# Halide-triggered assembly and selective bisulfate recognition in a quadruply interlocked coordination cage†

Jemma I. Virtue,  Steven Tsoukatos,  Martin R. Johnston   
and Witold M. Bloch \*

Interlocked coordination cages are a class of multi-cavity architectures with applications in selective anion recognition, adaptive sensing, and catalysis. Controlling the partitioning of their cavities through ligand design and appropriate anion templates is critical to their guest binding scope, yet remains a challenge. Here, we present a thermodynamically stable  $[\text{Pd}_2\text{L}_4](\text{BF}_4)_4$  cage assembled from a bis-monodentate ligand featuring a non-coordinating bis-pyrazole methane backbone. As a result of its idealized dimensions, NMR, ESI-MS, and X-ray analyses reveal that halides can trigger the interpenetration of this cage into a  $[\text{X}@\text{Pd}_4\text{L}_8]^{7+}$  dimer ( $\text{X} = \text{Cl}^-$  or  $\text{Br}^-$ ) where the halide template resides only in the central pocket. The anion–cation pattern of this interlocked host facilitates exceptional binding affinity for the bisulfate anion in its two outer pockets (up to  $10^6 \text{ M}^{-1}$  in MeCN), strongly outcompeting other tetrahedral anions of similar size.

## Introduction

The synthesis of interlocked systems has attracted considerable attention owing to their unique structural features, partitioned cavities, and dynamic mechanical properties.<sup>1–3</sup> For example, interlocked molecular dimers can exhibit allosteric guest recognition,<sup>4</sup> stimuli-responsive motion,<sup>5–7</sup> or photocatalytic activity<sup>8–10</sup> – unique characteristics that are not observed in their monomeric constituents.<sup>11</sup> Despite the recent progress in the synthesis and chemistry of various interlocked structures such as catenanes,<sup>1</sup> rotaxanes,<sup>12</sup> Borromean rings,<sup>13</sup> and molecular knots,<sup>14</sup> engineering the cavities of these interlocked architectures toward selective guest recognition continues to represent a formidable challenge.<sup>15</sup>

Coordination cages assembled from concave-shaped ligands and square-planar  $\text{Pd}^{\text{II}}$  cations have served as excellent precursors for interlocked molecules and other multi-cavity architectures.<sup>16,17</sup> In the presence of a suitable anion template, two  $\text{Pd}_2\text{L}_4$  monomers can interpenetrate, leading to a quadruply interlocked  $\text{Pd}_4\text{L}_8$  dimer. The stability of the interlocked product arises from favourable hydrogen bonding or coulombic interactions with the anion template, which compensate for the entropic penalty of interpenetration.<sup>16,18,19</sup>

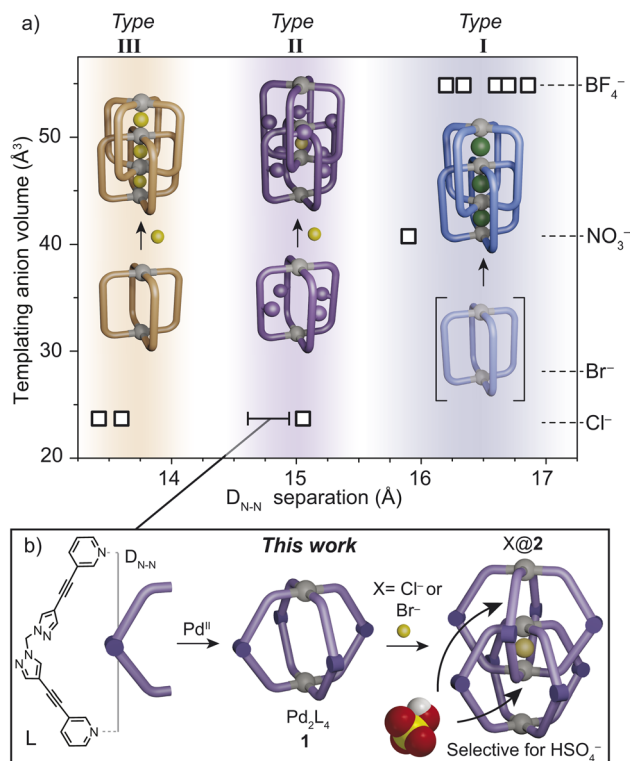

As a class of multi-cavity architectures, interpenetrated  $\text{Pd}_4\text{L}_8$  dimers carry a high charge of +8 (excluding the anion template) and are thus excellent hosts for anion recognition.<sup>20</sup> Compared to other multi-cavity cage systems that rely on synthetically demanding multi-dentate ligands,<sup>21–25</sup> interlocked cages are more straightforward to prepare, as they are assembled from a larger number of simpler ligand components.<sup>26</sup> In this context, it is important to note the extensive work of Clever,<sup>27</sup> Kuroda,<sup>28</sup> and others,<sup>19,29,30</sup> who have demonstrated the importance of ligand length (defined herein as  $D_{\text{N-N}}$ ), sterics, counterion, and solvent on whether or not interpenetration occurs, the cation–anion arrangement pattern of the interlocked dimer, as well as its binding scope and selectivity towards certain guests.

