# Reshaping and enzymatic activity may allow viruses to move through the mucus

Falko Ziebert,<sup>a</sup> Kenan G. Dokonon<sup>c</sup> and Igor M. Kulić<sup>de</sup>

Filamentous viruses like influenza and torovirus often display systematic bends and arcs of mysterious physical origin. We propose that such viruses undergo an instability from a cylindrically symmetric to a toroidally curved state. This “toro-elastic” state emerges *via* spontaneous symmetry breaking under prestress due to short range spike protein interactions magnified by surface topography. Once surface stresses are sufficiently large, the filament buckles and the curved state constitutes a soft mode that can potentially propagate through the filament’s material frame around a Mexican-hat-type potential. In the mucus of our airways, which constitutes a soft, porous 3D network, glycan chains are omnipresent and influenza’s spike proteins are known to efficiently bind and cut them. We next show that such a non-equilibrium enzymatic reaction can induce spontaneous rotation of the curved state, leading to a whole body reshaping propulsion similar to – but different from – eukaryotic flagella and spirochetes.

## 1. Introduction

Thin fibers are common structural elements in biology, from biofilaments to body shapes of viruses and bacteria. Notably, biological filaments like the bacterial flagellar hook,<sup>1–3</sup> microtubules,<sup>4,5</sup> and intermediate filaments<sup>6</sup> exhibit an unusual, common motif: their straight ground state can become unstable, reshaping them into polymorphic toroids and superhelices. Not less surprisingly, when driven out of equilibrium, stimuli-responsive but otherwise straight fibers can acquire a dissipative toroidal steady state of spontaneous rotation.<sup>7,8</sup> Visually inspecting the shapes of filamentous viruses like influenza C (IV-C)<sup>9,10</sup> or Torovirus,<sup>11</sup> see Fig. 1a and c, the natural question arises if viral envelopes possess a similar symmetry-broken, toroidal ground state. And as viruses like influenza A (IV-A) and C,<sup>12–14</sup> as well as paramyxovirus<sup>15</sup> have been shown to be able to roll on surfaces due to their spike proteins’ catalytic activity, can their toroidal state be driven catalytically and used for virus propulsion?

In the following we consider a plausible model for the emergence of curved states, that arise *via* a spontaneous symmetry breaking, represent a soft mode around the virus axis and which we call the “toro-elastic” state of the viral

envelope. It relies on surface switchability *via* spike protein contacts and a mismatch-stress with layers further inside the virus. Notably, recently resolved surface structures of influenza C<sup>17</sup> have shown extensive spike-spike contacts, establishing a hexagonal lattice on the envelope. The switch corresponds to the making-and-breaking of any reversible physical bond – including hydrogen bonds, screened-electrostatic, van der Waals bonds – as well as protein-tail-mediated interactions. After demonstrating the mechanism giving rise to the toro-elastic state, we explain how its continuous ground state can act as a “wheel within the material”,<sup>7</sup> mirroring the “universal joint” model of the bacterial flagellar hook.<sup>1–3</sup>

Finally, we consider such a filamentous virus with a toroidal mode embedded into a loose 3D mucus network, *cf.* (Fig. 1d). In this environment, polymeric ligands that can be bound to and cut by the enzymatic spikes on the viral envelope can induce dynamic force imbalances. This situation reflects what influenza is confronted within the mucus of our airways, a highly viscous environment containing polymers with sugary ends (glycans) the virus spikes interact with. We show that the cutting of glycans by enzymatic spikes can force the toroidally curved state to spontaneously rotate, once enzymatic activity surpasses a certain threshold. This dynamic shape rotation should allow the virus to move at small but noticeable speeds, and could explain why catalytic activity increases mucus penetration so strongly for influenza.<sup>18,19</sup>

## 2. Toro-elastic state

We focus here on influenza C, whose spike protein is called Hemagglutinin-esterase-fusion protein (HEF), for which

**Fig. 1** Emergent toroidal shapes of various biofilaments (a)–(c), a filamentous influenza virus in its natural environment – the mucus (d), and geometry of the virus and the toroidal mode (e) and (f). (a) Torovirus.<sup>16</sup> (b) The bacterial flagellar hook.<sup>2</sup> (c) Influenza C: long filamentous viruses display both straight and oscillatory shapes<sup>10</sup>; the inset shows a shorter, curved influenza C that is actively rolling on a glycan-coated surface.<sup>13</sup> (d) The mucus environment that the influenza virus has to bypass forms a loose protein fiber network decorated with sticky glycan chains. (e) In the considered filamentous virus, spike proteins are arranged on a typically staggered column lattice with spacing  $l_0$  and effective radius  $R$  (including the spikes). (f) Curving the lattice by a curvature  $\kappa$  allows some spikes to interact at the inside of the bend (left). Which particular spikes can interact depends on their orientation angle  $\theta$  (right) with respect to the angle  $\phi$  of the curvature vector  $\kappa$ .

spike–spike interactions have been experimentally evidenced.<sup>17</sup> We consider a virus whose surface is covered with radial spikes with initial axial spacing  $l_0$  (see Fig. 1e). If the virus curves, variations of strains  $\varepsilon$  and thus distances along the axis between spikes are amplified proportional to the effective radius of the cylindrical virus,  $R$ , and the centerline curvature  $\kappa$  like  $l(\kappa) \approx \varepsilon l_0 = \kappa R l_0$ . In addition, there is a geometric “shortcut factor” for finite deformations: For spiky surface elements that interact along the shortest spatial distance, this distance is given by the secant line, see Appendix A for details.

Introducing the vectorial curvature perpendicular to the axis  $\kappa = (\kappa_x, \kappa_y) = \kappa(\cos \phi, \sin \phi)$  with orientation angle  $\phi$  and magnitude  $\kappa$ , and parameterizing the material-fixed spike positions with angle  $\theta$  (with  $\theta = \phi$  corresponding to the orientation of the curvature vector, *i.e.* towards the bend), the spacing between surface contacts along the axis is given by, see Fig. 1f and Appendix A,

$$l(\kappa, \theta - \phi) = l_0 \frac{\sin(\kappa l_0/2)}{\kappa l_0/2} (1 - R\kappa \cos(\theta - \phi)). \quad (1)$$

Here the first term is the shortcut factor described above and the second reflects the dependence on angle differences. At this point we fix  $\kappa$  to point in the  $x$ -direction ( $\phi = 0$ ).

The spikes are assumed to be uniformly distributed over the surface, *cf.* Fig. 1f on the right, and every spike can interact with its axial neighbors that are within range, letting them gain a binding energy (per unit length),  $v(l)$ . On the flip side, binding along its long axis implies a curving of the cylindrical virus, which costs elastic bending energy. Modeling the latter contribution as a harmonic term with bending stiffness  $B$ , the total

energy per cross section is hence given by

$$E = E_{\text{bend}} + E_{\text{bind}} = \frac{1}{2} B \kappa^2 + \int_0^{2\pi} v(l(\kappa, \theta)) d\theta. \quad (2)$$

While HEF-spikes have been shown to strongly interact,<sup>17</sup> their detailed binding potential  $v(l)$  is yet unknown. However, as the sum of many small interactions between different regions along the spikes' surfaces, it will be of short-ranged nature. Interestingly, apart from its magnitude and short ranged nature, the detailed form of  $v$  turns out to be non-essential for the emergence of the toro-elastic state. For demonstration, we here use a linear-exponential potential,

$$v(l) = -v_0 \frac{l}{\sigma} \exp\left(1 - \frac{l}{\sigma}\right), \quad (3)$$

as sketched in Fig. 2a. It has a minimum, corresponding to the bound state, at  $l = \sigma$  with  $v(\sigma) = -v_0$  and quickly flattens for  $l > \sigma$ .

Inserting eqn (1) and (3) into eqn (2), the energy can be calculated analytically.<sup>†</sup> Importantly, for suitable parameters its shape is of Mexican-hat-type, see the inset showing the energy shape in the light green region of Fig. 2b. This is what we call the “toro-elastic” state: a finite curvature is preferred, whose direction (*i.e.*, angle  $\phi$ ) is arbitrary and hence corresponds to a soft mode. Fig. 2b shows the different energy landscapes/shapes when varying the depth,  $v_0$ , and the

<sup>†</sup> The result is

$$E = \frac{1}{2} B \kappa^2 - 2\pi v_0 \frac{a}{\kappa R} e^{(1-a/R)} (I_0(a) - \kappa R I_1(a)),$$

where  $a = \frac{2R}{\sigma} \sin(\kappa l_0/2)$  and  $I_0, I_1$  are the modified Bessel functions of the first kind.

