## Introduction

As a commonly used catalytic material, ZnO often plays crucial roles in catalyzing hydrogenation reactions, such as CO<sub>2</sub> selective hydrogenation to methanol and conversion of syngas (mixture gas of CO/CO<sub>2</sub>/H<sub>2</sub>) to light olefins.<sup>1–4</sup> A deep understanding of its catalytic activities would help construct Zn-based catalysts with better performances for these reactions, which may also contribute to the control of fossil fuel usage and the realization of carbon neutrality. However, a lot of debate still remains regarding the nature of the active site for the selective hydrogenation reactions.<sup>5–8</sup> For example, for the CO<sub>2</sub> selective hydrogenation catalyzed by the Cu/ZnO/Al<sub>2</sub>O<sub>3</sub> catalyst, Behrens *et al.*<sup>9</sup> suggested that the Cu–Zn alloys could form and promote the synthetic activity toward methanol, while the metal–oxide interface formed by Cu and ZnO was proposed as the active site by Kattel *et al.*<sup>10</sup> Chen *et al.*<sup>11</sup> found that the Cu/ZnO/ZrO<sub>2</sub> catalyst can also be used for CO<sub>2</sub> selective hydrogenation reactions, and they pointed out that the ZnO–ZrO<sub>2</sub> interface is the active site, while the copper species plays the role of activating H<sub>2</sub> and providing hydrogen for the reaction. In addition, Li and co-workers<sup>12</sup> found that the single Cu atoms loaded on the ZnO surface can catalyze the selective hydrogenation of CO<sub>2</sub> to

methanol with the selectivity of ~99.4%, and they also suggested that the water vapor in the system can act as a bridge between surface H and CO<sub>2</sub> intermediates and has the regulatory role of increasing methanol selectivity. In general, catalysts containing ZnO have been extensively used in the selective hydrogenation reactions of CO<sub>2</sub>,<sup>8–13</sup> and exploring its reaction mechanism is essential for further understanding their key features, especially the actual active site.

In fact, there have already been many studies about selective hydrogenation reactions on clean ZnO surfaces, which were mainly focused on the activation mechanisms of H<sub>2</sub> and CO<sub>2</sub>.<sup>13–15</sup> Wöll and co-workers<sup>16</sup> studied the CO<sub>2</sub> adsorption and activation on the ZnO(10̄10) surface with infrared reflection absorption spectroscopy (IRRAS) and showed that CO<sub>2</sub> can be adsorbed along the [0001] direction and form the carbonate (CO<sub>3</sub><sup>2–</sup>) species. Ling *et al.*<sup>17</sup> obtained the scanning tunneling microscope (STM) images of the heterolytically dissociated H<sub>2</sub> on the ZnO(10̄10) surface under ambient pressure, and the adsorption structure was expected to be beneficial to the stabilization of the formed active H species. Peng and co-workers<sup>18</sup> examined the mechanism of H<sub>2</sub> activation on ZnO nanorods with and without surface oxygen vacancies by applying <sup>17</sup>O nuclear magnetic resonance spectroscopy (NMR), and they found that more hydride species can be produced through homolytic and heterolytic dissociation at the oxygen vacancy sites of the reduced ZnO(10̄10). Theoretically, Tang *et al.*<sup>19</sup> performed systematic on-site Coulomb interaction corrected density functional theory (DFT+U) calculations of the adsorption of CO<sub>2</sub> and found that the adsorbed CO<sub>2</sub> molecules tend to form linear structures on the polar ZnO facets (such as {0001} and {0001̄}), while the bending structures are produced on the nonpolar ZnO facets (such as {10̄10}, {11̄20} and {11̄21}).

Li and co-workers<sup>20</sup> calculated the pathways of H<sub>2</sub> activation on the pristine ZnO(1010) surface, and they determined the heterolytic dissociation of H<sub>2</sub> rather than the homolytic one. Furthermore, through DFT calculations, Zhao *et al.*<sup>21</sup> located the complete reaction routes of CO hydrogenation to methanol on the Zn-terminated ZnO(0001) surface and showed that CO would follow the route of being consecutively hydrogenated to formyl (HCO), formaldehyde (H<sub>2</sub>CO), and methoxy (H<sub>3</sub>CO) before the formation of methanol. Thus, we can find that the catalytic reactions at ZnO are closely related to its surface structures. However, the relationship between the unique electronic properties of ZnO and the catalytic activities in selective hydrogenation reactions has not been thoroughly investigated.

In this work, the wurtzite ZnO(1010) surface, which has a rather low surface energy and exists under real catalytic conditions,<sup>9</sup> was constructed for the DFT calculations. Both the pristine and defective surfaces were considered. Specifically, the surface defect structures were confirmed by the calculated *p-T* phase diagrams.<sup>6,11,22</sup> Moreover, their electronic structures were also carefully studied, and the density of states (DOS) calculations showed a shrinkage of the unfilled dsp hybridized orbitals when excess electrons are present on the surfaces; at the same time, no new occupied states appear under the Fermi energy level ( $E_F$ ), indicating a unique strategy of electron storage and release by ZnO. Systematic calculations were then performed to investigate the generation of active H species on these surfaces and their reactivities in the CO<sub>2</sub> selective hydrogenation reactions. It was found that the various vacancy defects are beneficial to the stabilization of the hydride species (H<sup>-</sup>), which can be generated through the heterolytic dissociation of H<sub>2</sub>. Interestingly, the calculated results also showed that the occurrence of H<sup>+</sup> (proton) from heterolytic H<sub>2</sub> dissociation on the ZnO(1010) surface can be involved in activating the adsorbed H on Zn to the hydride species, and it can also help enhance the adsorption of CO<sub>2</sub> as well. This work revealed why the ZnO surface and its defects are favorable for catalyzing hydrogenation reactions as well as the 'multifunction role' of surface H in these reactions. It may provide some assistance for the rational design of Zn-based catalysts with high activities and selectivities.

## Computational methods

In this work, all spin-polarized DFT calculations were carried out using the Vienna *Ab initio* Simulation Package (VASP).<sup>23</sup> The projector augmented wave (PAW)<sup>24</sup> method and the Perdew–Burke–Ernzerhof (PBE)<sup>25</sup> functional under the generalized gradient approximation (GGA)<sup>26</sup> were applied throughout the geometry and energy calculations. The kinetic energy cut-off was set to 400 eV, with H(1s), C(2s, 2p), O(2s, 2p) and Zn(3d, 4s) being treated as valence electrons. The force threshold in structure optimization was 0.02 eV Å<sup>-1</sup>. By adopting these calculation settings, the optimized lattice constants of ZnO are  $a = b = 3.26$  Å and  $c = 5.24$  Å, which is in good agreement with the experimental values of  $a = b = 3.25$  Å, and  $c = 5.21$  Å.<sup>27</sup> For the model construction, we built a *p*(4 × 3) surface slab containing three O–Zn atomic layers for the ZnO(1010) surface, and

the top two layers were allowed to fully relax, while the bottom O–Zn layer was kept fixed to mimic the bulk region. We used a large vacuum of ~12 Å to eliminate the interactions between neighboring slabs, and hence a *k*-point mesh of 2 × 2 × 1 was applied to the system. Since the valence shells of Zn are filled with d and s electrons, which are strongly correlated, the properties relevant to the electronic structures were calculated by the hybrid functional raised by Heyd, Scuseria and Ernzerhof (HSE06),<sup>30</sup> which may give reliable electronic information and avoid errors from the unique deep-lying 3d electron distribution of Zn.<sup>20,31</sup>

The transition states (TSs) of surface reactions were located using a constrained optimization scheme and were verified when (i) all forces on the relaxed atoms vanish and (ii) the total energy is a maximum along the reaction coordinate, but it is a minimum with respect to the rest of the degrees of freedom.<sup>32,33</sup>

The adsorption energies of different species ( $X$ ) on the surface ( $E_{\text{ads}}(X)$ ) were calculated with:

$$E_{\text{ads}}(X) = -(E_{X/\text{slab}} - E_{\text{slab}} - E_X) \quad (1)$$

where  $E_{X/\text{slab}}$  represents the total energy of the adsorption system, while  $E_{\text{slab}}$  and  $E_X$  are the calculated energies of the slab and the gas-phase molecular  $X$ , respectively. Note that for  $E_H$ , it was calculated with respect to half of the energy of a H<sub>2</sub> molecule (1/2 $E_{H_2}$ ). Obviously, the positive adsorption energy value indicates an exothermic adsorption process, and the more positive it is, the stronger the binding between the adsorbate and the surface is.