For the purpose of this work, we define the three common anion–cation patterns (or motifs) for  $\text{Pd}_4\text{L}_8$  interlocked cages as type I, II, and III (Fig. 1a). In the assembly of type I motifs, the monomeric  $\text{Pd}_2\text{L}_4$  cage ( $D_{\text{N-N}} > 15.8 \text{ \AA}$ ) is a kinetic intermediate that progresses to an interpenetrated product with the same anionic guest ( $\text{BF}_4^-$  or  $\text{NO}_3^-$ ) in all three cavities.<sup>38</sup> The outer pockets of type I motifs can exhibit allosteric binding of smaller halide guests (relative to the larger, initially bound  $\text{BF}_4^-$  anions), leading to structural compression along the  $\text{Pd}\cdots\text{Pd}$  axis and simultaneous expansion of the central cavity.<sup>4,31</sup> Shorter bis-monodentate ligands (*e.g.*,  $D_{\text{N-N}} = 13\text{--}13.5 \text{ \AA}$ ) lead to monomeric cages as the thermodynamic product when larger  $\text{BF}_4^-$  counter-ions are employed. In this case, a halide additive can trigger the formation of a type III interlocked motif where the same halide guest occupies the three cavities.<sup>32,33</sup> The type II motif is an interesting and rare case, which also arises from a thermodynamically stable  $\text{Pd}_2\text{L}_4$  monomeric cage. However,

**Fig. 1** (a) The three types of  $\text{Pd}_4\text{L}_8$  interlocked motifs according to the templating anion volume and ligand  $D_{\text{N-N}}$  separation, where squares represent X-ray data from previous studies;<sup>4,29,31–37</sup> note: in the type II motif, the outer pockets are occupied by weakly bound counter-ions. (b) This work: utilizing a bis-pyrazole methane ligand with idealized dimensions to access a type II interlocked motif with high binding selectivity for bisulfate.

halides trigger the assembly of an interlocked cage where only the central pocket is occupied by the halide, leaving the two outer pockets available for exchange with larger anions. This motif was previously isolated from a  $\text{Pd}_2\text{L}_4$  cage possessing bulky ligands that allowed only halides to template the dimer for steric reasons (Fig. 1a).<sup>34</sup> Currently, this interlocked motif remains a challenge to access and derivatize,<sup>39</sup> limiting the host-guest chemistry and further exploration of this class of multi-cavity architectures.

Mapping the ligand  $D_{\text{N-N}}$  separation from X-ray data of reported dimeric  $\text{Pd}_4\text{L}_8$  structures, type I and III motifs are observed for  $D_{\text{N-N}}$  greater than 15.8 Å ( $\text{BF}_4^-$  or  $\text{NO}_3^-$  anion template) and less than 13.5 Å (halide template), respectively (Fig. 1a). We hypothesized that type II interlocked structures may be accessible simply by targeting an intermediate  $D_{\text{N-N}}$  of ~15 Å, where only halide anions induce interpenetration due to their small volume relative to the dimensional constraints of the monomeric cage. Herein, we report the coordination-driven self-assembly of a  $\text{Pd}_2\text{L}_4$  cage composed of a flexible, non-coordinating bis-pyrazole methane backbone (Fig. 1b). We show that halides ( $\text{Cl}^-$  and  $\text{Br}^-$ ) can trigger the interpenetration of this cage into an interlocked type II motif without the requirement of steric bulk at the ligand backbone. The two outer cavities of the interpenetrated dimers preferentially bind

tetrahedral guests and show high selectivity toward  $\text{HSO}_4^-$ , an anion of substantial environmental importance.<sup>40</sup>