**Fig. 2** (a) Spike interaction potential with a minimum at a finite distance  $\sigma$ . (b) “Phase diagram” in the plane potential depth,  $v_0$ , vs. potential minimum position,  $\sigma$ . The straight ground state (dark green) has  $B_{\text{eff}} > 0$  (usual elasticity) and its energy minimum is at  $\kappa = 0$ . However, it can become unstable through spike–spike interactions and give rise to a Mexican-hat-type potential (light green), where  $B_{\text{eff}} < 0$  and the energy minimum is at finite  $\kappa$  and arbitrary angle, reflecting a soft mode (“toro-elastic” mode). There also exists a coexistence region (yellow) where  $\kappa = 0$  and the toro-elastic state are separated by an energy barrier. Parameters:  $\sigma$  in nm and  $v_0$  in  $k_B T \text{ nm}^{-1}$  for fixed  $l_0 = 25 \text{ nm}$ . Virus radius  $R = 50 \text{ nm}$ ; bending rigidity  $B = 3k_B T \mu\text{m}$ . (c) Phase diagram as function of the unperturbed spike spacing,  $l_0$  (in nm) vs. potential minimum position,  $\sigma$  (in nm), for fixed contact potential strength  $v_0 = 1k_B T \text{ nm}^{-1}$ , other parameters as in (b).

minimum position,  $\sigma$ , of the potential for fixed spike distance  $l_0$  and virus stiffness  $B$ . This phase diagram displays: (i) an elastic state (dark green) where  $\kappa = 0$  is the energy minimum, corresponding to a straight virus; (ii) the toro-elastic region (light green), where the minimum is a circle with  $|\kappa| = \kappa_{\text{tor}}$  and arbitrary angle  $\phi$ ; and (iii) a coexistence region (yellow), where both previous states are local minima, with a barrier in between. Fig. 2c shows a similar phase diagram in the plane spike distance  $l_0$  vs. minimum position of the potential  $\sigma$ , now for fixed potential depth  $v_0$ .

To understand when the straight state becomes unstable, we expand the energy up to second order in curvature, yielding  $E = E_0 + \frac{1}{2}B_{\text{eff}}\kappa^2$  with  $E_0 = -\frac{2\pi l_0 v_0}{\sigma}e^{-\frac{l_0}{\sigma}}$  and an effective bending stiffness  $B_{\text{eff}} = B + B_{\text{bind}}$  with  $B_{\text{bind}} = 2\pi v_0 l_0^2 e^{-l_0/\sigma} \left[ \frac{R^2}{\sigma^2} \left( 1 - \frac{l_0}{2\sigma} \right) + \frac{l_0}{12\sigma} \left( 1 - \frac{l_0}{\sigma} \right) \right]$ . This binding-induced part of the effective stiffness can become negative. In fact, this can be always satisfied for  $l_0 \gtrsim 2\sigma$  if in addition the interaction is sufficiently large,  $v_0 \gg e^{l_0/\sigma} B/l_0^2$ : then  $B_{\text{bind}}$  overrules  $B$  and the filament curves, with higher order terms stabilizing a finite toroidal curvature  $\kappa_{\text{tor}}$ .

This toro-elastic state generically appears for short ranged potentials; a general condition can be determined by expanding an arbitrary potential  $v(l)$  around its straight state  $l_0$ , see Appendix B. Then for  $\frac{R^2}{l_0^2} \gg 1$ ,  $B_{\text{eff}} = B + \pi v''(l_0) l_0^2 R^2$ , implying that the curvature  $v''(l_0)$  of the potential must be sufficiently negative,

$$v''(l_0) < -\frac{B}{\pi l_0^2 R^2}. \quad (4)$$

This is in fact fulfilled by many short ranged potentials, when crossing over from the minimum to the plateau at large distances.

The virus curvature in the toro-elastic state adjusts such that a significant portion of the cross-section (typically half of it),

benefits from the surface interactions. For that, the elements of the surface need to shift from their unperturbed distance  $l_0$  to  $\sigma$ , *i.e.* by an amount  $l_0 - \sigma \sim \kappa_{\text{tor}} R l_0$ , which yields an estimate for the curvature of the toro-elastic state

$$\kappa_{\text{tor}} \sim R^{-1}(1 - \sigma/l_0). \quad (5)$$

The stiffness of the toroelastic state (*i.e.* the curvature orthogonal to the rim of the “Mexican hat”) is dominated by surface interactions. To estimate it, we assume a curvature variation  $\delta\kappa$  around  $\kappa_{\text{tor}}$ , such that the binding distance changes by  $\sim\sigma$ , implying  $\delta\kappa \sim \frac{\sigma}{R l_0}$ , and the binding energy by  $\delta E \approx |E_0|$ . Equating  $\frac{1}{2}K_{\text{tor}}(\delta\kappa)^2 \approx |E_0|$  then yields

$$K_{\text{tor}} \approx 4\pi \left( \frac{l_0}{\sigma} \right)^3 e^{1-\frac{l_0}{\sigma}} R^2 v_0 \quad (6)$$

up to subdominant contributions from bending elasticity.

Considering numbers, typical scales are  $l_0 = 25 \text{ nm}$ ,  $\sigma = 10 \text{ nm}$  and  $R = 50 \text{ nm}$ ; potential strength around  $v_0 = 1k_B T \text{ nm}^{-1}$ . The bending rigidity of a virus is hard to measure,<sup>20</sup> but considering the virus as a membrane tube we estimate  $B = 2\pi R \times 10k_B T \simeq 3k_B T \mu\text{m}$ . Using these values, one finds  $B_{\text{bind}} \simeq -5.7k_B T \mu\text{m}$ , hence indeed  $B_{\text{eff}} < 0$  is at reach. Further we estimate from eqn (5) and (6) that  $\kappa_{\text{tor}} \simeq (100 \text{ nm})^{-1}$  and the toro-elastic stiffness  $K_{\text{tor}} \simeq 100k_B T \mu\text{m}$ , which is much larger than the usual bending rigidity.

### 3. Toroelastic state driven by ligand dynamics

Having seen how the toro-elastic, curved state arises, we now show how the orientation angle of the curved state – representing a soft mode due to the Mexican-hat-type potential – can be driven to rotate in an out-of-equilibrium situation. For this we assume that the virus is embedded in a solvent that contains a substantial

concentration of glycan-coated polymers which the virus spikes' can attach to and enzymatically cut. This reflects the situation in the mucus, which is a gel/network of long and heavily (up to 80%) glycosylated mucins,<sup>21</sup> having a pore size of 100–500 nm,<sup>22</sup> hence larger than the virus diameter. For simplicity, we model this situation *via* di-glycan “dumbbells” floating in solution, representing attachment to glycans from the same mucin backbone. We would like to stress that we consider the virus to be embedded in a 3D environment, *cf.* (Fig. 1d). This should be contrasted to the catalytic spike-induced motion of viruses on surfaces.<sup>12,13,23</sup> In the latter case, strategies like the burnt-bridge mechanism, employing the trail of cut glycans behind to rectify the motion, or rolling<sup>14,24</sup> can be used. In contrast, in the absence of surfaces both mechanisms are not possible or not effective (with the trail in 3D having a mathematical measure close to zero).

The argument for rotation involves two steps: first, when glycan dumbbells attach to two axially neighboring spikes, they introduce longitudinal tensions on top of the toro-elastic state, creating a torque. Second, the cutting of the glycan dumbbells leads to a release of tension with a certain dead time for new binding, since cut glycans have yet to detach. Like that, torque is maintained by breaking of detailed balance and the dead time gives the system a “directional memory”, once a direction of rotation is picked.<sup>‡</sup>

To calculate the torque due to dumbbell attachment, we assume the di-glycans to be harmonic polymer springs with spring constant  $S$  and vanishing preferred length. They can be unbound (state  $B_0$ ), bound to one spike (state  $B_1$ ) or to two neighboring spikes – along the backbone – defining the double bound state  $D$ , see the upper part of the reaction scheme in Fig. 3b. In the double bound state, glycans stretch out to a non-zero length given by eqn (1), with  $\phi$  the orientation of the curvature  $\kappa$  and  $\theta$  the angular position of the spike it attaches to in the considered cross-section.

Note that, for simplicity, we consider here only relevant spike-glycan interactions, which are the ones along the virus axis, or having, when projected, a component along the axis. Couplings along the azimuthal direction are neglected, since they do not contribute to axial bending. Note that this simplification introduces effective, phenomenological binding rates.

As the spikes are assumed to be uniformly distributed over the surface, all states have to be described by a function of the azimuthal angle  $\theta$ . In general, a cross-section will have an azimuthal imbalance of the (double-)bound density  $D(\theta)$ . The total glycan stretching energy per cross-section of thickness  $l_0$  then reads  $E_{\text{str}}(D) = \frac{S}{2} \int D(\theta) l^2(\kappa, \theta)$ . Assuming small curvatures  $\kappa R, \kappa l_0 \ll 1$  and applying a mode ansatz  $D(\theta) = D_0 + D_s \sin \theta + D_c \cos \theta$ , to linear order  $E_{\text{str}}(D) \approx \frac{S}{2} l_0^2 (D_0 - R\kappa(D_c \cos \phi + D_s \sin \phi))$ . The corresponding torque (per  $l_0$  section) is given by  $M_{\text{dr}} = -\frac{\partial E_{\text{str}}}{\partial \phi}$  and in

the frame co-moving with the toro-elastic curvature evaluates to

$$M_{\text{dr}} = \frac{Sl_0^2}{2} R\kappa D_s = m_{\text{dr}} D_s. \quad (7)$$

This is the driving torque from the inhomogeneously distributed double bound glycans, with  $m_{\text{dr}}$  the characteristic torque scale. Assuming a Kuhn length of a glycan chain of  $b \sim 0.5 \text{ nm}^{25}$  and a number of bonds of  $N \sim 40$  or larger one expects typical spring constants  $S \simeq \frac{k_B T}{bN^2} \sim 0.01 - 0.1 k_B T \text{ nm}^{-2}$ . Together with the above parameters and  $\kappa = \kappa_{\text{tor}}$ , we estimate  $m_{\text{dr}} \simeq 2-20 k_B T$ , which is much larger than the hydrodynamic resistance of such a small cross-section. In view of this, we will first study the case, where resistance can be completely neglected, implying that the total torque is zero. It should be however noted that the attachment-detachment dynamics to the sticky mucin network elements of the mucus can contribute an additional friction term due to dragging a portion of the mucins along with the virus. Therefore, in a next step, we will add the (rotational) resistance perturbatively.