In addition, we also calculated the formation energies of different defects of ZnO surfaces.<sup>34</sup> Firstly, the oxygen vacancy formation energy ( $E_f^{\text{Ov}}$ ) was calculated as:

$$E_f^{\text{Ov}} = E_{\text{slab}}^{\text{Ov}} + \frac{1}{2}E_{\text{mol}}^{\text{O}_2} - E_{\text{slab}}^{\text{pristine}} + \Delta\mu_{\text{O}} \quad (2)$$

where the difference in chemical potential of an O<sub>2</sub> molecule under given conditions and standard conditions ( $\Delta\mu_{\text{O}}$ ) was calculated as:

$$\Delta\mu_{\text{O}} = \mu_{\text{O}} - \mu_{\text{O}}^{\theta} = RT \ln \frac{P}{P^{\theta}} \quad (3)$$

and  $E_{\text{slab}}^{\text{Ov}}$  is the total energy of the surface containing a single oxygen vacancy,  $E_{\text{mol}}^{\text{O}_2}$  is the energy of a gas-phase O<sub>2</sub> molecule and  $E_{\text{slab}}^{\text{pristine}}$  is the total energy of the pristine ZnO surface. To compare the formation energies of different defects, we used the chemical potential of oxygen in the gas phase to align the environmental effects.  $\mu_{\text{O}}^{\theta}$  is the standard chemical potential of O, and  $R$ ,  $T$ , and  $p$  represent the ideal gas constant, temperature, and the partial pressure of O<sub>2</sub>, respectively. Secondly, the Zn–O dimer vacancy formation energy ( $E_f^{(\text{Zn–O})_{\text{div}}}$ ) was calculated as:

$$E_f^{(\text{Zn–O})_{\text{div}}} = E_{\text{slab}}^{(\text{Zn–O})_{\text{div}}} + E_{\text{bulk}}^{\text{ZnO}} - E_{\text{slab}}^{\text{pristine}} \quad (4)$$

where  $E_{\text{slab}}^{(\text{Zn–O})_{\text{div}}}$  is the total energy of the surface with a Zn–O dimer vacancy, and  $E_{\text{bulk}}^{\text{ZnO}}$  is obtained by calculating the energy of a 'Zn–O' group in the bulk wurtzite-ZnO. Notably, we can find that the formation energy of the Zn–O dimer vacancy is constant

under various conditions of oxygen potential. Finally, the zinc vacancy formation energy ( $E_f^{ZnV}$ ) was calculated according to

$$E_f^{ZnV} = E_{\text{slab}}^{\text{ZnV}} + E_{\text{bulk}}^{\text{ZnO}} - \frac{1}{2}E_{\text{mol}}^{\text{O}_2} - E_{\text{slab}}^{\text{pristine}} - \Delta\mu_{\text{O}} \quad (5)$$

where  $E_{\text{slab}}^{\text{ZnV}}$  is the total energy of the surface with a single zinc vacancy.

Notably, the choice for the size of the slab model has been systematically tested by the formation energy of different defects (Fig. S1†), and it was found that the formation energies of the various types of surface defects ( $\text{O}_V$  and  $(\text{Zn}-\text{O})_{\text{Div}}$ ) largely converged with the size above  $p(4 \times 3)$  ( $\theta = 1/12$  ML), which is also in agreement with previous reports.<sup>28,29</sup>

## Results and discussion

### Pristine and defect $\text{ZnO}(10\bar{1}0)$ surfaces

The  $\{10\bar{1}0\}$  facet is the most stable one for  $\text{ZnO}$  in the hexagonal wurtzite phase.<sup>35</sup> The surface Zn and O atoms on the  $\text{ZnO}(10\bar{1}0)$  surface are three-fold coordinated (denoted as  $\text{Zn}_{3c}$  and  $\text{O}_{3c}$ ), while the Zn and O atoms in the subsurface and bulk region are four-fold coordinated (denoted as  $\text{Zn}_{4c}$  and  $\text{O}_{4c}$ ). The exposed surface Zn–O pairs can be recognized as the Zn–O dimer and Zn–O trench, as shown in Fig. 1a. When an O or Zn atom or Zn–O dimer is removed from the surface, the coordination number of the surface/subsurface Zn/O around the vacancy is reduced to

2 or 3. Considering that under real reaction conditions, the  $\text{ZnO}$  surface may have these different forms of defects,<sup>28,36</sup> i.e., zinc vacancy (denoted as  $\text{Zn}_V$ ), Zn–O dimer vacancy (denoted as  $(\text{Zn}-\text{O})_{\text{Div}}$ , see Fig. 1b) and oxygen vacancy (denoted as  $\text{O}_V$ , see Fig. 1c), we first systematically investigated their relative stabilities by calculating the formation energies of different defect  $\text{ZnO}(10\bar{1}0)$  surfaces with respect to the oxygen chemical potentials ( $\Delta\mu_{\text{O}}$ ) ( $E_f - \Delta\mu_{\text{O}}$ , Fig. S2†). The plotted equilibrium phase diagrams of these surfaces under different ( $p_{\text{CO}_2}/p_{\text{CO}}$ ) and  $T$  (Fig. 1d) showed that, consistent with the previously reported stable structures,<sup>34</sup> both  $(\text{Zn}-\text{O})_{\text{Div}}$  and  $\text{O}_V$  surfaces ( $\text{ZnO}(10\bar{1}0)-(\text{Zn}-\text{O})_{\text{Div}}$  and  $\text{ZnO}(10\bar{1}0)-\text{O}_V$ , see Fig. 1b and c) can occur favorably under reaction conditions ( $T = 400\text{--}900\text{ K}$ ,  $(p_{\text{CO}_2}/p_{\text{CO}}) = 10^{-3}\text{--}10^3$ ).<sup>37,38</sup> The  $(\text{Zn}-\text{O})_{\text{Div}}$  is relatively more likely to form under atmospheric  $\text{CO}_2/\text{CO}$  pressure ratio ( $(p_{\text{CO}_2}/p_{\text{CO}}) \sim 10^3$ , with the corresponding  $\text{O}_2$  partial pressure being 0.2 bar). In addition, it needs to be noted that the formation of an O vacancy will leave 2 excess electrons in the  $\text{ZnO}(10\bar{1}0)-\text{O}_V$  system (Fig. 1c), which could help the adsorption of electrophilic species and its transformation into negatively charged species (such as the hydride).<sup>39,40</sup> When the Zn–O dimer vacancy occurs, the  $\text{ZnO}(10\bar{1}0)-(\text{Zn}-\text{O})_{\text{Div}}$  surface remains charge balanced, though this defect surface obviously becomes more open for the adsorption and activation of relevant reactants.