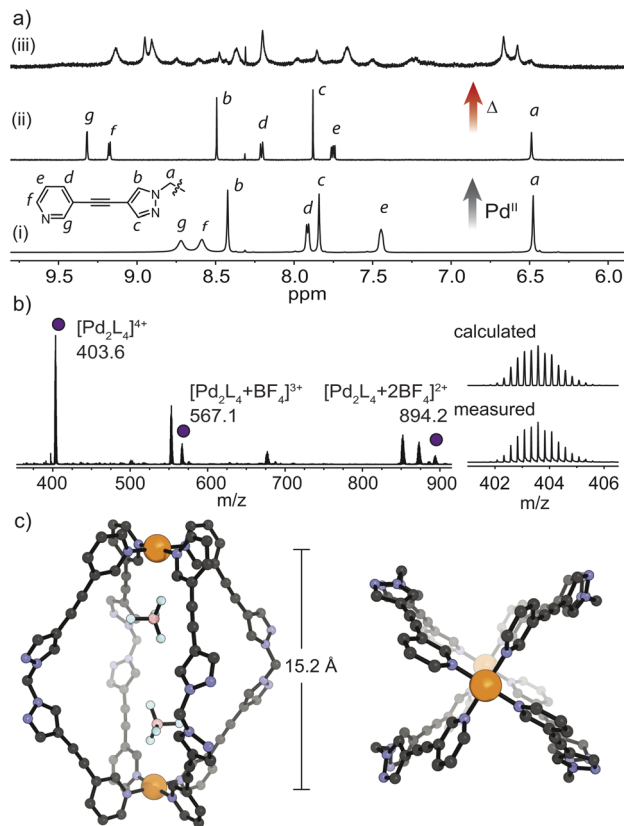

## Results and discussion

Our interest in bis-pyrazole methane (bpm) has been driven by its straightforward derivatization<sup>41</sup> and utility for heterometallic metal-organic framework and cage-based porous solids.<sup>42,43</sup> Despite its appeal as a chelating backbone, we realized that when equipped with 3-ethynyl pyridine donors, its  $D_{\text{N-N}}$  separation should fall roughly between the dimensions of type I and type III  $\text{Pd}_4\text{L}_8$  structures. Indeed, preliminary DFT modelling revealed this ligand should adopt a concave geometry with a  $D_{\text{N-N}}$  separation between 14.1–14.5 Å, depending on whether the bpm core adopts a *syn* or *anti* conformation. Therefore, bis(4-(pyridin-3-ylethynyl)-1H-pyrazol-1-yl)methane (**L**) was synthesized through a simple Sonogashira cross-coupling reaction (Fig. S1†). Single-crystal X-ray diffraction confirmed the concave shape of the ligand, with  $D_{\text{N-N}}$  dimensions in close agreement with that predicted by DFT calculations (Fig. S2†).

With **L** in hand, we hypothesized that correct stoichiometry may prevent the bpm core from chelating  $\text{Pd}^{\text{II}}$ , thus promoting a monomeric cage through self-assembly with the ligand's pyridine donors.<sup>43</sup> Pleasingly, when combining  $[\text{Pd}(\text{CH}_3\text{CN})_4](\text{BF}_4)_2$  and **L** in a 1 : 2 ratio in DMSO at 25 °C, <sup>1</sup>H NMR analysis revealed a rather simple spectrum that could be assigned to a single product. The pyridyl protons of the coordinated ligand appeared downfield shifted relative to the free ligand (+0.6 ppm, proton g, Fig. 2a), whilst the pyrazole resonances remained relatively unchanged (+0.04 ppm, proton c, Fig. 2a). Importantly, the NMR data indicates that a chelate complex is not formed, which is unusual given the strong prevalence of bpm and its derivatives forming chelate complexes with  $\text{Pd}^{\text{II}}$  ions.<sup>44</sup> Electrospray ionization mass spectrometry (ESI-MS) revealed prominent peaks corresponding to  $[\text{Pd}_2\text{L}_4 + n\text{BF}_4]^{4-n}$  ( $n = 0-2$ ) (Fig. 2b), confirming the presence of the anticipated cage product (**1**). However, heating the DMSO solution of **1** at 70 °C resulted in a complex mixture, as revealed by <sup>1</sup>H NMR spectroscopy and ESI-MS (Fig. 2a and S5†). This suggests that the cage is a kinetic intermediate, and entropically driven mixtures involving the pyrazole and pyridine donors of the ligand are energetically favorable in this solvent.

We observed a different outcome when using  $\text{CD}_3\text{CN}$  as the solvent. Heating a 1 : 2 mixture of  $[\text{Pd}(\text{CH}_3\text{CN})_4](\text{BF}_4)_2$  and **L** at 70 °C for 2 h resulted in monomeric cage **1** as the only product (Fig. 3a). More complex mixtures could be obtained when an excess of  $\text{Pd}^{\text{II}}$  was used (Fig. S4†), confirming the importance of stoichiometry in the assembly of **1**. Allowing the  $\text{CD}_3\text{CN}$  solution of **1** to stand at 25 °C for 72 h resulted in the formation of large block-shaped crystals. Single-crystal X-ray analysis confirmed the  $[\text{Pd}_2\text{L}_4](\text{BF}_4)_4$  structure, wherein the bpm core remains non-coordinated despite its *syn*-conformation in the solid state (Fig. 2c). The  $D_{\text{N-N}}$  separation of **1** measures 15.2 Å, which reflects the flexibility of the bpm ligand afforded by the rotational freedom around the methylene hinge. Additionally, the crystal packing of **1** sheds light on its crystallization, where numerous close  $\pi$ -stacking interactions (closest contact = 3.30