To describe the possible steady-state torque generation, we now consider the enzymatic glycan cutting activity of the HEF spike. The reaction scheme just discussed has to be extended by two more states associated to the cutting reaction, as sketched in the lower part of Fig. 3(b): First, a double bound glycan can be cut into two, to a state  $C_2$  that still blocks both spikes for further attachments. If one of these cut parts detaches, or if a single bound glycan is cut, this yields state  $C_1$ . Importantly, only if all cut parts have left, one recovers state  $B_0$  and the spike can be “reused” for attachment.

The full reaction scheme of Fig. 3b translates into

$$\begin{aligned} \frac{d}{dt} B_1 &= k_1 G B_0 - (k_{-1} + k_2(\theta - \phi) + k_{\text{cut}}) B_1 + k_{-2} D, \\ \frac{d}{dt} D &= k_2(\theta - \phi) B_1 - k_{-2} D - k_{\text{cut}} D, \\ \frac{d}{dt} C_1 &= k_{\text{cut}} B_1 + k_{-1} C_2 - k_{-1} C_1, \\ \frac{d}{dt} C_2 &= k_{\text{cut}} D - k_{-1} C_2, \end{aligned} \quad (8)$$

where all considered states are functions of  $\theta$ . An additional equation for the unbound state  $B_0$  can be eliminated *via*  $B_0 + B_1 + C_1 + C_2 + D = 1$ , since all quantities are site population fractions. These dynamic equations can be directly deduced from the scheme in Fig. 3b. Exemplarily, the equation for the single bound state  $B_1$  has a gain term from the attachment of a glycan ( $G$ ) to a free spike ( $B_0$ ) with rate  $k_1$ ; loss terms proportional to  $B_1$  and reflecting detachment (with rate  $k_{-1}$ ), attachment to a second spike (with rate  $k_2$ ) and getting cut (with rate  $k_{\text{cut}}$ ), and another gain term if a double bound state ( $D$ ) detaches from the adjacent spike (rate  $k_{-2}$ ). Importantly, the double binding rate  $k_2(\theta - \phi)$  depends on the position relative to

<sup>‡</sup> Note that this value is large, considering that it acts on a short section of size  $l_0$ . As a reference, the rotational friction at an angular frequency  $\omega = 2\pi \text{ s}^{-1}$  in a rather viscous medium of  $\eta = 0.1 \text{ Pa s}$  (100 times of water) for  $R = 50 \text{ nm}$  is approximately  $M \approx 0.05 k_B T$ , *i.e.* largely subdominant compared to the linker-induced torque  $M_{\text{dr}}$  for not too low  $D_s$ .

<sup>‡</sup> Jumping bit ahead, as we will see later in this section, the direction of rotation is set by the phase-shift of certain ligand-binding populations introduced in Fig. 3 and plotted in Fig. 4.

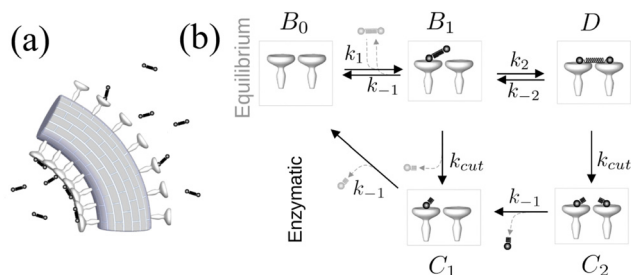

Fig. 3 (a) Interaction of tension-inducing polymeric ligand springs (glycan dumbbells) with the virus spikes. (b) The reaction kinetics of equilibrium binding and catalytic cutting.

the curvature vector: for a bent virus, di-glycans bind more easily at the inside of bent regions where they stretch less, cf. (Fig. 3a).

We now consider the steady-state, where the virus curvature  $\kappa$  is rotating with constant angular frequency  $\omega$  – that has to be determined, and could of course be zero – implying  $\phi(t) = \omega t$ , and where  $\kappa = \text{const.}$  as suggested by the high stiffness of the toroidal state estimated above. We hence transform eqn (8) into the co-moving frame,  $\phi = 0$ , where steady states become time independent and the total time derivative transforms into an advective derivative  $\frac{d}{dt} \rightarrow \frac{\partial}{\partial \theta}$ .

The double binding rate,  $k_2(\theta)$  in the co-moving frame, can be specified as follows: we expect a relation

$$k_2(\theta) = k_2^0(1 + \alpha \cos \theta), \quad (9)$$

with a coupling constant  $\alpha > 0$  that that will depend on the stretching constant of the glycan polymer chains that connect neighboring spikes. For small curvatures  $\kappa R$ ,  $\kappa l_0 \ll 1$ , one can relate the binding rates on the two opposing

$$\text{sides } \frac{k_2(\theta)}{k_2(\theta + \pi)} = e^{\frac{S - l^2(\theta) + l^2(\theta + \pi)}{k_B T}} \approx 1 + \left( \frac{2Sl_0^2}{k_B T} R\kappa \right) \cos \theta.$$

Matching this result with eqn (9),  $\frac{k_2(\theta)}{k_2(\theta + \pi)} = \frac{1 + \alpha \cos \theta}{1 - \alpha \cos \theta} \approx 1 + 2\alpha \cos \theta$ , yields the estimate

$$\alpha = \frac{Sl_0^2}{k_B T} R\kappa \quad (10)$$

for the dimensionless coupling constant, which in the following is assumed to be small for simplicity.

The equations for the steady state dynamics in the co-moving coordinate system can be solved by applying a mode ansatz, similar as above for the driving torque. Now all chemical species are expressed as  $X = X^0 + X^c \cos \theta + X^s \sin \theta$  for  $X = B_1, D, C_1, C_2$ . In the case of negligible fluid friction, and fast binding of the second bond of the dumbbell,  $k_2^0 \gg k_{\text{others}}$ , the solution can be given analytically, see appendix C. One finds that  $\omega = 0$  – i.e. no rotation – is always a solution. However, solutions with finite angular velocity, given by

$$\omega^2 = \frac{k_1 G k_{cut}}{2} \left( 1 + \sqrt{1 + \frac{8k_{-1}^2}{k_1 G k_{cut}}} \right) - k_{-1}^2, \quad (11)$$

bifurcate from the no-rotation branch for sufficiently rapid glycan cutting rate

$$k_{cut} > k_{cut}^{c,0} = \frac{k_{-1}^2}{3k_1 G}. \quad (12)$$

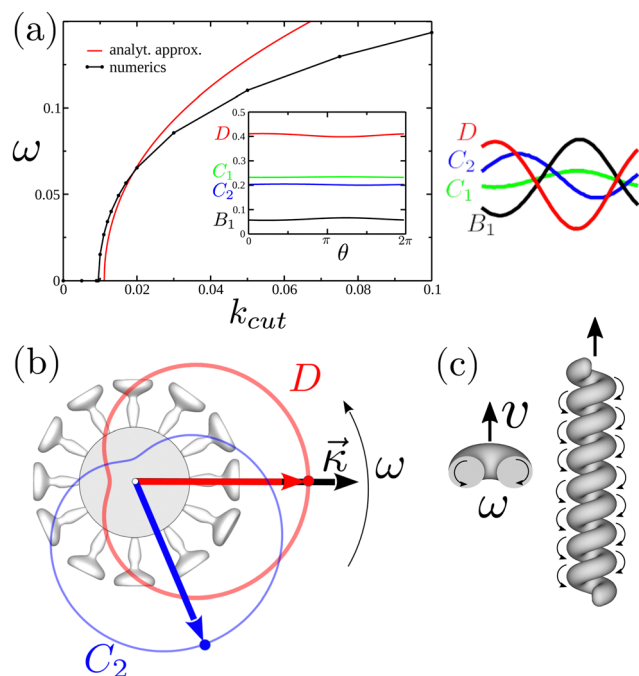

Rephrasing eqn (12) as  $\frac{k_1 G k_{cut}}{k_{-1} k_{-1}} > \frac{1}{3}$ , the first ratio demands a sufficiently large effective attachment rate ( $k_1 G$ ) to supply for new  $D$  (for large  $k_2$ ,  $B_1$  converts to  $D$  fast) and the second a sufficiently large cutting rate to maintain non-equilibrium. Due to the product, faster attachment can compensate for slower cutting and *vice versa*. Notably, the rotating state also requires a sufficiently long “dead time” interval  $t_{dt} = 1/k_{-1}$ , i.e. a sufficiently small off-rate  $k_{-1}$  compared to  $k_{cut}$ . This is intuitively understandable, as large dead times allow for the maintenance of the angular direction (clockwise/anticlockwise rotation), while too short dead times would effectively erase the directional memory of the main force-generating “power-stroke” sequence  $B_0 \rightarrow D \rightarrow C_i \rightarrow B_0$  and the time-ordering of the force-generating state  $D(\theta, t)$  in the azimuthal direction necessary for persistent rotation.