We also investigated the electronic properties of the pristine and various defect  $\text{ZnO}(10\bar{1}0)$  surfaces by calculating the density

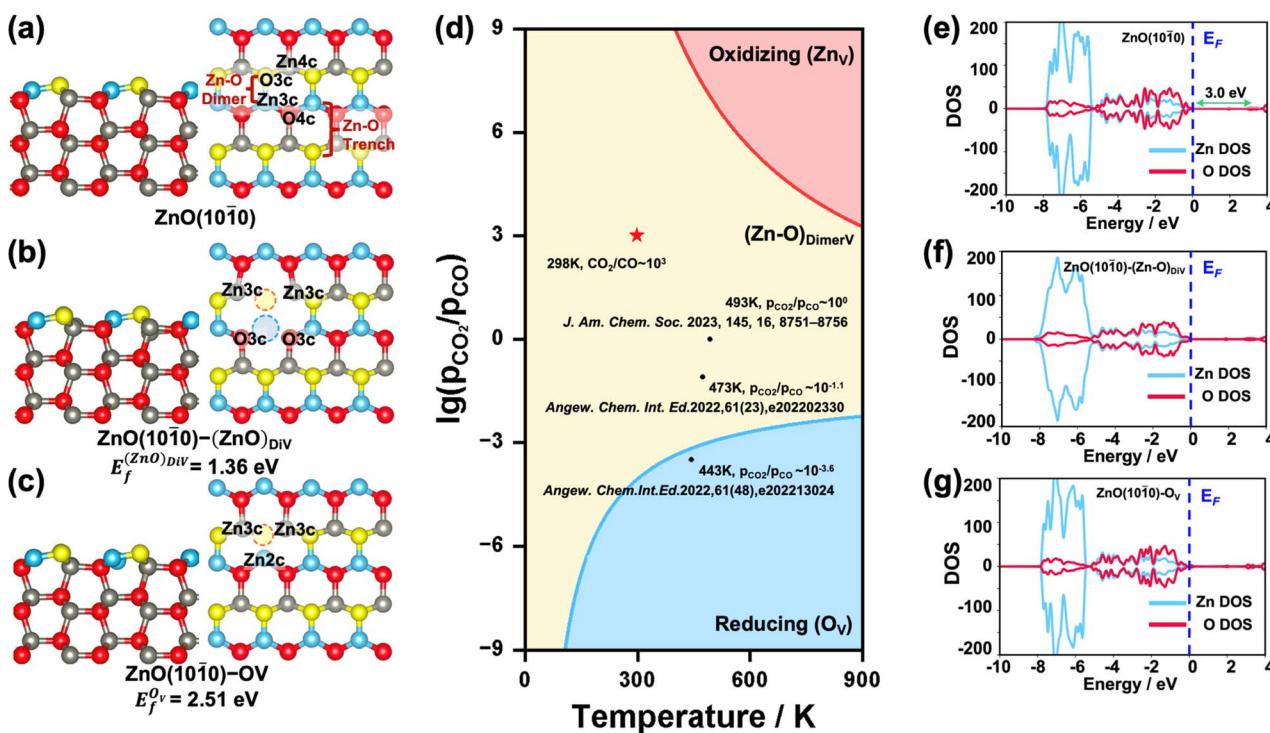

Fig. 1 (a–c) Calculated structures of pristine and various defect  $\text{ZnO}(10\bar{1}0)$  surfaces, and coordinate numbers of surface/subsurface atoms around defects. Left: side view, right: top view. Blue and yellow spheres represent surface Zn and O atoms, and grey and red spheres represent subsurface Zn and O atoms, while dotted lines of blue and red represent Zn and O vacancies, respectively. (d) Calculated  $\lg(p_{\text{CO}_2}/p_{\text{CO}})$ – $T$  phase diagrams of different defect  $\text{ZnO}(10\bar{1}0)$  surfaces; red star denotes normal temperature and atmospheric conditions, and black dots denote some reported conditions of relevant reactions catalyzed by  $\text{ZnO}$ . (e–g) Calculated DOS of (e) pristine and (f and g) defect  $\text{ZnO}(10\bar{1}0)$  surfaces. All DOS are aligned with respect to the Fermi energy level ( $E_F$ ). These notations are used throughout this paper.

of states (DOS) (Fig. 1e–g). The calculated band gap of the pristine  $\text{ZnO}(10\bar{1}0)$  surface was 3.0 eV, which largely agrees with the experimental result (3.3 eV).<sup>41</sup> Further analysis of the partial DOS (pDOS) showed that most of the Zn 3d electrons lay deeply below the Fermi energy level ( $E_F$ ), clearly caused by the fully filled orbitals with strong correlations,<sup>42</sup> and it also hints at a unique bonding pattern with other species. Besides, from the calculated DOS of the defect surface, we can clearly see that the bonding symmetry change caused by the Zn–O dimer vacancy also has a strong influence on the shape of Zn 3d orbitals (Fig. 1f and S2a†), which are broadened obviously. By contrast, the excess electrons contributed by the O vacancy do shrink the unoccupied  $d_{sp}$  hybrid orbital (Fig. S3a†), but they do not change the shape of the Zn orbitals or bring about a new electronic state under  $E_F$ , indicating a new way of storing electrons that is different from that of some reducible metal oxides,<sup>43,44</sup> whose extra electrons would be localized at specific atomic orbitals. In fact, we have also determined that when the 2 electrons resulting from the formation of an oxygen vacancy are forced to be localized at the oxygen vacancy site, the corresponding vacancy formation energy is 0.70 eV higher than that when the 2 electrons are delocalized in the system (Fig. 2c and S3b†); and the pDOS calculation (Fig. S3b†) suggested that these excess electrons would exist within the hybrid orbitals throughout the  $\text{ZnO}$  bulk, just like the electrons from other atoms. Thus, the Zn orbitals appear to be rather flexible for electron storage.

### Adsorption of a single H atom on different $\text{ZnO}(10\bar{1}0)$ surfaces

Previous studies showed that the hydride species is key to the CO/CO<sub>2</sub> selective hydroonation at metal oxides.<sup>45,46</sup> To determine if one H adsorbed on the  $\text{ZnO}(10\bar{1}0)$ ,  $\text{ZnO}(10\bar{1}0)\text{--O}_V$  and  $\text{ZnO}(10\bar{1}0)\text{--(Zn--O)}_{\text{Div}}$  surfaces can form a proton ( $\text{H}^+$ ), hydride ( $\text{H}^-$ ) or H radical ( $\text{H}^\cdot$ ), we performed the Bader charge analysis

and calculated the corresponding spin charge density differences (Fig. 2 and S3†). Notably, the hydride species does not show net spin density, while for the H radical, it usually possesses a net spin density with the calculated Bader charge close to zero.