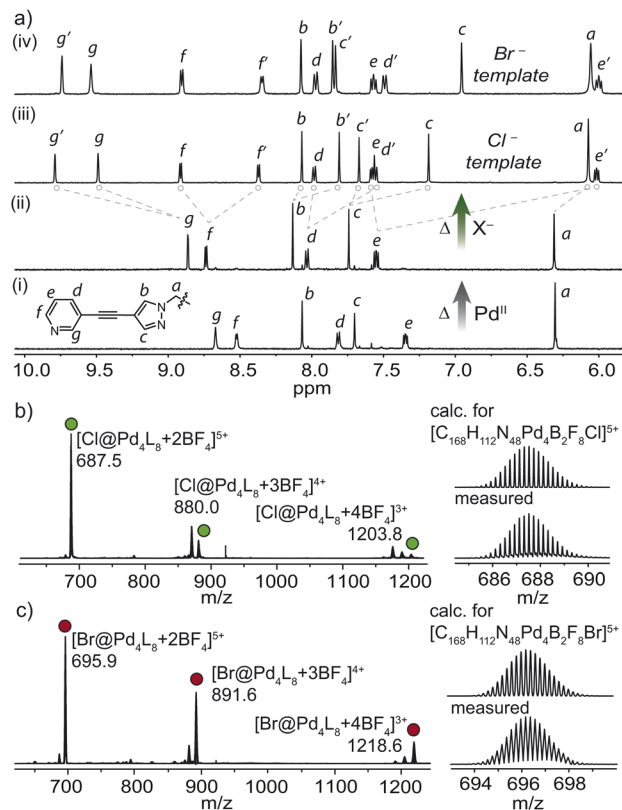

**Fig. 2** (a)  $^1\text{H}$  NMR spectra (500 MHz,  $\text{DMSO-d}_6$ , 25  $^\circ\text{C}$ ) of (i) L; (ii) cage 1, the kinetic product in  $\text{DMSO}$ ; (iii) the same solution heated at 70  $^\circ\text{C}$  for 2 h; (b) ESI-MS spectrum of 1:  $[\text{Pd}_2\text{L}_4 + n\text{BF}_4]^{4-n+}$  ( $n = 0-2$ ) indicated by purple spheres (c) X-ray structure of 1.

$\text{\AA}$ ) occur between the pyrazole and pyridine rings of neighbouring cage molecules (Fig. S66 $\dagger$ ).

The isolation of 1 is worth highlighting, given the tendency of bpm derivatives to chelate  $\text{Pd}^{\text{II}}$ .<sup>43,44</sup> Previous work by Crowley and co-workers showed that the assembly of di-pyridyl ligands bearing pendant chelating groups results in chelate complexes with  $\text{Pd}^{\text{II}}$ , rather than  $\text{Pd}_2\text{L}_4$  cages.<sup>45</sup> In the case of 1, the  $\text{Pd}_2\text{L}_4$  cage may be entropically favored due to the preservation of the rotational freedom of the non-coordinated bpm core.

Given the intermediate  $D_{\text{N-N}}$  distance of 1, we next investigated its propensity to interpenetrate in the presence of halides. Indeed, heating 1 in the presence of 0.5 equivalents of  $\text{Cl}^-$  resulted in the clean formation of a new interpenetrated assembly denoted as  $\text{Cl@2}$ . Characteristic two-fold splitting of the ligand resonances in the  $^1\text{H}$  NMR spectrum along with major peaks in the ESI-MS spectrum, assigned to  $[\text{Cl@Pd}_4\text{L}_8 + n\text{BF}_4]^{8-n+}$  ( $n = 3-5$ ) confirmed the interlocked product (Fig. 3a and b). Using 1.1 equivalents of  $\text{Cl}^-$  in the synthesis of  $\text{Cl@2}$  resulted in a mixture of the same interpenetrated product and free ligand (Fig. S8 $\dagger$ ).  $^1\text{H}$ - $^1\text{H}$  NOESY of  $\text{Cl@2}$  revealed several cross-peaks that confirmed the interpenetrated structure, such as a contact between pyridyl proton  $e'$  and pyrazole proton  $c$  (Fig. S12 $\dagger$ ).

$\text{F}^-$  and  $\text{I}^-$  proved to be poor templates for cage dimerization, resulting in mixtures dominated by free ligand and monomeric

**Fig. 3** (a)  $^1\text{H}$  NMR spectra (600 MHz,  $\text{CD}_3\text{CN}$ , 25  $^\circ\text{C}$ ) of (i) L; (ii) cage 1, the thermodynamic product in  $\text{CD}_3\text{CN}$ ; (iii)  $\text{Cl@Pd}_4\text{L}_8 - \text{Cl@2}$  and (iv)  $\text{Br@Pd}_4\text{L}_8 - \text{Br@2}$ ; (b) ESI-MS spectrum of  $\text{Cl@2}$  (green spheres); (c) ESI-MS spectrum of  $\text{Br@2}$  (red spheres).

cage 1. On the other hand, heating 1 with 0.5 equivalents of  $\text{Br}^-$  yielded  $\text{Br@2}$  almost quantitatively, as shown by  $^1\text{H}$  NMR spectroscopy and ESI-MS (Fig. 3a and c). Whereas only a single broad  $^{19}\text{F}$  resonance corresponding to solvated  $\text{BF}_4^-$  was observed for  $\text{Cl@2}$ , the  $^{19}\text{F}$  NMR spectrum for the  $\text{Br}^-$  templated dimer showed two distinctive resonances at  $-151$  and  $-146$  ppm (Fig. 4c). These were assigned to the free and encapsulated  $\text{BF}_4^-$  anion, respectively, and  $^{19}\text{F}$  exchange spectroscopy (EXSY) confirmed their exchange at 25  $^\circ\text{C}$  (Fig. 4d). The tighter binding of the  $\text{BF}_4^-$  anions in the outer pockets of  $\text{Br@2}$  can be explained by the larger  $\text{Br}^-$  template, which resides in the central pocket, pushing the interpenetrating cages closer together, diminishing the available volume of the outer cavities. DOSY analysis suggested that these differences are subtle, with both templated dimers diffusing at  $\sim 4.6 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$  (Fig. S10 and S15 $\dagger$ ).