It is also possible to solve the problem in the presence of the small, hydrodynamic rotational resistance. Assuming a hydrodynamic (Stokes) rotational friction torque  $M_h = \xi_h \omega = 4\pi\eta R^2 l_0 \omega$  and equating it with the driving torque, eqn (7), one gets  $k_{cut}^c = k_{cut}^{c,0} + k_{cut}^{c,1}(\eta)$ . The correction is to leading order linear in fluid viscosity  $\eta$ , proportional to  $\frac{R}{\alpha^2 S l_0 \kappa}$  and in addition depends on the chemical rates. See Appendix C for the result, eqn (46), and how it is obtained.

Fig. 4a shows the angular velocity  $\omega$  as a function of the cutting rate  $k_{cut}$ ; the red curve shows (the positive branch of) eqn (11) and the black curve are numerical results including the frictional torque. Since the kinetic parameters of IV-C have not been characterized, we had to resort to estimates for IV-A here:  $G = 3 \text{ mM}$ ;  $k_1 = 0.1 \text{ mM}^{-1} \text{ s}^{-1}$ ,  $k_{-1} = 0.1 \text{ s}^{-1}$ ,<sup>26,27</sup>  $k_2^0 = 1 \text{ mM}^{-1} \text{ s}^{-1}$ ,  $k_{-2} = 0.1 \text{ s}^{-1}$ . Note that cutting rates are estimated conservatively, IV-A's neuraminidase reaches rates of up to  $k_{cut} = 15 \text{ s}^{-1}$ .<sup>28</sup>

We have shown that dynamic force imbalances, caused by interactions of the virus spikes with glycans from the 3D environment, can lead to a rotation of the toroidal state. We note that in Section 2, we considered the toroidal state to be caused by spike-spike interactions. Hence the creation of the toroidal state, and its rotation outside of equilibrium, have different causes: spike-spike vs. spike-glycan interactions. While the former needs localized, anharmonic interactions, for the additional imbalance caused by the latter linear springs are sufficient. Experimental evidence shows strong spike-spike interactions, at least for IV-C.<sup>17</sup> Nevertheless, one could also imagine the toroidal state to be caused (or modulated) by spike-glycan interactions as well. In that case, the rotation is probably less stable: when the virus moves, its rear will be exposed to fewer uncut glycans, and the helix at the rear may unfold. Such effects, as well as considering a varying density of the enzymatic spikes along the virus backbone – or a phase-separated one, as in IV-A<sup>23</sup> – would be interesting to investigate in the future.

**Fig. 4** (a) The toroidal mode's angular frequency as a function of the cutting rate  $k_{\text{cut}}$  (both in units  $\text{s}^{-1}$ ). Red curve: analytical result, eqn (11), obtained without friction. Black curve: numerical result with realistic frictional torque coefficient  $\zeta_h/m_{\text{dr}} = 0.01$ . Parameters as described in the main text. Inset: The angular dependence of the steady-state populations. Right hand side: Scaled and shifted populations for visual comparison. Note their typical phase lag. (b) The polar plot of the double-bound and cut state populations,  $D(\theta, t)$  and  $C_2(\theta, t)$  respectively, shows their characteristic phase-shift determining the direction of toroidal rotation. Polar plots are schematic and not to scale. (c) The latter kinetics induces a uniform, shape-invariant rotation of a short toroidal virus or an elongated helical virus with frequency  $\omega$ . When embedded in a viscous fluid the rotation leads to a swimming kinematics similar to fluid vortex lines.<sup>29,30</sup>

## 4. Helix formation

Let us now come back to the helical shapes of IV-C as shown in Fig. 1c, noting that also filamentous IV-A sometimes displays curvature.<sup>31</sup> So far, we considered a single cross-section, hence the natural question arises how different cross-section are coupled. As sketched in Fig. 1e as pairs 1–2 and 3–4, in general viruses have staggered spike sub-lattices.

Assuming for simplicity two sub-lattices, I and II, these experience the mean effective curvature induced by the other sub-lattice over their length scale ( $l$ ) as  $\kappa_{\text{II}} = \left| \frac{1}{l} \int_{-l/2}^{+l/2} \kappa_1(s) ds \right|$  and analogously for  $\kappa_{\text{I}}$ , implying a smearing-out of sectional curvature over the two lattices. For a curvature vector of constant amplitude slowly winding with a torsion rate  $\tau \ll l^{-1}$  like  $\kappa(s) = \kappa(\cos(\tau s)\mathbf{e}_x + \sin(\tau s)\mathbf{e}_y)$ , the total energy of the two sub-lattices can be calculated to be, see Appendix D, as

$$E_{\text{tot}}/K_{\text{tor}} = \frac{1}{4}(\kappa_{\text{tor}} - \kappa)^2 + \frac{1}{4} \left[ (\kappa_{\text{tor}} - \kappa) + \kappa \frac{l^2 \tau^2}{24} \right]^2. \quad (13)$$

This energy is positive definite. Its ground state is curved and untwisted,  $\kappa = \kappa_{\text{tor}}$  and  $\tau = 0$ . The first term is similar to classical bending energy, followed by a torsion–bend coupling

that is quartic for  $\kappa = \kappa_{\text{tor}}$ . Notably, for curvatures larger than optimal,  $\kappa > \kappa_{\text{tor}}$ , the torsion becomes bistable with two new preferred states  $\tau_{1,2} = \pm \frac{\sqrt{24}}{l} \sqrt{1 - \kappa_{\text{tor}}/\kappa}$ . Hence external bending torques – like those due to the above-discussed glycan binding – will turn the toroidal ground state into a bistable helix. The symmetry between the two helical states is likely broken by a geometrical chirality of the natural spike lattice – an effect neglected here for simplicity.

## 5. Discussion and conclusions

There is an old question from biology asking “why nature does not have wheel and axles”. In the light of what we know about the emergence of toroidal zero-energy modes in the bacterial flagellar hook<sup>2,3</sup> (and possibly microtubules<sup>4,5</sup>), the question can be tentatively answered by: Nature has something better – the “wheel within (the filament)”. In fact, to implement and maintain bi-component wheel-axle system is hard to achieve biologically, but a very practical replacement exists: any elastic object equipped with a circularly symmetric zero-energy mode. Such structures have the great advantage of being single piece continuous structures that are containing both an axle (the material frame of the structure), and the wheel – the deformation propagating (rotating) with respect to the material frame at virtually no elastic energy cost. The simplest of such ZEEMs<sup>7</sup> (zero elastic energy modes) seems to be the toro-elastic mode we revisited here for filamentous viruses.

We have shown that such a mode can generically appear for any rough surface spiked cylinder – like a filamentous influenza virus – for sufficiently strong and short ranged spike interactions, competing with elastic restoring forces of the elastic core of the cylinder. Once this toro-elastic ZEEM emerges and equilibrium detailed balance is somehow broken – as by the spike-catalysed glycan-cutting investigated here – it becomes possible for this “wheel-like” mode to actively rotate in a particular direction, randomly picked by a non-equilibrium bifurcation as investigated here. The resulting spatial motion, that could be seen as a shape invariant, constant angular velocity “re-bending” dynamics of the filament perpendicular to its axis is similar to the anholonomic body reshaping of a falling cat<sup>32,33</sup> and has been described in various terms and contexts in the literature. Other examples include the “eversion/inversion” for self-rolling polymer fibers,<sup>8,34</sup> “wobbling motion” in clamped, superhelical microtubules<sup>4</sup> and the “ideal joint” rotation for the bacterial flagellar hook driven by the flagellar motor.<sup>3</sup> A related active re-bending/eversion motion in the soft, body reshaping bacterium *Spiroplasma* has been also recently described.<sup>35</sup>

Furthermore we have shown that the toro-elastic mode in a long filament equipped with a sticky surface lattice can induce helix formation in addition to toroids. The spontaneous emergence of multi-stable and rearranging helices is very common in biological filaments and their origins have been studied in various systems including bacterial flagella,<sup>36–39</sup> microtubules,<sup>4,5</sup>

intermediate filaments<sup>6</sup> and spiroplasma.<sup>35</sup> Looking at the wealth of examples, one is tempted to suspect that the cylindrically symmetric filament shape could be structurally unstable against perturbations and that the superhelical filament is the rule rather than the exception in Nature. The common theme behind the emergent helicity in these filaments seems to be some form of core-shell stress mismatch combined with various forms of elastic anharmonicity, that originates from mechanical, geometric or molecular nonlinearities. In contrast to these previous examples, in the proposed virus model, the helical states are still subcritical or “evanescent”, that is, only upon (arbitrary small) additional stresses, the straight state spontaneously breaks the symmetry and picks one of two handed helices. However, it appears possible or even likely that specific spike-lattice arrangement and chiral spike-spike interactions would give rise to more specific, additional effects, so far neglected here. This would lead to definite handedness helices in the ground state of the virus and be described by similar physics as in the other helical systems.<sup>36,37,39,40</sup>