Firstly, we calculated the adsorption of one H atom at O sites on these surfaces. The calculated results showed that one electron from the H would preferentially transfer to the pristine and different defect  $\text{ZnO}(10\bar{1}0)$  surfaces (Fig. S4†), and the corresponding Bader charges are +0.62, +0.63 and +0.66 |e| for the adsorbed H on the pristine,  $(\text{Zn--O})_{\text{Div}}$  and  $\text{O}_V$  surfaces, respectively, indicating that the proton species are formed. The calculated results also showed that the adsorption of the H atom at the  $\text{O}_{3c}$  site on the  $\text{ZnO}(10\bar{1}0)\text{--(Zn--O)}_{\text{Div}}$  surface is exothermic by 1.28 eV. Such a favorable adsorption can be due to the fact that the adsorption location is rather open and the adsorbed H species can form the hydrogen bond with the neighboring  $\text{O}_{3c}$  (the distance between  $\text{O}_{3c}$  and H atoms is 2.05 Å, Fig. S4d†). The adsorption of one H atom at the  $\text{O}_{3c}$  site on the  $\text{ZnO}(10\bar{1}0)\text{--O}_V$  surface was calculated to be exothermic by 0.71 eV only. This is mainly because the presence of the two excess electrons on the reduced  $\text{ZnO}(10\bar{1}0)$  surface further increases the electron repulsion within the system. Notably, we can also find that the extra electron from an adsorbed H (Fig. S4c, f and i†) barely has any influence on the overall shape of the Zn orbitals of the various  $\text{ZnO}(10\bar{1}0)$  surfaces, which again suggests the flexibility of Zn orbitals in storing electrons.

In addition, we also calculated the adsorption of one H atom at Zn sites on these surfaces. The results showed that the H species, as a radical, is barely adsorbed at the Zn site on the  $\text{ZnO}(10\bar{1}0)$  surface since the adsorption is endothermic by 1.48 eV (Fig. 2a and d). By contrast, the H adsorbed on the  $\text{ZnO}(10\bar{1}0)\text{--O}_V$  surface can actually form three H–Zn bonds at the  $\text{O}_V$  site, and it turns into a hydride species (Fig. 2c, the

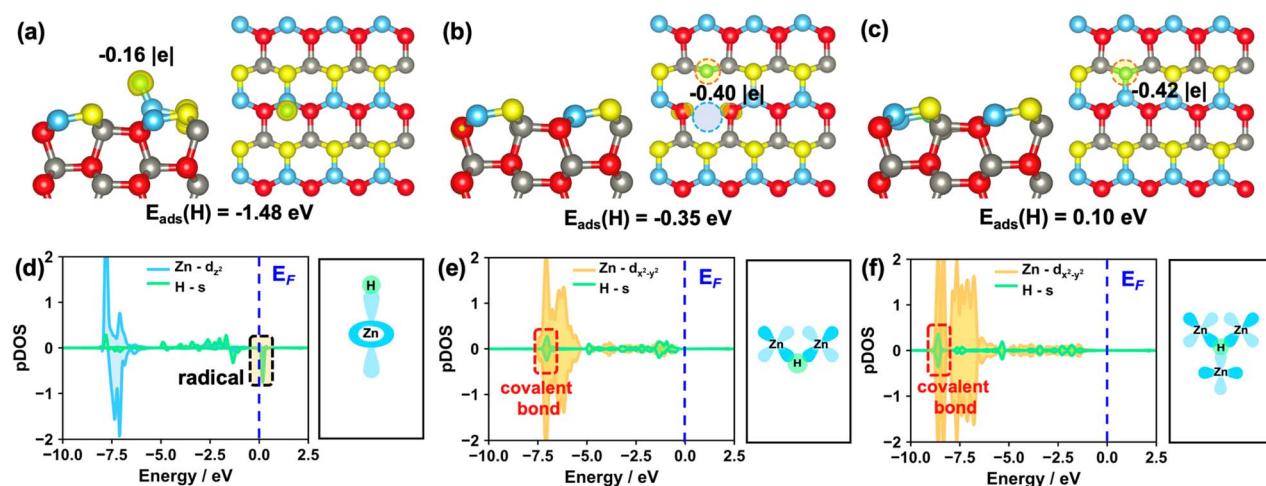

Fig. 2 (a–c) Calculated structures and energies of the single H atom adsorption at the surface/subsurface Zn sites of pristine and various defect  $\text{ZnO}(10\bar{1}0)$  surfaces. Calculated Bader charges of H and spin charge density differences are also shown. The spin iso-surfaces (yellow) are plotted at a value of  $0.05 \text{ e} \text{ Å}^{-3}$ , this notation is used throughout the paper. Green: H atoms. (d–f) Calculated partial DOS (pDOS) of the adsorbed H and corresponding Zn on the pristine and defect  $\text{ZnO}(10\bar{1}0)$  surfaces.  $E_F$  is labelled with dashed blue lines, and all pDOS are aligned with respect to the  $E_F$ .

corresponding Bader charge is  $-0.42 |e|$  with the exothermic adsorption energy of 0.10 eV. This result is largely consistent with the findings that the hydride species can form on some reduced metal oxide surfaces such as  $\text{CeO}_2$ .<sup>39,45</sup> For the adsorption of a single H atom at the Zn site on the  $\text{ZnO}(10\bar{1}0)$ –(Zn–O)<sub>Div</sub> surface, the hydride, rather than a H radical, is also formed (Fig. 2b, the calculated Bader charge is  $-0.40 |e|$ ), though this process is endothermic by 0.35 eV. In this case, the adsorbed H species would interact with the two  $\text{Zn}_{3c}$  (Fig. 2e). Notably, the electronic analysis suggested that the hydrides on both the O<sub>V</sub> and (Zn–O)<sub>Div</sub> surfaces occur *via* the covalent bonds contributed by the s electron from H and the multiple symmetric d electrons from Zn, in particular  $d_{x^2-y^2}$  (Fig. 2e and f), and the energy levels of the as-formed covalent Zn–H bonds at  $\text{ZnO}(10\bar{1}0)$ –(Zn–O)<sub>Div</sub> and  $\text{ZnO}(10\bar{1}0)$ –(Zn–O)<sub>O<sub>V</sub></sub> are far below  $E_F$ .

### H<sub>2</sub> dissociation on different $\text{ZnO}(10\bar{1}0)$ surfaces

In real applications, the hydride species for selective hydrogenation reactions usually come from the dissociation of H<sub>2</sub> molecules on the catalysts.<sup>42,47</sup> Accordingly, we also systematically studied the possible pathways of the dissociative adsorption of H<sub>2</sub> on the pristine and various defect  $\text{ZnO}(10\bar{1}0)$  surfaces (Fig. 3, S5 and S6†), including the homolytic dissociation at (i) two O sites to produce two hydroxyl (O–H) groups or (ii) two Zn sites to produce two Zn–H species, as well as (iii) the heterolytic dissociation at the Zn and O sites for the formation of Zn–H and O–H species.

The calculated results showed that the homolytic dissociation of H<sub>2</sub> to form two O–H species at O sites on the pristine, Zn–O dimer vacancies and oxygen vacancies of the  $\text{ZnO}(10\bar{1}0)$  surfaces needs to overcome the energy barriers of 1.48 eV,

0.70 eV and 1.52 eV (Fig. 3a and S6b, e and h†), respectively, and they are exothermic by 0.64 eV, 1.57 eV and 0.98 eV (Fig. 3a, c, f and i), respectively. Our results also showed that the homolytic H<sub>2</sub> dissociation can produce two Zn–H species at adjacent  $\text{Zn}_{3c}$  sites on the  $\text{ZnO}(10\bar{1}0)$ ,  $\text{ZnO}(10\bar{1}0)$ –(Zn–O)<sub>Div</sub> and  $\text{ZnO}(10\bar{1}0)$ –O<sub>V</sub> surfaces, and the corresponding electronic analyses indicated that they are 2Zn–H<sup>+</sup>, Zn–H<sup>+</sup> and Zn–H<sup>–</sup>, and O<sub>V</sub>–H<sup>–</sup> and Zn–H<sup>–</sup> species, respectively. Moreover, these processes need to overcome energy barriers as high as 2.81 eV, 2.38 eV and 1.43 eV, respectively (Fig. 3a and S6c, f and i†), and the calculated reaction energies also indicated that these processes are energetically unfavorable.