Single crystals of both interlocked structures were isolated by slow vapor diffusion of chloroform into solutions of  $\text{Cl@2}$  and  $\text{Br@2}$  in  $\text{MeCN}$ , allowing us to unequivocally confirm their structures and compare their dimensions through X-ray analysis. Both the  $\text{Cl}^-$  and  $\text{Br}^-$  templated dimers crystallize in an orthorhombic space group ( $Pbcn$  for  $\text{Cl@2}$  and  $Ccc2$  for  $\text{Br@2}$ ) with half of the double cage in the respective asymmetric unit. In contrast to the X-ray structure of 1, the bis-pyrazole methane moieties in  $\text{X@2}$  are present in the *anti*-conformation, with two

Note:  $D_{N-N} = 14.8$  Å, and the anions residing in the cavities are shown as space-filling models; (c) <sup>19</sup>F NMR spectra (565 MHz, CD<sub>3</sub>CN, 25 °C) of (i) Br@2 and (ii) Cl@2; (d) <sup>19</sup>F-<sup>19</sup>F EXSY spectrum (376.5 MHz, CD<sub>3</sub>CN, 25 °C) of Br@2.

identical rotational conformers comprising each Pd<sub>2</sub>L<sub>4</sub> unit. This highlights the rotational freedom of the bpm core, which is supported by the number of <sup>1</sup>H NMR resonances of the monomeric and dimeric cage species. The interlocked structures host one halide in the smaller central cavity and a BF<sub>4</sub><sup>-</sup> in each of the two larger outer pockets. Although the intermolecular H...F contacts between the host and guest do not differ significantly between the two structures (Fig. S73<sup>†</sup>), the distance between the outermost Pd<sup>II</sup> and the next inner Pd<sup>II</sup> is shorter for Br@2 by 0.07 Å. VOIDOO calculations provided a clearer picture of the effect of the larger Br<sup>-</sup> template. These revealed that the outer cavities of Cl@2 possess a volume of 128.5 Å<sup>3</sup>, whilst the same cavities in the Br<sup>-</sup> templated dimer reduce to 108.5 Å<sup>3</sup>. A higher packing coefficient of 51% for the BF<sub>4</sub><sup>-</sup> anion in Br@2 (compared to 43% for Cl@2) is consistent with its tighter binding. On the other hand, the volume of the central cavity measures 12.7 Å<sup>3</sup> and 15.8 Å<sup>3</sup> for Cl@2 and Br@2 respectively, indicative of extremely tight binding of the respective halides. This was further supported by the high stability of X@2 in the presence of AgBF<sub>4</sub> (Fig. S37 and S53<sup>†</sup>).

Since the bpm ligand lacks bulky groups that would prevent interpenetration in the presence of BF<sub>4</sub><sup>-</sup>, we propose that the intermediate  $D_{N-N}$  separation of the ligand facilitates the assembly of a Pd<sub>2</sub>L<sub>4</sub> monomeric cage that later can be triggered by halides to form X@2 – a rare example of a type II interlocked motif. It is worth noting that Pd<sub>2</sub>L<sub>4</sub> cages that accommodate BF<sub>4</sub><sup>-</sup> anions typically require a  $D_{N-N}$  distance >8 Å.<sup>17,46,47</sup> Thus, we hypothesize based on the dimensions of X@2, that a BF<sub>4</sub><sup>-</sup>

anion in the central cavity would result in outer cavities too small to accommodate BF<sub>4</sub><sup>-</sup> anions favorably, or the ligand would incur an energetic penalty in bond-strain to expand its  $D_{N-N}$ . These scenarios may also disrupt the favorable C–H  $\pi$  interactions (proton e and adjacent pyrazole ring,  $D_{C-H...N} = 2.72$  Å, 174°), that stabilize the interlocked complex. Interestingly, NO<sub>3</sub><sup>-</sup> ( $V = 40.7$  Å<sup>3</sup>) could not template the interlocked dimer in the presence of the BF<sub>4</sub><sup>-</sup> counterions ( $V = 54.8$  Å<sup>3</sup>) of cage 1 (Fig. 5a). In contrast, the self-assembly of L with Pd(NO<sub>3</sub>)<sub>2</sub> led directly to a mixture of the dimeric cage and free ligand, and the monomeric cage could not be detected in this experiment (Fig. 5b). ESI-MS corroborated this result with prominent peaks assignable to 3NO<sub>3</sub>@2 (Fig. 5c). The clear transition from a type II to a typical type I interlocked motif in the presence of smaller NO<sub>3</sub><sup>-</sup> counter ions further underscores the importance of the  $D_{N-N}$  separation in restricting the volume of the central and outer cavities.