Finally, if – *via* the enzymatic drive described above – the toroidal or helical virus uniformly rotates its body keeping its shape invariant, see (Fig. 4c), we expect it to self-propel and swim. Whether the motion corresponds to a toroidal or a helical rotation depends on the presence (or absence) of angular shift between the directions of curving of two subsequent cross-sections. In the case that all curvature directions are found in a single (osculating) plane, an ideal toroidal rotation occurs, see (Fig. 4c) on the left. If the plane of curvature is changing along the contour, the rotation is helical, see (Fig. 4b) on the right. The swimming kinematics will be that of a helically shaped spinning cable. Mathematically this is a vortex line of fixed vorticity  $\propto \omega$ , self-advecting through the fluid.<sup>29</sup> In leading order the self-propulsion is independent of the (small) helical torsion and occurs at typical velocities of spinning tori  $v \sim \omega \kappa R^2$ .<sup>30,41</sup> Note that the predicted shape invariant swimming contrasts body-reshaping swimmers (like spirochetes) using propagating bending waves, where the velocity depends on undulation amplitude and wavelength but not on radius.<sup>42</sup>

The described motility mechanism should be directly applicable to IV-C. It could also be relevant for influenza A, where, however, the two dynamic properties of the spike – the binding to/unbinding from glycan and the cutting of glycan residues – are not co-localized in a single HEF spike. In IV-A, these tasks are performed by two different spike proteins, hemagglutinin (HA) for the binding/unbinding and neuraminidase (NA) for the cutting. This makes the surface structure of IV-A more complex, and in fact, HA and NA are often phase-separated on the virus surface,<sup>23</sup> implying that the theory developed here has to be generalized to inhomogeneous spike distributions. Our theory is also relevant for the design of synthetic self-propelled objects, where the adhesion-cutting mechanism has been already implemented, *e.g.*, *via* DNA-RNA hybridization (binding/unbinding) and catalytic action of RNase H (selectively cutting duplexes), to induce surface-based motion.<sup>43–46</sup> The here-described 3D toroidal motion should be at reach for DNA nano-tubes floating in a

solution of RNA, able to bind to two DNAs along the backbone, and RNase H. One could also think of synthetically motorizing the flagellar hook.<sup>2,3</sup>

Coming back to viruses, while IV-C has rarely been studied, many studies on IV-A suggest that the enzymatic activity (of NA in case of IV-A) is important for mucus penetration, both on the macroscopic level,<sup>18,19</sup> as well as by observing filamentous viruses directly.<sup>23</sup> For purely spherical viruses, however, it seems that NA is less relevant and it is rather the mesh size of the mucus that determines the diffusion, as reported in ref. 47. This finding is in accordance with our model and the one by Vahey and Fletcher,<sup>23</sup> where only filamentous viruses can profit from enzymatic mechanisms. We note that the mechanism described in ref. 23 is ratchet-based, hence the longer the filament, the slower the motion – since then the virus engages many links, causing increasing friction, proportional to virus length. In contrast, the mechanism proposed here would be effective independent of virus length.

In future studies, the nature of the mucus as a natural habitat environment for filamentous influenza viruses needs some deeper considerations. Regardless of the detailed motility mechanism, the mucus poses a significant barrier to viral motion. Depending on its mesoscale morphological features, like its pore size<sup>47</sup> or glycan density and type,<sup>21</sup> it will impose different constraints to the viral filament in various shapes and modes of motion. Large scale motion through such an environment would not be easily possible for a virus that is straight or a piece of a torus, while a helical filament could easily “follow its own footprint” and retrace its way through the mucus pores.

In conclusion, filamentous viruses like influenza C, possessing the toro-elastic state due to axial interactions can develop helical shapes and can attain a spontaneous rotation upon binding and cutting interactions with the glycans floating in the mucus. The predicted angular velocities are comparable to the rolling angular velocities of surface attached viruses (fractions of  $s^{-1}$ <sup>13,14</sup>). The expected swimming velocity of tens of nm/s is rather modest compared to swimming speeds of microorganisms, yet still of the order of one virus size per second and hence preferable to staying immobilized in the extremely viscous, sticky environment faced in the mucus. The proposed mechanism adds another possible motility mode – effective in 3D surroundings such as loose mucus networks – to the existing repertoire of the influenza family and torovirus, beyond ratchet-like motion<sup>23</sup> and rolling,<sup>12,13</sup> which both employ glycan-coated surfaces.

### A. Derivation of the “shortcut factor”: surface–surface contact spacing

To derive the formula for the spacing between surface contacts from the main text, eqn (1), we assume that deformations are linear, keeping the “neutral line” arc-length contour distances unchanged, *i.e.*  $d_{12} = \text{const.}$ , independent of  $\kappa$ . After uniformly bending the virus with a center line curvature  $\kappa$ , *cf.* Fig. 5, the surface elements on the outside of the bend (found at a radial spacing  $R$  from the neutral line) change their distances along the circular contour proportional to the curvature  $\kappa$

$$d'_{12} = d_{12}(1 + R\kappa).$$

For spiky surface elements that interact along the shortest spatial distance, the relevant spatial distance  $s_{12}$  between two spikes is shorter than the surface arc-length  $d'_{12}$ : it is given by the length of the secant line corresponding to an opening angle  $\gamma = \frac{1}{2}\angle(S_1OS_2) = \frac{1}{2}\kappa d_{12}$  with length

$$s_{12} = \frac{\sin(\gamma)}{\gamma} d'_{12} = \frac{\sin\left(\frac{1}{2}\kappa d_{12}\right)}{\frac{1}{2}\kappa d_{12}} d_{12}(1 + R\kappa).$$

The spatial distance can be simply generalized to any azimuthal orientation  $\theta$  of the bent cylinder (where  $\theta = 0$  points to the “inside” of the bend) such that

$$s_{12}(\theta) = \frac{\sin\left(\frac{1}{2}\kappa d_{12}\right)}{\frac{1}{2}\kappa d_{12}} d_{12}(1 - R\kappa \cos \theta).$$

With  $d_{12} = l_0$  and giving the curvature direction another angle,  $\phi$ , this is eqn (1) from the main text.

Fig. 5 Sketch of the geometry of a strongly bent cylinder (the virus capsid/envelope) and the emergence of the short-cut factor.

### B. Influence of the potential shape on the emergence of the toro-elastic state

#### Gaussian potential

We investigated a more general potential of Gaussian form,

$$v(l) = -v_0 \exp\left(-\frac{(l - \sigma)^2}{2\delta}\right), \quad (14)$$

where one can vary the position of the minimum ( $\sigma$ ), the depth ( $v_0$ ) and in addition the width of the potential well (variance  $\delta$ ) all independently.

Unfortunately, the energy cannot be calculated analytically anymore. Fig. 6 shows results for the “phase” diagrams obtained by numerical minimization. The color code is the same as in Fig. 2. The left figure shows the plane  $l_0$  vs. variance  $\delta$  for fixed  $\sigma = 10$  nm. One can see a certain symmetry with respect to  $l_0 = 10$  nm: now, the spikes can also induce the toro-elastic state by stretching out towards the minimum of the potential. The toro-elastic state is easiest to attain for a short ranged (variance)  $\delta$  of the potential, but on the other hand its existence region shrinks for small  $\delta$  and the region of coexistence increases. The right figure shows the plane  $l_0$  vs.  $\sigma$  for fixed  $\delta = 10$  nm<sup>2</sup>. One can see interesting series of transitions. For instance, choosing  $\sigma = 15$  nm, upon increasing  $l_0$  from a small value one finds first the elastic state, then coexistence, then the toro-elastic state, again an elastic region and a toro-elastic region (and again coexistence for larger  $l_0$ , beyond the region visible in the figure).

The additional study of the Gaussian potential shows that the shape of the potential of course matters, but that the three states described in the main text – elastic, toro-elastic and coexistence – are again found.