On the other hand, according to our calculated results, the heterolytic H<sub>2</sub> dissociation on the different ZnO surfaces ( $\text{ZnO}(10\bar{1}0)$ ,  $\text{ZnO}(10\bar{1}0)$ –(Zn–O)<sub>Div</sub> and  $\text{ZnO}(10\bar{1}0)$ –O<sub>V</sub> surfaces) can readily occur to form the Zn–H<sup>–</sup> and O–H species, which only need to overcome the small energy barriers of 0.45 eV, 0.10 eV and 0.45 eV (Fig. 3a and S6a, d and g†), respectively, and the corresponding processes are exothermic by 0.53 eV, 1.51 eV and 0.77 eV, which are consistent with those reported in previous experimental and theoretical studies.<sup>20,48,49</sup> The stabilities could be attributed to the structural features of the transition states of the heterolytic H<sub>2</sub> dissociations: the characteristic [H–O–Zn–H] four-membered ring at  $\text{ZnO}(10\bar{1}0)$ , the [H–O–Zn–O–Zn–H] hexatomic ring at  $\text{ZnO}(10\bar{1}0)$ –(Zn–O)<sub>Div</sub> and a double [H–O–Zn–O–Zn–H] hexatomic ring at  $\text{ZnO}(10\bar{1}0)$ –O<sub>V</sub>.

From the above results, we can find that H<sub>2</sub> can be activated more readily through heterolytic dissociation rather than homolytic cleavage on the different ZnO surfaces, which is also consistent with the previously reported results on some other metal oxides.<sup>18,20,50</sup> Specifically, among the different  $\text{ZnO}(10\bar{1}0)$  surfaces, the (Zn–O)<sub>Div</sub> surface is the most active one for the

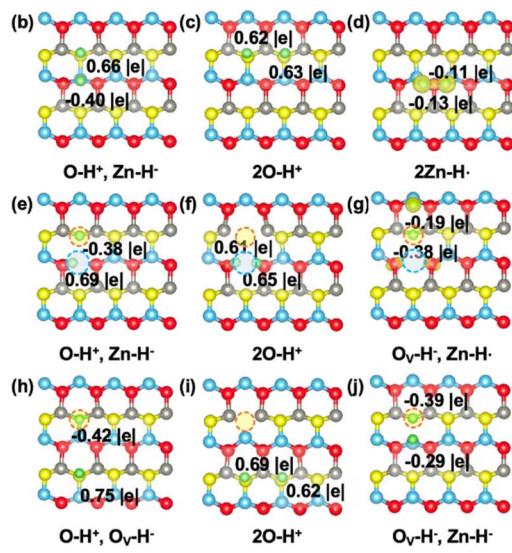

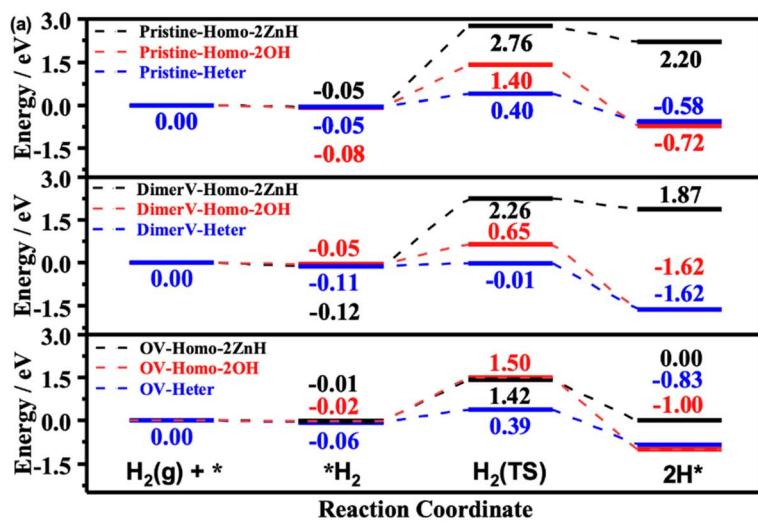

Fig. 3 (a) Calculated energy profiles of H<sub>2</sub> adsorption and dissociation on the pristine and various defect  $\text{ZnO}(10\bar{1}0)$  surfaces. H<sub>2</sub>(g), \*H<sub>2</sub>, H<sub>2</sub>(TS), and 2H<sup>\*</sup> represent the states of gas-phase H<sub>2</sub>, surface adsorbed H<sub>2</sub>, transition state for the surface adsorbed H<sub>2</sub> to dissociate into two surface adsorbed H, and co-adsorption of two H species, respectively. (b–j) Calculated structures (top view) of the products of H<sub>2</sub> dissociation on the pristine and defect  $\text{ZnO}(10\bar{1}0)$  surfaces, and the calculated Bader charges and spin charge densities of the co-adsorption of two H species are also shown.

heterolytic  $\text{H}_2$  dissociation. This is because the low-coordinated O species around the  $\text{Zn}_V$  site on the  $\text{ZnO}(10\bar{1}0)$ – $(\text{Zn}-\text{O})_{\text{D}\text{IV}}$  surface are rather active for the transformation of the adsorbed H into stable protons, while the  $\text{O}_V$  site on the  $(\text{Zn}-\text{O})_{\text{D}\text{IV}}$  surface can help produce the stable hydrides that interact with the surface through covalent Zn–H bonds. We also performed the density-functional perturbation theory (DFPT) calculations<sup>51,52</sup> of the O–H and Zn–H species produced by the heterolytic  $\text{H}_2$  dissociation on the  $\text{ZnO}(10\bar{1}0)$  and  $\text{ZnO}(10\bar{1}0)$ – $(\text{Zn}-\text{O})_{\text{D}\text{IV}}$  surfaces, and obtained the corresponding simulated infrared (IR) spectra (3550 (O–H) and 1773 (Zn–H)  $\text{cm}^{-1}$  for pristine  $\text{ZnO}(10\bar{1}0)$ ; 3345 (O–H) and 1522 (Zn–H)  $\text{cm}^{-1}$  for  $\text{ZnO}(10\bar{1}0)$ – $(\text{Zn}-\text{O})_{\text{D}\text{IV}}$ ; see Fig. S7†). The wavenumber differences for the species on the pristine and  $(\text{Zn}-\text{O})_{\text{D}\text{IV}}$  surfaces are due to their different structures, *i.e.* on the  $(\text{Zn}-\text{O})_{\text{D}\text{IV}}$  surface, the O–H species can also form a hydrogen bond with the neighboring lattice O, and the hydride actually bonds with two Zn sites. These calculated wavenumbers are largely consistent with the reported experimental results that the pristine  $\text{ZnO}(10\bar{1}0)$  surface gives rise to 3490 (O–H) and 1710 (Zn–H)  $\text{cm}^{-1}$  and the  $\text{ZnO}(10\bar{1}0)$ – $(\text{Zn}-\text{O})_{\text{D}\text{IV}}$  gives rise to 3400 (O–H) and 1475 (Zn–H)  $\text{cm}^{-1}$ .<sup>48,53,54</sup>

Besides, to further understand the energy barrier and product stability of heterolytic  $\text{H}_2$  dissociation on the different surfaces, we also calculated the partial DOS of the H species in the transition and final states of these processes (Fig. 4, S8 and S9†). The results indicated that the Zn–H ionic bonds occur in the transition states on the  $\text{ZnO}(10\bar{1}0)$  and  $\text{ZnO}(10\bar{1}0)$ – $\text{O}_V$  surfaces (Fig. 4a). Moreover, the structural properties of the Zn–H bonds in the transition states (Fig. S8†) also showed that only a single asymmetric Zn–H bond forms on the pristine and  $\text{O}_V$

surfaces, while the double symmetric Zn–H bond occurs on the  $(\text{Zn}-\text{O})_{\text{D}\text{IV}}$  surface. Accordingly, higher energy barriers were obtained on the pristine and  $\text{O}_V$  surfaces (0.45 eV) compared with that on the  $(\text{Zn}-\text{O})_{\text{D}\text{IV}}$  surface (0.10 eV). Interestingly, stable covalent Zn–H bonds with relatively low energy levels can be formed on the defect surfaces, while Zn–H ionic bonds with relatively high energy levels were formed on the pristine  $\text{ZnO}(10\bar{1}0)$  surface, leading to the different stabilities of the hydride species on the three surfaces.