Next, we examined the anion binding capabilities of the halide-templated dimeric cages with a range of monoanionic guests in CD<sub>3</sub>CN. As tetrabutylammonium salts of ClO<sub>4</sub><sup>-</sup>, ReO<sub>4</sub><sup>-</sup> and NO<sub>3</sub><sup>-</sup> were added in increasing equivalents to Cl@2, the inner pointing protons of the outer pocket (g, c, f' and e') underwent shifting with fast exchange kinetics relative to the <sup>1</sup>H NMR time scale (Fig. S20–S26<sup>†</sup>). A Job plot analysis indicated that ClO<sub>4</sub><sup>-</sup>, ReO<sub>4</sub><sup>-</sup> bind with the expected 1 : 2 host-guest stoichiometry (Fig. S21–S27<sup>†</sup>). This was further corroborated by a single-crystal structure of (ClO<sub>4</sub>)<sub>2</sub>Cl@2, which confirmed that after treating Cl@2 with 2.1 equivalents of tetrabutylammonium perchlorate, the BF<sub>4</sub><sup>-</sup> anions are exchanged for ClO<sub>4</sub><sup>-</sup> anions in the two outer cavities of the interlocked host (Fig. S75<sup>†</sup>). Fitting the NMR data to a 1 : 2 binding model based on shifts in proton g gave  $K_1$  and  $K_2$  values of  $3.4 \pm 0.8 \times 10^4$  M<sup>-1</sup>;

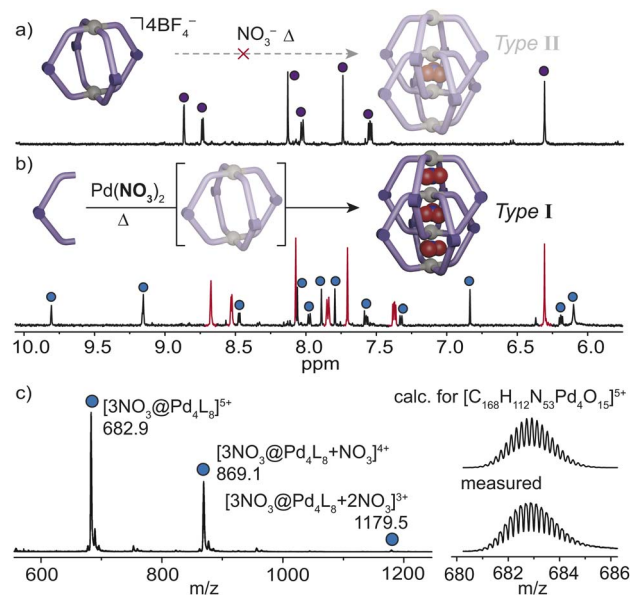

Fig. 5 <sup>1</sup>H NMR spectra (600 MHz, CD<sub>3</sub>CN, 25 °C) of (a) 1 + 0.5 equivalents of NO<sub>3</sub><sup>-</sup>, heated at 70 °C for 2 h; (b) a 2 : 1 mixture of L and Pd(NO<sub>3</sub>)<sub>2</sub>, heated at 70 °C for 3 h. Red colour denotes free ligand; (c) ESI-MS spectrum of 3NO<sub>3</sub>@2 (blue spheres).

$K_2 = 1.5 \pm 0.03 \times 10^3 \text{ M}^{-1}$  for  $\text{ClO}_4^-$  and  $K_1 = 1.2 \pm 0.4 \times 10^4 \text{ M}^{-1}$ ;  $K_2 = 3.8 \pm 0.2 \times 10^3 \text{ M}^{-1}$  for  $\text{ReO}_4^-$ .<sup>48</sup> This indicates non-cooperative binding since these values are close to the statistically expected  $K_2 = K_1/4$ . For the  $\text{NO}_3^-$  guest, inner (g, f', e' and c) and outer (f and c') pointing protons concurrently underwent downfield shifting suggesting non-specific binding.<sup>34</sup> Larger  $\text{PF}_6^-$  and  $\text{OTf}^-$  anions were observed to bind only to the outside of the cage (Table 1, Fig. S32 and S33†), whilst charge-dense anions  $\text{I}^-$  and  $\text{Br}^-$  decomposed Cl@2 at low equivalents (Fig. S35 and S36†).

To compare the effect of the halide template in the inner cavity, the anion-binding behavior of Br@2 was investigated (Table 1).  $^1\text{H}$  NMR analysis revealed host-guest binding for  $\text{ClO}_4^-$  and  $\text{ReO}_4^-$ , although intermediate exchange kinetics hindered the fitting of the NMR data, particularly for proton g (Fig. S38 and S41†). Closer inspection of the data revealed that pyrazole proton c (which also points towards the outer cavity) is affected more by the binding of  $\text{ReO}_4^-$ , compared to  $\text{ClO}_4^-$ ; an effect further amplified in the case of the  $\text{Br}^-$  template. For the  $\text{ReO}_4^-$  anion, we also observed a notable shift in proton e', suggesting that the larger  $\text{ReO}_4^-$  guest does not reside directly between the  $\text{Pd}^{\text{II}}$  centers, but rather adjacent to the pyrazole units of the ligand (Fig S57†). This difference in binding may relate to the relative size of these two anions ( $59.1 \text{ \AA}^3$  vs.  $55.4 \text{ \AA}^3$ ) with the  $\text{ReO}_4^-$  guests being too large to align with the  $\text{Pd}_4$  axis. Pyrazole proton c could be monitored to compare the binding of the  $\text{ClO}_4^-$  guest for Br@2 and Cl@2. Fitting the isotherm data yielded  $K_1 = 8.0 \pm 0.2 \times 10^3 \text{ M}^{-1}$  and  $K_2 = 1.7 \pm 0.1 \times 10^3 \text{ M}^{-1}$  – an order of magnitude lower than that obtained by monitoring the same proton for Cl@2:  $K_1 = 2.9 \pm 0.4 \times 10^4 \text{ M}^{-1}$  and  $K_2 = 1.2 \pm 0.02 \times 10^3 \text{ M}^{-1}$ . The weaker binding of Br@2 compared to Cl@2 can be explained by the smaller outer cavities that result in stronger competition between the tightly bound  $\text{BF}_4^-$  and the  $\text{ClO}_4^-$  guests.