#### Harmonic potential

To shed some light on which properties the binding potential has to fulfill in order for the toro-elastic instability to occur, let us study the simplest case of a harmonic binding potential. Note that a harmonic  $v(l)$  is not physically realistic, as every realistic binding potential will have a finite range. Using  $v(l) = a(l - b)^2$  with some spring stiffness  $2a$  and preferred length  $b$ ,

Fig. 6 (a)  $l_0$  in nm and  $\delta$  in nm<sup>2</sup> for  $\sigma = 10$  nm. (b)  $l_0$  and  $\sigma$  in nm for  $\delta = 10$  nm<sup>2</sup>. Color-code is according to the energy minima, as in Fig. 2b and c. Dark green: elastic state, straight state is stable; light green: toro-elastic state, with an energy minimum at finite  $\kappa$ ; yellow: coexistence region. Parameters: virus radius  $R = 50$  nm; virus bending rigidity  $B = 3k_B T \mu\text{m}$ ; contact potential strength  $v_0 = 1k_B T \text{nm}^{-1}$ .

the binding energy reads (note that  $l = l(\kappa, \theta)$ )

$$E_{\text{bind}} = \int_0^{2\pi} v(l(\kappa, \theta)) d\theta = \text{const} + a \int_0^{2\pi} l^2 d\theta - 2ab \int_0^{2\pi} l d\theta$$

The two integrals can be evaluated

$$\begin{aligned} L_1(\kappa, \theta) &= \int_0^{2\pi} l(\kappa, \theta) d\theta = 2\pi l_0 \frac{\sin(\kappa l_0/2)}{\kappa l_0/2}, \\ L_2(\kappa, \theta) &= \int_0^{2\pi} l^2(\kappa, \theta) d\theta = l_0^2 \left( \frac{\sin(\kappa l_0/2)}{\kappa l_0/2} \right)^2 (2\pi + \pi R^2 \kappa^2), \end{aligned} \quad (15)$$

and dropping the constant energy shift, one gets

$$E_{\text{bind}} = 2\pi a l_0^2 \frac{\sin(u)}{u} \left( \frac{\sin(u)}{u} \left( 1 + 2 \left( \frac{R}{l_0} \right)^2 u^2 \right) - 2 \frac{b}{l_0} \right)$$

with  $u = \kappa l_0/2$ . Expanding for small  $u$  shows that in the relevant limit  $R > l_0$  and for any positive preferred length  $b$  of the harmonic spring, the quadratic term is always positive.

But in principle, a negative quartic term could still induce an instability. To investigate this, adding the bending stiffness

term  $\frac{B}{2} \kappa^2 = \frac{B}{2} \left( 2 \frac{u}{l_0} \right)^2 = \frac{2B}{l_0^2} u^2$  yields the total energy

$$\frac{E_{\text{tot}}(u)}{2\pi a l_0^2} = \gamma u^2 + \frac{\sin(u)}{u} \left( \frac{\sin(u)}{u} (1 + 2\rho^2 u^2) - 2\beta \right) \quad (16)$$

with the three dimensionless constants

$$\gamma = \frac{B}{\pi a l_0^4}, \quad \rho = \frac{R}{l_0}, \quad \beta = \frac{b}{l_0}$$

where  $\rho > 1$ , typically even  $\rho \gg 1$ .

Taylor expanding for small  $u$  yields, neglecting a constant,

$$\frac{E_{\text{tot}}(u)}{2\pi a l_0^2} = \frac{(3\gamma + 6\rho^2 + \beta - 1)u^2}{3} - \frac{(120\rho^2 + 3\beta - 8)u^4}{180}.$$

When the (negative) quartic and the (positive) quadratic term become comparable, we expect a barrier  $u \approx u_{\text{bar}}$  to occur which for the special case of  $\beta = 0$  can be given as

$$u_{\text{bar}} \simeq \left( \frac{3\gamma + 6\rho^2 - 1}{2\rho^2 - \frac{2}{15}} \right)^{1/2}$$

which typically is  $\gg 1$ . That means in practice this case is not relevant, as excluded volume effects should enter way before, at  $u$  of order 1.

In summary, we have just shown that for a harmonic potential, the straight state increases in stability and cannot show an instability.

### Criterion for toro-elasticity for a general potential

Let us now assume a general potential  $v(l)$  and investigate, when the straight state can become unstable. For that we

expand  $v(l)$  around its straight state  $l = l_0$ ,

$$v(l) = v_0 + v'(l_0)(l - l_0) + \frac{1}{2} v''(l_0)(l - l_0)^2 + \dots \quad (17)$$

The binding energy can again be evaluated, expanding the functions  $L_1$ ,  $L_2$  defined in eqn (15) in powers of  $\kappa$ . Again dropping constant energy contributions, we get

$$E_{\text{bind}} = \frac{1}{2} l_0^4 \pi \left[ -\frac{v'(l_0)}{6l_0} + v''(l_0) \frac{R^2}{l_0^2} \right] \kappa^2 + \dots \quad (18)$$

Interestingly, going on in the expansion of eqn (17), the contribution from  $v''(l_0)$  cancels in  $O(\kappa^2)$ . Furtheron, it is easy to check that, using eqn (18) for the linear-exponential potential, eqn (3), exactly recovers the criterion discussed in the main text. This both corroborates that the contributions from  $v'(l_0)$  and  $v''(l_0)$  are the most relevant contributions.

For the toro-elastic state to emerge, the prefactor of the term  $\propto \kappa^2$  in eqn (18) has to be negative. In general, the second term is the dominant one, due to its large geometric prefactor  $\frac{R^2}{l_0^2} \gg 1$ . As a generic necessary condition for the toro-elastic instability – in the relevant parameter range for a thin virus – one can hence state that  $v''(l_0) < 0$  should hold. A harmonic potential is strictly convex and  $v''(l_0) > 0$  forbids the instability, as shown before. But  $v''(l_0) < 0$  is of course possible for a short ranged potential in its concave region. In fact, all short ranged potentials have a concave region, namely when crossing over from the minimum to the zero-level plateau at large distances.

Including the bending rigidity, the total potential reads

$$E_{\text{tot}} = \frac{1}{2} \left( B + \pi v''(l_0) l_0^2 R^2 - \frac{\pi}{6} l_0^3 v'(l_0) \right) \kappa^2 + \dots$$

and for  $\frac{R^2}{l_0^2} \gg 1$  is dominated by the first two terms. The toroelastic state then emerges for

$$v''(l_0) < -\frac{B}{\pi l_0^2 R^2}, \quad (19)$$

as stated in the main text.

## C. Perturbation theory for the rotating state

We now consider the case where the toro-elastic curvature  $\kappa$  may rotate in the lab frame with angular velocity  $\omega$ , due to the chemical reactions (attachment and cutting of glycan dumbbells). We place ourselves in the co-moving coordinate system where  $\kappa$  is stationary and can rewrite the dynamics by replacing the time derivative in terms of the advective derivative  $\frac{d}{dt} \rightarrow \frac{\partial}{\partial t} + \omega \frac{\partial}{\partial \theta}$ . As we are only interested in the steady state, the partial time derivative drops out and we are left with the replacement rule

$$\frac{d}{dt} \rightarrow \omega \frac{\partial}{\partial \theta}$$

for the chemical reactions in the main manuscript. Eliminating  $B_0$  by using  $B_0 = 1 - B_1 - C_1 - C_2 - D$ , eqn (8) in the stationary, co-moving frame now read

$$\begin{aligned}\omega \frac{\partial}{\partial \theta} B_1 &= +k_1 G - k_1 G(C_1 + C_2) - (k_1 G + k_{-1} + k_2(\alpha, \theta) + k_{\text{cut}}) B_1 \\ &\quad + (k_{-2} - k_1 G) D, \\ \omega \frac{\partial}{\partial \theta} D &= +k_2(\alpha, \theta) B_1 - k_{-2} D - k_{\text{cut}} D, \\ \omega \frac{\partial}{\partial \theta} C_1 &= +k_{\text{cut}} B_1 + k_{-1} C_2 - k_{-1} C_1, \\ \omega \frac{\partial}{\partial \theta} C_2 &= +k_{\text{cut}} D - k_{-1} C_2.\end{aligned}\quad (20)$$

Now we make the simple mode ansatz already mentioned in the main part: all chemical species  $X = B_1, D, C_1, C_2$  can have a constant, a cos- and a sin-mode,

$$X = X^0 + X^c \cos \theta + X^s \sin \theta. \quad (21)$$

The amplitudes  $X^0, X^c, X^s$  need to be determined, except for the  $D^s$  - mode - existing in the presence of external torques - which is fixed by the torque balance: in the general case, where an external torque is present, we have (in the co-moving frame)

$$D^s = m, m = \frac{M_h}{m_{\text{drive}}}, \quad (22)$$

where  $m$  is the non-dimensional torque.  $M_h$  is the hydrodynamic resistance torque. If any external torque is neglected, one simply has  $D^s = 0$ .

We exemplify the method for the equation for  $C_2$ . One inserts the mode ansatz into  $\omega \frac{\partial}{\partial \theta} C_2 = +k_{\text{cut}} D - k_{-1} C_2$ , to obtain

$$\begin{aligned}\omega \frac{\partial}{\partial \theta} (C_2^0 + C_2^c \cos \theta + C_2^s \sin \theta) &= \omega (-C_2^s \sin \theta + C_2^c \cos \theta) \\ &= +k_{\text{cut}} (D^0 + D^c \cos \theta + D^s \sin \theta) \\ &\quad - k_{-1} (C_2^0 + C_2^c \cos \theta + C_2^s \sin \theta).\end{aligned}$$

Now we project on the modes by performing integrations like  $\int d\theta$ ,  $\int \sin \theta d\theta$  and  $\int \cos \theta d\theta$ . This yields three conditions - for the constant, sin- and cos-mode, respectively:

$$\begin{aligned}0 &= k_{\text{cut}} D^0 - k_{-1} C_2^0, \\ -\omega C_2^c &= -k_{-1} C_2^s + k_{\text{cut}} D^s, \\ \omega C_2^s &= k_{\text{cut}} D^c - k_{-1} C_2^c.\end{aligned}$$

Note that terms  $\propto D^s$  are only present in the case of an external torque. The equations can be solved and simplified.