The corresponding Bader charge and spin charge density difference analyses (Fig. 3b–j) also supported that the heterolytic  $\text{H}_2$  dissociation on the various surfaces indeed produced a hydride and a hydroxyl species. The calculated Bader charges of the formed  $\text{H}^+$  and  $\text{H}^-$  species are  $+0.66 \text{ |e|}$  and  $-0.40 \text{ |e|}$  at  $\text{ZnO}(10\bar{1}0)$ ,  $+0.69 \text{ |e|}$  and  $-0.38 \text{ |e|}$  at  $\text{ZnO}(10\bar{1}0)$ – $(\text{Zn}-\text{O})_{\text{D}\text{IV}}$ , and  $+0.75 \text{ |e|}$  and  $-0.42 \text{ |e|}$  at  $\text{ZnO}(10\bar{1}0)$ – $\text{O}_V$ . Interestingly, one can notice that the value of the calculated charge of  $\text{H}^+$  is approximately two times that of  $\text{H}^-$  on the different  $\text{ZnO}(10\bar{1}0)$  surfaces. This suggested that only some part of the charge contributed by the H during  $\text{H}_2$  dissociation is used to activate another H to form the hydride species, while the other part of the charge might be transferred to the  $\text{ZnO}(10\bar{1}0)$  surface (Table S2†). This is very different from some other metal oxides (*e.g.*,  $\text{MgO}$  and  $\text{CeO}_2$ ), on which the calculated Bader charges of the  $\text{H}^+$  and  $\text{H}^-$  species generated through heterolytic  $\text{H}_2$  dissociation are approximately equal.<sup>45,55</sup>

For this unusual phenomenon, the calculated DOS (Fig. S8†) of the products of heterolytic  $\text{H}_2$  dissociation showed that the shapes of the Zn orbitals are almost unchanged, which is consistent with the situations of single H adsorption at surface O explored earlier on. In fact, the hydrides from these heterolytically dissociated  $\text{H}_2$  molecules can be recognized to evolve from the H adsorbing immediately following the  $\text{H}^+$  formation at the surface O site, in which case the electrons are released after storage. Therefore, it can also be concluded that the Zn orbitals are indeed quite flexible since they largely maintain the same shape during electron storage/release.

Finally, we further investigated if the transferred charge from the adsorbed H can be involved in the generation of multiple hydrides on the  $\text{ZnO}(10\bar{1}0)$ – $(\text{Zn}-\text{O})_{\text{D}\text{IV}}$  surface (Fig. 5). The calculated results showed that, together with the surface  $\text{H}^+$ , two hydride species can indeed occur, and their corresponding Bader charges are  $-0.36 \text{ |e|}$  and  $-0.31 \text{ |e|}$  (Fig. 5a). However, the charge contributed by one adsorbed H species

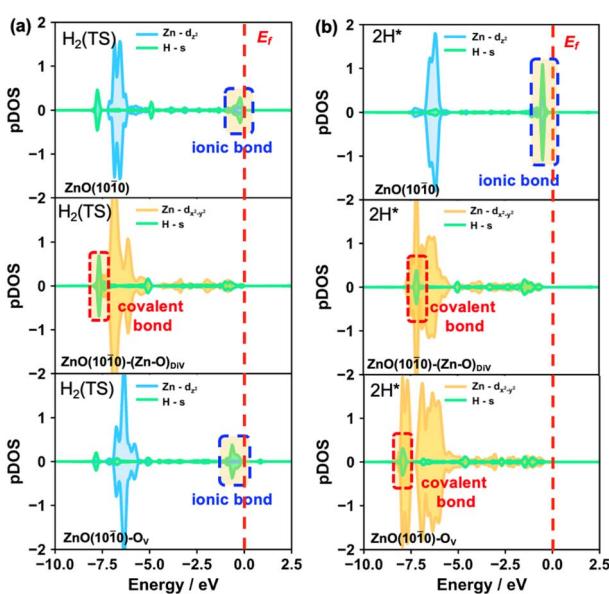

Fig. 4 Calculated partial DOS of the adsorbed H species at Zn or  $\text{O}_V$  sites and the interacting Zn. The results for the (a) transition and (b) final states of heterolytic  $\text{H}_2$  dissociation on the pristine and various defect  $\text{ZnO}(10\bar{1}0)$  surfaces.  $E_F$  is labelled by red dashed lines, and all pDOS are aligned with respect to the  $E_F$ .

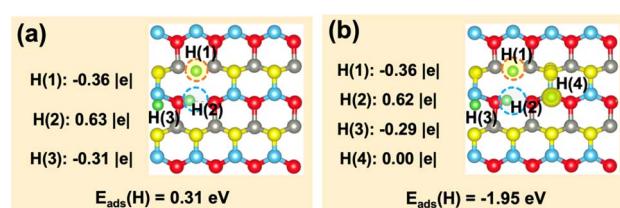

Fig. 5 Calculated adsorption energies and structures of co-adsorption of one  $\text{H}^+$  +  $2\text{H}^-$  and  $\text{H}^+$  +  $2\text{H}^-$  +  $\text{H}^-$ . (a)  $\text{H}^+$  co-adsorption with  $2\text{H}^-$ . (b)  $\text{H}^+$  co-adsorption with  $2\text{H}^-$  and one  $\text{H}^-$ . Calculated Bader charge values of H and spin charge density differences are also shown.

cannot be used to activate more adsorbed H to the hydride species (*e.g.*, the corresponding Bader charges of the three co-adsorbed H species are  $-0.36$ ,  $-0.29$  and  $0.00$   $|e|$ , respectively, forming only two hydride species; Fig. 5b). Thus, we can expect that the charge released by the formation of a proton may perform dual functions for the simultaneous activation of two electrophilic adsorbates (*e.g.*,  $\text{CO}_2^{\delta-}$  and hydride).