Next, we examined whether the selective binding of X@2 toward tetrahedral anions can be extended to bisulfate ( $\text{HSO}_4^-$ ) – an anion of environmental importance and considerable concern due to its contamination of agricultural fields.<sup>40</sup> It is

worth noting that selective receptors for bisulfate are scarce,<sup>49–51</sup> reflecting challenges in their design and synthesis. Given that  $\text{HSO}_4^-$  is a tetrahedral anion with a volume of  $58.9 \text{ \AA}^3$  (falling between that of  $\text{ClO}_4^-$  and  $\text{ReO}_4^-$ ) we hypothesized that it should be readily encapsulated by the interlocked host. Indeed, upon the addition of 2 equivalents of  $\text{HSO}_4^-$  to Cl@2, a significant shift of protons g and f' (+0.48 and +0.3 ppm respectively) which point into the outer pockets, was observed to occur slowly relative to the  $^1\text{H}$  NMR timescale (Fig. S29 and S47†).<sup>‡</sup> In contrast to the  $\text{ReO}_4^-$  guest, the pyrazole proton c showed minimal shifting, suggesting that the bisulfate guest is in line with the  $\text{Pd}_4$  axis, positioned directly between the  $\text{Pd}^{\text{II}}$  of the outer cavities. Evidence for a  $(\text{HSO}_4^-)_2\text{X@2}$  host-guest complex was obtained from ESI-MS analysis (Fig. S64 and S67†). Since initial estimates indicated that the binding affinity of  $\text{HSO}_4^-$  was an order of magnitude greater than that of  $\text{ClO}_4^-$ , (thus approaching the accuracy limit of  $^1\text{H}$  NMR spectroscopy), we turned to Isothermal Titration Calorimetry (ITC).

Titration of Cl@2 with the bisulfate anion produced an isotherm that was fitted to a multiple-sites model. Values for the binding sites ( $n_1 = 1$ ;  $n_2 = 1$ ) confirmed the expected 1 : 2 host-guest stoichiometry (Fig. 6a and b). Data fitting yielded anion-exchange equilibrium constants of  $K_1 = 3.3 \times 10^6 \text{ M}^{-1}$  and  $K_2 = 3.1 \times 10^4 \text{ M}^{-1}$  which indeed is an order of magnitude higher than  $\text{ClO}_4^-$  and  $\text{ReO}_4^-$ . The thermodynamic data revealed that anion exchange at both sites of Cl@2 is enthalpically and entropically driven (Fig. 6c). The binding of  $\text{HSO}_4^-$  was also observed for Br@2, although unsurprisingly, the binding constants were an order of magnitude lower compared to Cl@2 (Table 1). For Br@2, the exchange of the second  $\text{BF}_4^-$  anion for  $\text{HSO}_4^-$  appears to be somewhat entropically disfavoured,

**Fig. 6** (a) Heat flow produced upon titrating a MeCN solution of Cl@2 with tetrabutylammonium bisulfate; (b) binding isotherm according to the cumulative heat of injection and equivalents of the guest; (c) thermodynamic parameters of guest exchange ( $\text{BF}_4^-$  for  $\text{HSO}_4^-$ ) (d)  $^1\text{H}$  NMR spectra (600 MHz,  $\text{CD}_3\text{CN}$ , 25 °C) of a competition experiment: (i) Cl@2; (ii) Cl@2 + 2 equiv. of  $\text{ClO}_4^-$ ; (iii) Cl@2 + 2 equiv. of  $\text{ClO}_4^-$  and  $\text{HSO}_4^-$ ; (iv) Cl@2 + 2 equiv. of  $\text{HSO}_4^-$ .

suggesting the host may lose degrees of freedom (presumably manifested by the flexible bis-pyrazole ligand) when accommodating the larger  $\text{HSO}_4^-$  anion. Given that  $K_2$  is  $\sim 100$  and  $\sim 350$  times smaller than  $K_1$  for  $\text{Cl}@2$  and  $\text{Br}@2$  respectively, the host-guest binding occurs with negative cooperativity. Interestingly, both interlocked cages showed no binding affinity toward dihydrogen phosphate ( $\text{H}_2\text{PO}_4^-$ ), which is remarkable given it is also a tetrahedral anion albeit with a marginally higher volume than  $\text{HSO}_4^-$  ( $63.1 \text{ \AA}^3$  vs.  $58.9 \text{ \AA}^3$ , Fig. S33 and S50†). This suggests that the anion volume plays an important role in determining the cooperativity of this semi-flexible interlocked host. As observed in the X-ray structure of  $(\text{ClO}_4)_2\text{Cl}@2$ , the exchange of  $\text{BF}_4^-$  for the larger  $\text{ClO}_4^-$  guest results in a  $0.16 \text{ \AA}$  compression along the  $\text{Pd}_4$  axis (Fig. S75†), which may reduce the available volume in the second outer cavity after the first binding event. This effect is likely to be amplified for anions approaching a volume of  $\sim 60 \text{ \AA}^3$  which can explain the negative cooperativity in the case of  $\text{HSO}_4^-$ .