Proceeding the same way for all equations, one gets expressions for  $B_1, C_1, C_2$  as functions of  $D^0, D^c, D^s$

$$\begin{aligned}B_1^0 &= \frac{k_{-2} + k_{\text{cut}}}{k_2^0 \left(1 - \frac{\alpha^2}{2}\right)} \left(D^0 - \frac{\alpha}{2} D^c\right) - \frac{\alpha}{2} \frac{\omega}{k_2^0 \left(1 - \frac{\alpha^2}{2}\right)} D^s, \\ B_1^s &= -\frac{\omega}{k_2^0} D^c + \frac{k_{-2} + k_{\text{cut}}}{k_2^0} D^s,\end{aligned}\quad (23)$$

$$\begin{aligned}B_1^c &= \frac{k_{-2} + k_{\text{cut}}}{k_2^0 \left(1 - \frac{\alpha^2}{2}\right)} (D^c - \alpha D^0) + \frac{\omega}{k_2^0 \left(1 - \frac{\alpha^2}{2}\right)} D^s, \\ C_1^0 &= \frac{k_{\text{cut}}}{k_{-1}} B_1^0 + C_2^0, \\ C_1^s &= \frac{k_{-1} (k_{\text{cut}} B_1^s + k_{-1} C_2^s) + \omega (k_{\text{cut}} B_1^c + k_{-1} C_2^c)}{k_{-1}^2 + \omega^2}, \\ C_1^c &= \frac{k_{-1} (k_{\text{cut}} B_1^c + k_{-1} C_2^c) - \omega (k_{\text{cut}} B_1^s + k_{-1} C_2^s)}{(k_{-1}^2 + \omega^2)},\end{aligned}\quad (24)$$

$$\begin{aligned}C_2^0 &= \frac{k_{\text{cut}}}{k_{-1}} D^0, \\ C_2^s &= \frac{\omega k_{\text{cut}}}{k_{-1}^2 + \omega^2} D^c + \frac{k_{-1} k_{\text{cut}}}{k_{-1}^2 + \omega^2} D^s, \\ C_2^c &= \frac{k_{\text{cut}} k_{-1}}{k_{-1}^2 + \omega^2} D^c - \frac{k_{\text{cut}} \omega}{k_{-1}^2 + \omega^2} D^s,\end{aligned}\quad (25)$$

and three additional equations

$$\begin{aligned}0 &= k_1 G - k_1 G C_1^0 - k_1 G C_2^0 + (k_{-2} - k_1 G) D^0 \\ &\quad - (k_1 G + k_{-1} + k_2^0 + k_{\text{cut}}) B_1^0 + k_2^0 \alpha \frac{1}{2} B_1^c, \\ -\omega B_1^c &= -k_1 G C_1^s - k_1 G C_2^s - (k_1 G + k_{-1} + k_2^0 + k_{\text{cut}}) B_1^s \\ &\quad + (k_{-2} - k_1 G) D^s,\end{aligned}\quad (26)$$

$$\begin{aligned}\omega B_1^s &= -k_1 G C_1^c - k_1 G C_2^c + (k_{-2} - k_1 G) D^c - (k_1 G + k_{-1} + k_2^0 + k_{\text{cut}}) B_1^c \\ &\quad + k_2^0 \alpha B_1^0,\end{aligned}\quad (27)$$

for the three unknowns  $D^0, D^c$ , and  $\omega$  - note that  $D^s$  is not an unknown, since it is fixed by  $m$  (or zero in absence of external torque).

### Approximation of fast binding rate $k_2$

To be able to proceed, we now assume that the binding of the second "leg" of a glycan dumbbell that is already attached to the virus,  $k_2$ , is faster than all other processes. More specifically, we assume  $k_2^0 \gg k_{\text{others}}, \omega$  while  $k_{\text{others}} B_1 \rightarrow 0$ ,  $\omega B_1 \rightarrow 0$  and only  $B_1 k_2^0 \sim O(1)$  stays finite.

The effect is that we can drop all terms with  $k_{\text{others}}B_1$ , express everything in terms of  $D^0$ ,  $D^c$ ,  $D^s$  and get  $C_1^0 = \frac{k_{\text{cut}}}{k_{-1}}D^0 = C_2^0$  and

$$\begin{aligned} C_1^s &= \frac{k_{-1}k_{\text{cut}}}{(k_{-1}^2 + \omega^2)^2}(2\omega k_{-1}D^c + (k_{-1}^2 - \omega^2)D^s), \\ C_1^c &= \frac{k_{-1}k_{\text{cut}}}{(k_{-1}^2 + \omega^2)^2}((k_{-1}^2 - \omega^2)D^c - 2\omega k_{-1}D^s), \end{aligned} \quad (29)$$

while the other expressions for  $C_2^0$ ,  $C_2^s$ ,  $C_2^c$ ,  $B_1^0$ ,  $B_1^s$  and  $B_1^c$  stay the same. Eqn (26)–(28) simplify to

$$0 = k_1 G(1 - C_1^0 - C_2^0) + (k_{-2} - k_1 G)D^0 - k_2^0 B_1^0 + k_2^0 \alpha \frac{1}{2} B_1^c, \quad (30)$$

$$0 = -k_1 G(C_1^s + C_2^s) - k_2^0 B_1^s + (k_{-2} - k_1 G)D^s, \quad (31)$$

$$0 = -k_1 G(C_1^c + C_2^c) + (k_{-2} - k_1 G)D^c - k_2^0 B_1^c + k_2^0 \alpha B_1^0. \quad (32)$$

From eqn (29), we can now extract

$$(C_1^s + C_2^s) = \frac{\omega k_{\text{cut}}(3k_{-1}^2 + \omega^2)}{(k_{-1}^2 + \omega^2)^2}D^c + \frac{2k_{-1}^3 k_{\text{cut}}}{(k_{-1}^2 + \omega^2)^2}D^s$$

and

$$(C_1^c + C_2^c) = \frac{2k_{-1}^3 k_{\text{cut}}}{(k_{-1}^2 + \omega^2)^2}D^c - \frac{k_{\text{cut}}\omega(3k_{-1}^2 + \omega^2)}{(k_{-1}^2 + \omega^2)^2}D^s$$

and inserting all known fields into eqn (30)–(32) results in three closed equations for  $D^0$ ,  $D^c$  and  $\omega$  for given  $D^s$ :

$$\begin{aligned} 0 &= k_1 G + \left( k_{-2} - k_1 G - \frac{2k_{\text{cut}}k_1 G}{k_{-1}} - \frac{(k_{-2} + k_{\text{cut}})\left(1 + \frac{\alpha^2}{2}\right)}{\left(1 - \frac{\alpha^2}{2}\right)} \right) D^0 \\ &+ \alpha \frac{k_{-2} + k_{\text{cut}}}{\left(1 - \frac{\alpha^2}{2}\right)} D^c + \frac{\alpha\omega}{\left(1 - \frac{\alpha^2}{2}\right)} D^s, \end{aligned} \quad (33)$$

$$\begin{aligned} 0 &= \left( \omega - \frac{k_1 G k_{\text{cut}}(3k_{-1}^2 + \omega^2)}{(k_{-1}^2 + \omega^2)^2} \right) D^c \\ &- \left( \frac{k_1 G 2k_{-1}^3 k_{\text{cut}}}{(k_{-1}^2 + \omega^2)^2} + k_1 G + k_{\text{cut}} \right) D^s, \end{aligned} \quad (34)$$

$$\begin{aligned} 0 &= \left( -\frac{k_1 G 2k_{-1}^3 k_{\text{cut}}}{(k_{-1}^2 + \omega^2)^2} + k_{-2} - k_1 G - \frac{(k_{-2} + k_{\text{cut}})\left(1 + \frac{\alpha^2}{2}\right)}{\left(1 - \frac{\alpha^2}{2}\right)} \right) D^c \\ &+ 2\alpha \frac{k_{-2} + k_{\text{cut}}}{\left(1 - \frac{\alpha^2}{2}\right)} D^0 + \left( \frac{k_1 G k_{\text{cut}}\omega(3k_{-1}^2 + \omega^2)}{(k_{-1}^2 + \omega^2)^2} - \frac{\omega\left(\frac{\alpha^2}{2} + 1\right)}{\left(1 - \frac{\alpha^2}{2}\right)} \right) D^s. \end{aligned} \quad (35)$$

### Case of negligible external torque/friction

The simplest result can be obtained, if one assumes that the external torque – which is due to hydrodynamic friction, and for such a small object as a 100 nm thin virus should be very small – is negligible.  $m = 0$  then immediately implies  $D^s = 0$ , cf. eqn (22).

