers, characterized the structures of the polymers and investigated the Michael reaction. R.-T. Gao and S.-Y. Li took part in the reaction development. L. Zhou and Z.-Q. Wu prepared the manuscript, guided and supervised the project. N. Liu reviewed and edited the manuscript. All of the authors discussed the experimental results.

Conflicts of interest

There are no conflicts to declare.