Finally, we performed competition experiments to assess the selectivity of  $\text{X}@2$  for  $\text{HSO}_4^-$  over  $\text{ClO}_4^-$  and  $\text{ReO}_4^-$ . Upon titrating two equivalents of  $\text{ClO}_4^-$  and  $\text{HSO}_4^-$  to  $\text{Cl}@2$ , diagnostic downfield shifts of proton g indicated that the  $(\text{HSO}_4)_2\text{Cl}@2$  complex dominates the mixture (Fig. 6d and S58†). In this experiment, the presence of  $\text{ClO}_4^-$  resulted only in the shifting of proton f, which points outside the cage cavity (Fig. 6d). In nearly all cases, the competing  $\text{ClO}_4^-$  or  $\text{ReO}_4^-$  complexes could not be detected by  $^1\text{H}$  NMR spectroscopy (Fig. S58–S61†). This is fully consistent with the higher binding strength of  $\text{HSO}_4^-$  and further confirms that the interlocked cage is a highly selective receptor for  $\text{HSO}_4^-$ . The stability of the  $\text{HSO}_4^-$  host-guest complex may relate to the guest's optimal size as well as the possibility of forming  $\text{O-H}\cdots\pi$  interactions between the acidic proton of the guest and the electron-rich pyrazole rings of the host.<sup>52,53</sup>

## Conclusions

In summary, we have reported the anion-templated assembly of a novel interlocked coordination cage with two outer pockets poised to bind  $\text{HSO}_4^-$  anions selectively. First, we showed that a thermodynamically stable monomeric cage composed of a non-coordinating bpm backbone could be isolated through appropriate solvent choice and stoichiometric control. The intermediate dimensions of this  $\text{Pd}_2\text{L}_4$  cage (as defined by the ligand's  $D_{\text{N-N}}$  of  $\sim 15 \text{ \AA}$ ) facilitated the formation of a rare type II interlocked dimer in the presence of  $\text{Cl}^-$  or  $\text{Br}^-$  templates, and  $\text{BF}_4^-$  counter ions. The self-assembly experiments with  $\text{NO}_3^-$  counterions further highlighted the importance of counter ion volume in accessing type I or type II motifs. Whilst this is only one more piece of the puzzle to understand the anion-cation patterns of catenation, it may open up opportunities to design and access a greater range of multi-cavity cage structures with guest-accessible cavities.

Comparing the host-guest chemistry between the  $\text{Br}^-$  and  $\text{Cl}^-$  templated dimer revealed large differences in anion binding strength (up to an order of magnitude in favor of  $\text{Cl}@2$ ), despite the small difference in the volume of the

templating anion. These findings may be relevant for tuning cavity dimensions and thus enhancing guest binding selectivity in this class of interlocked dimers. Finally, ITC and  $^1\text{H}$  NMR experiments revealed strong and selective binding of  $\text{HSO}_4^-$  by  $\text{X}@2$ , outcompeting similarly sized anions in binary mixtures. These results may inspire future studies on interlocked hosts for biphasic anion separation systems<sup>51</sup> or selective ion channels.<sup>54,55</sup>

## Data availability

The data supporting this article have been included as part of the ESI.†

## Author contributions

J. I. V. conducted the NMR analysis and host-guest studies. S. T. conducted ligand synthesis and contributed to data analysis. M. R. J. aided in 2D NMR measurements and performed EXSY analysis. W. M. B. conceived the idea, solved and refined the X-ray structures, performed ITC analysis, and wrote the manuscript. All authors commented and provided input into the final version of the manuscript.

## Conflicts of interest

There are no conflicts to declare.

## Acknowledgements

W. M. B gratefully acknowledges Flinders University EMCR start-up grant and the Australian Research Council (DE190100327) for financially supporting this project. Aspects of this research were undertaken on the MX1 (ref. 56) and MX2 (ref. 57) beamlines at the Australian Synchrotron, Victoria, Australia. J. I. V. acknowledges support from an ATSE Elevate PhD Scholarship.

## Notes and references

‡ The  $^1\text{H}$  NMR spectra indicated that protonation of the dimeric cages does not occur when bisulfate is added; the cage remained stable at higher equivalents (judged by no free ligand being released) and the pyrazole protons (b and c) remained relatively sharp after the addition of  $>2$  equivalents of  $\text{HSO}_4^-$  to  $\text{Cl}@2$  and  $\text{Br}@2$  (Fig. S29 and S47†). Moreover, titrating  $\text{HSO}_4^-$  in a  $\text{CD}_3\text{CN}$  solution of **L** did not result in protonation of the ligand (Fig. S56†).