### Selective $\text{CO}_2$ hydrogenation on pristine and various defect $\text{ZnO}(10\bar{1}0)$ surfaces

To unveil the catalytic reactivities of the hydride species, we then proceeded to investigate the  $\text{CO}_2$  activation and hydrogenation on the  $\text{ZnO}(10\bar{1}0)$ ,  $\text{ZnO}(10\bar{1}0)-\text{O}_v$  and  $\text{ZnO}(10\bar{1}0)-(\text{Zn}-\text{O})_{\text{div}}$  surfaces (Fig. 6 and S10–S19†). It is well known that the adsorption and activation of  $\text{CO}_2$  are the key steps of the overall  $\text{CO}_2$  reduction reactions.<sup>56,57</sup> Our calculated results showed that the  $\text{CO}_2$  adsorptions on the  $\text{ZnO}(10\bar{1}0)$ ,  $\text{ZnO}(10\bar{1}0)-\text{O}_v$  and  $\text{ZnO}(10\bar{1}0)-(\text{Zn}-\text{O})_{\text{div}}$  surfaces all lead to the formation of carbonate ( $\text{CO}_3^{2-}$ )-like species, and these processes are exothermic by  $1.01$  eV,  $0.98$  eV and  $1.03$  eV, respectively (Fig. 6a). The Bader charge analysis also showed that the adsorbed  $\text{CO}_2$  is negatively charged on these surfaces (the corresponding Bader charges are  $-0.20$   $|e|$ ,  $-0.22$   $|e|$  and  $-0.21$   $|e|$ , respectively (see Fig. 6b–d)).

Next, we calculated the further adsorption of  $\text{H}_2$  and found that it is generally rather weak on the pristine and different defect  $\text{ZnO}(10\bar{1}0)$  surfaces with the pre-adsorbed  $\text{CO}_2$  (the corresponding adsorption energies are close to  $0$  eV; see Fig. 6a and S11†). The adsorbed  $\text{H}_2$  then undergoes heterolytic dissociation to produce one hydride and one proton species with the barriers of  $0.49$  eV,  $0.30$  eV and  $0.42$  eV on the pristine and defect

$\text{ZnO}(10\bar{1}0)$  surfaces, and the corresponding processes are exothermic by  $0.53$  eV,  $1.69$  eV and  $0.77$  eV. Interestingly, we also found that the adsorption energies of  $\text{CO}_2$  were enhanced by  $0.18$  eV and  $0.06$  eV on the pristine and  $(\text{Zn}-\text{O})_{\text{div}}$  surfaces, respectively, following the heterolytic dissociation of the  $\text{H}_2$ , in comparison with the  $\text{CO}_2$  adsorbed alone. This is consistent with our findings above that the charges provided by the H that turns into a proton have ‘dual functions’ in activating multiple adsorbates.

We next considered two possible routes for  $\text{CO}_2$  activation, *i.e.* direct dissociation of  $\text{CO}_2$  and direct hydrogenation of  $\text{CO}_2$ . The results indicated that the direct  $\text{CO}_2$  dissociation into co-adsorbed  $^*\text{CO}$  and  $^*\text{O}$  on the  $\text{ZnO}(10\bar{1}0)$ ,  $\text{ZnO}(10\bar{1}0)-(\text{Zn}-\text{O})_{\text{div}}$  and  $\text{ZnO}(10\bar{1}0)-\text{O}_v$  surfaces requires endothermic energies of  $5.09$  eV,  $5.04$  eV and  $4.78$  eV (Fig. S12†), respectively, and such high energy demands suggested that direct  $\text{CO}_2$  dissociation is unfavorable. In the route of direct hydrogenation of  $\text{CO}_2$ , two possible pathways were then tested (Fig. 6 and S13–S15†). The first is the so-called  $\text{COOH}$  (carboxyl) pathway, in which the  $\text{H}^+$  or  $\text{H}^-$  binds with the  $\text{O}^{\delta-}$  of the adsorbed  $\text{CO}_2$  to form a  $^*\text{COOH}$  species; the second is the so-called  $\text{HCOO}$  (formate) pathway, in which the  $\text{H}^+$  or  $\text{H}^-$  reacts with the  $\text{C}^{\delta+}$  of the adsorbed  $\text{CO}_2$  to produce a  $^*\text{HCOO}$  species. According to our calculated results, the processes with the  $\text{H}^+$  attacking the adsorbed  $\text{CO}_2$  to form the  $^*\text{HCOO}$  species need to overcome enormously large energy barriers of  $4.29$  eV,  $2.76$  eV and  $6.42$  eV on the  $\text{ZnO}(10\bar{1}0)$ ,  $\text{ZnO}(10\bar{1}0)-\text{O}_v$  and  $\text{ZnO}(10\bar{1}0)-(\text{Zn}-\text{O})_{\text{div}}$  surfaces, respectively, and they are also highly endothermic ( $4.13$  eV,  $1.92$  eV and  $4.13$  eV, respectively; Fig. S13a, e and i, and S14a, e and ii†). When the  $\text{H}^+$  species attacks the  $\text{O}^{\delta-}$  of the adsorbed  $\text{CO}_2$  to generate a  $^*\text{COOH}$  species (Fig. S13c, g, and k, and S14c, g and ii†).

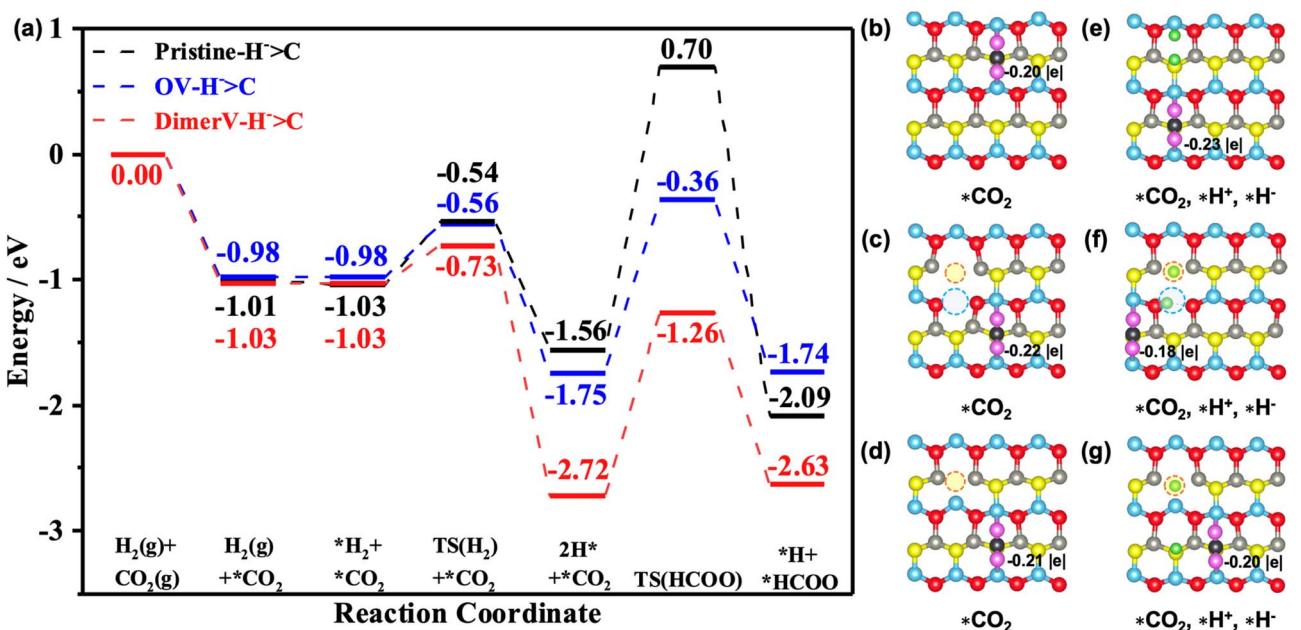

Fig. 6 (a) Calculated energy profiles of the most favorable routes of selective  $\text{CO}_2$  hydrogenation on the pristine and defect  $\text{ZnO}(10\bar{1}0)$  surfaces. (b–d) Calculated structures (top view) of  $\text{CO}_2$  adsorption and (e–g) co-adsorption with heterolytically dissociated  $\text{H}_2$  on the pristine and defect  $\text{ZnO}(10\bar{1}0)$  surfaces. Black: C atoms, pink: O atoms of  $\text{CO}_2$ . Calculated Bader charges of  $\text{CO}_2$  species are also shown.

$k\ddagger$ ), it also needs to overcome very large energy barriers (4.25 eV, 1.43 eV and 4.06 eV on the  $\text{ZnO}(10\bar{1}0)$ ,  $\text{ZnO}(10\bar{1}0)\text{-O}_\text{v}$  and  $\text{ZnO}(10\bar{1}0)\text{-(Zn-O)}_\text{div}$  surfaces, respectively) and these processes are highly endothermic (1.05 eV, 1.02 eV and 1.34 eV). Interestingly, for the processes with the  $\text{H}^-$  species as the active H species to react with  $\text{CO}_2$ , both the carboxylate and formate pathways can occur quite easily. For the pathway for the hydride species to attack the  $\text{C}^{6+}$  of the adsorbed  $\text{CO}_2$  to form the  $^*\text{HCOO}$  species, the energy barriers are 2.26 eV, 1.39 eV and 1.46 eV on the pristine and the two defect  $\text{ZnO}(10\bar{1}0)$  surfaces and they are exothermic by 0.53 eV and endothermic by 0.01 eV and 0.09 eV, respectively. At the same time, the reactions between  $\text{H}^-$  and the  $\text{O}^{\delta-}$  of the adsorbed  $\text{CO}_2$  (the  $\text{COOH}$  pathway) need to overcome the energy barriers of 2.42 eV, 1.40 eV and 1.71 eV, while they are endothermic by 0.09 eV, 0.05 eV and 0.67 eV.

In addition, we also calculated the subsequent hydrogenation reaction steps in both the  $\text{HCOO}$ -to-methanol pathway and the  $\text{COOH}$ -to-methanol pathway (Fig. S16–19 $\ddagger$ ) on the  $\text{ZnO}(10\bar{1}0)\text{-(ZnO)}_\text{div}$  surface. The results indicated that the  $\text{HCOO}$ -to-methanol pathway is more favorable than the  $\text{COOH}$ -to-methanol pathway in the formation of  $^*\text{H}_2\text{CO}$  species, where the maximum endothermic step ( $^*\text{HCOO} + ^*\text{H}^- \rightarrow ^*\text{HCOOH}$ ,  $\Delta E = 0.78$  eV) of the  $\text{HCOO}$ -to-methanol pathway is lower than that of the  $\text{COOH}$ -to-methanol pathway ( $^*\text{CO} + ^*\text{OH} + ^*\text{H}^+ \rightarrow ^*\text{CO} + \text{H}_2\text{O(g)}$ ,  $\Delta E = 1.29$  eV) (Fig. S16 and S18 $\ddagger$ ). After the formation of the  $^*\text{H}_2\text{CO}$  species, the  $\text{H}_2$  dissociation into  $\text{H}^+$  and  $\text{H}^-$  species releases an exothermic energy of 0.56 eV, while the formation of  $^*\text{H}_3\text{CO}$  is exothermic by 1.67 eV. The subsequent step of  $\text{H}_2$  adsorption and dissociation is exothermic by 0.18 eV, and the formation of  $^*\text{CH}_3\text{OH}$  species is highly exothermic by 1.89 eV. Therefore, it can be concluded that the  $^*\text{HCOO}$  species is more readily formed and more stable during the  $\text{CO}_2$  hydrogenation to methanol reaction, and we believe that the  $^*\text{HCOO}$  intermediate species is the most abundant reactive intermediate (MARI) in the  $\text{CO}_2$  hydrogenation reaction, which is consistent with other reports.<sup>58,59</sup>

From the above results, one can surely expect that the  $\text{CO}_2$  hydrogenation with the  $\text{H}^-$  species on the  $\text{ZnO}(10\bar{1}0)\text{-(Zn-O)}_\text{div}$  surface is more likely to follow the  $\text{HCOO}$  pathway, which may lead to the formation of  $\text{CH}_3\text{OH}$  as the main product,<sup>60</sup> and this stoichiometric surface with  $(\text{Zn-O})_\text{div}$  defects is more active than the reduced one with  $\text{O}_\text{v}$  defects. This result is consistent with those reported recently by Ling *et al.*<sup>17</sup> Moreover, the simulated infrared spectra (calculated by the DFPT method<sup>51,52</sup>) of formate (1355 and 1515  $\text{cm}^{-1}$ , Fig. S20 $\ddagger$ ) are also consistent with the reported experimental results<sup>61,62</sup> (1370 and 1595  $\text{cm}^{-1}$ ). In general, we can learn from the calculated results in the current work that defects on the  $\text{ZnO}(10\bar{1}0)$  surface are key to its improved catalytic activities in  $\text{H}_2$  activation and  $\text{CO}_2$  hydrogenation, and the  $\text{Zn-O}$  dimer vacancy appears even more active than the usual  $\text{O}$  vacancy.

## Conclusions

In summary, this study has systematically explored the catalytic roles of  $\text{ZnO}$  in  $\text{CO}_2$  hydrogenation to methanol, with

a particular focus on the generation of active hydrogen species and their impact on catalysis. Our comprehensive computational analyses, based on density functional theory, have revealed the unique electronic properties of  $\text{ZnO}$  and their substantial influence on the catalytic processes. The characteristic  $\text{ZnO}(10\bar{1}0)$ ,  $\text{ZnO}(10\bar{1}0)\text{-O}_\text{v}$  and  $\text{ZnO}(10\bar{1}0)\text{-(Zn-O)}_\text{div}$  surfaces were constructed, and their stabilities were verified with the calculated equilibrium phase diagrams under reaction conditions. The calculated DOS further showed that for the pristine and various defect  $\text{ZnO}(10\bar{1}0)$  surfaces, the size of the unfilled hybrid orbitals changes while the shape of the occupied orbitals remains unchanged when excess electrons exist, revealing the unique way of storing electrons for  $\text{ZnO}$ . We also determined that the hydride species can form through heterolytic  $\text{H}_2$  dissociation on the pristine and various defect  $\text{ZnO}(10\bar{1}0)$  surfaces. Among these surfaces, the  $\text{ZnO}(10\bar{1}0)\text{-(Zn-O)}_\text{div}$  is the most active one for the heterolytic dissociation of  $\text{H}_2$ , which demonstrates a notably low energy barrier ( $\sim 0.10$  eV), largely due to the fact that the low-coordinated surface  $\text{Zn}_{3c}$  is helpful for the stabilization of  $\text{H}^-$  species. Moreover, it was found that the unique way of storing and releasing electrons in  $\text{Zn}$  orbitals gives  $\text{ZnO}$  the characteristic capacity of activating two electrophilic adsorbates simultaneously as excess electrons exist. Calculations of the key reaction steps further showed that the covalent  $\text{Zn-H}$  species can regulate the activities and selectivities in  $\text{CO}_2$  hydrogenation, by preferentially producing  $^*\text{HCOO}$  intermediates, and revealed a lower reaction barrier on the  $\text{Zn-O}$  dimer vacancy surface. Our study provides valuable insights into the catalytic mechanisms of  $\text{ZnO}$  in hydrogenation reactions, highlighting the importance of its surface structures and electronic properties, and suggests the potential of the  $(\text{Zn-O})_\text{div}$ -containing  $\text{ZnO}$  surface as an efficient catalyst for hydrogenation reactions.