In this case, from eqn (34), we immediately get the following instructive result:

$$0 = \omega \left( 1 - \frac{k_1 G k_{\text{cut}}(3k_{-1}^2 + \omega^2)}{(k_{-1}^2 + \omega^2)^2} \right) D^c. \quad (36)$$

First of all,  $\omega = 0$  – i.e. no rotation at all – is always a solution, as it should. The term in brackets could yield non-trivial solutions, but only in case that  $D^c \neq 0$ . This also makes sense, since otherwise  $D$  would be constant and no torque is created. In fact, for  $\alpha \neq 0$  one has  $D^c \neq 0$  – which can be seen from eqn (33) and (35). There is one more condition:  $k_{-1} > 0$  has also to be finite. Otherwise one can show that  $D(\omega) = 0$ , which reflects a “blocking effect”: all initially existing double bound states were cut and the cut glycans never can detach.

In total, this yields (in case  $\alpha$ ,  $k_{-1} \neq 0$ ) three possible solutions for the angular velocity  $\omega$ :

$$\omega = 0 \text{ or } \omega^2 = \frac{k_1 G k_{\text{cut}}}{2} \left( 1 + \sqrt{1 + \frac{8k_{-1}^2}{k_1 G k_{\text{cut}}}} \right) - k_{-1}^2, \quad (37)$$

as given in the main text. The latter yields two symmetric branches,

$$\omega = \pm \sqrt{\frac{k_1 G k_{\text{cut}}}{2} \left( 1 + \sqrt{1 + \frac{8k_{-1}^2}{k_1 G k_{\text{cut}}}} \right) - k_{-1}^2}. \quad (38)$$

This is the pitchfork bifurcation explained in the main manuscript: for sufficiently large cutting rate  $k_{\text{cut}}$ , namely if

$$k_{\text{cut}} > k_{\text{cut}}^{c,0} = \frac{k_{-1}^2}{3k_1 G} \quad (39)$$

such that the radicand becomes positive, two new branches with finite angular velocity emerge from the trivial branch  $\omega = 0$ . The turning direction is spontaneously chosen, depending on the initial conditions.

### General case and obtaining the motor relation

To treat the general case, we consider the limit of small  $\alpha$ , i.e. small variations of  $k_2(\theta)$  with  $\theta$ . We expand eqn (33)–(35) to

linear order in  $\alpha$ , and notice that a certain symmetry emerges:

$$0 = k_1 G - \left( k_1 G + \frac{2k_{\text{cut}} k_1 G}{k_{-1}} + k_{\text{cut}} \right) D^0 + \alpha(k_{-2} + k_{\text{cut}}) D^c + \alpha \omega D^s, \quad (40)$$

$$0 = u(\omega) D^c - v(\omega) D^s, \quad (41)$$

$$0 = -v(\omega) D^c - u(\omega) D^s + 2\alpha(k_{-2} + k_{\text{cut}}) D^0, \quad (42)$$

where we introduced the quantities

$$u(\omega) = \omega \left( 1 - \frac{k_1 G k_{\text{cut}} (3k_{-1}^2 + \omega^2)}{(k_{-1}^2 + \omega^2)^2} \right), \quad (43)$$

$$v(\omega) = \left( \frac{2k_1 G k_{-1}^3 k_{\text{cut}}}{(k_{-1}^2 + \omega^2)^2} + k_1 G + k_{\text{cut}} \right).$$

From (41) we immediately get  $D^c = \frac{v}{u} D^s$ , inserting into (42) yields

$$D^0 = \frac{\frac{v^2}{u} + u}{2\alpha(k_{-2} + k_{\text{cut}})} D^s.$$

and inserting into (40), one obtains

$$0 = k_1 G - \left( k_1 G + \frac{2k_{\text{cut}} k_1 G}{k_{-1}} + k_{\text{cut}} \right) \frac{\frac{v^2}{u} + u}{2\alpha(k_{-2} + k_{\text{cut}})} D^s + \alpha(k_{-2} + k_{\text{cut}}) \frac{v}{u} D^s + \alpha \omega D^s.$$

Dropping orders  $O(\alpha^2)$  we solve for

$$D^s = \frac{2\alpha k_1 G (k_{-2} + k_{\text{cut}})}{v_0} \frac{u}{v^2 + u^2}, \quad (44)$$

where  $v_0 = v(\omega = 0)$ . Remembering the relation between the torque and  $D^s$ , eqn (22), we finally obtain the “motor relation”

$$M_h = m_{\text{drive}} \frac{\alpha^2 k_1 G (k_{-2} + k_{\text{cut}})}{v_0} \frac{u(\omega)}{v^2(\omega) + u^2(\omega)}. \quad (45)$$

It relates any external torque (here the hydrodynamic frictional torque  $M_h$ ) to the kinetics of the rotation.

### Dynamics under Stokes friction

Assuming the external torque is Stokes friction in a fluid of viscosity  $\eta$ , yields the explicit expression

$$M_h = 4\pi\eta R^2 l_0 \omega$$

and

$$\frac{4\pi\eta R^2 l_0 \omega}{m_{\text{drive}}} = \alpha^2 \frac{k_1 G (k_{-2} + k_{\text{cut}})}{v_0} \frac{u}{v^2 + u^2}.$$

Considering that for small torques,  $u$  is small as well – note that  $u(\omega) = 0$  was the relation determining  $\omega$  in the case of no frictional torque, cf. eqn (36) – we drop the  $u^2$  – term in the denominator and expand the r.h.s. for  $\omega^2$  small (close to the onset of motion). The leading order constant term  $O(\omega^0)$

cancels on both sides for the motion to occur

$$\frac{\left( 1 + \frac{2k_{\text{cut}}}{k_{-1}} + \frac{k_{\text{cut}}}{k_1 G} \right) 4\pi R^2 l_0}{(k_{-2} + k_{\text{cut}}) \alpha^2 m_{\text{drive}}} \eta = \frac{\left( 1 - \frac{3k_1 G k_{\text{cut}}}{k_{-1}^2} \right)}{\left( \frac{2k_1 G k_{\text{cut}}}{k_{-1}} + (k_1 G + k_{\text{cut}}) \right)^2},$$

where  $k_{\text{cut}}$  is now the critical value for the onset of motion. This condition can now be solved perturbatively, for small l.h.s., in the relevant activity parameter  $k_{\text{cut}}$ . The latter deviates from the case without frictional torque,  $k_{\text{cut}}^0$  like  $k_{\text{cut}} = k_{\text{cut}}^0 + c\eta$  with some proportionality constant  $c$ . Inserting this expansion we get  $c$  to lowest order in  $\eta$ . The result for the finite, but small viscosity correction to the critical cutting rate is (inserting  $m_{\text{drive}} = \frac{S}{2} l_0^2 R \kappa$ ):

$$k_{\text{cut}}^c = k_{\text{cut}}^{c,0} + k_{\text{cut}}^{c,1}(\eta) \text{ with } k_{\text{cut}}^{c,0} = \frac{k_{-1}^2}{3k_1 G},$$

$$k_{\text{cut}}^{c,1} = \frac{k_{\text{cut}}^0 \left( k_1 G + \left( \frac{2k_1 G}{k_{-1}} + 1 \right) k_{\text{cut}}^0 \right)^3}{k_1 G (k_{-2} + k_{\text{cut}}^0)} \frac{8\pi R}{\alpha^2 S l_0 \kappa} \eta. \quad (46)$$

## D. Details on helix formation

In general a virus surface displays multiple interdigitated and mutually staggered sub-lattices of switchable spike-pairs, as sketched in (Fig. 1e) (pairs 1–2 and 3–4). We assume here for simplicity just two sub-lattices, I and II.

In the following we make the intuitive assumption that the curvature vector is a smooth function along the contour  $s$ , regardless of how it is measured, over sub-lattice I or II. This in particular implies that one sub-lattice will experience the mean effective curvature of the other sub-lattice (averaged over the smallest characteristic length scale  $\sim l$ ). Due to the smoothness, the curvature vector felt by sub-lattice II at some position  $s$  can be formally expressed by the mean of curvature vector over the sub-lattice I in its close vicinity, i.e. as

$$\kappa_{\text{II}}(s) = \frac{1}{l} \int_{s-l/2}^{s+l/2} \kappa_{\text{I}}(s') ds'. \quad (47)$$

For a constant modulus  $\kappa_{\text{I}}$ , and a slowly rotating curvature vector on the sub-lattice I,

$$\kappa_{\text{I}}(s) = \kappa_{\text{I}} (\cos(\tau s) \mathbf{e}_x + \sin(\tau s) \mathbf{e}_y)$$

with some small torsion rate  $\tau \ll l^{-1}$ , the effective curvature of sub-lattice-II can be evaluated to

$$\kappa_{\text{II}} = \kappa_{\text{I}} \frac{1}{l} \left| \left( \frac{1}{\tau} \sin(\tau s) \right) \Big|_{-l/2}^{+l/2} \mathbf{e}_x - \frac{1}{\tau} \cos(\tau s) \Big|_{-l/2}^{+l/2} \mathbf{e}_y \right|$$

$$= \kappa_{\text{I}} \left| \frac{2 \sin\left(\frac{l}{2}\right)}{l\tau} \right| \approx \kappa_{\text{I}} \left( 1 - \frac{l^2 \tau^2}{24} + \frac{l^4 \tau^4}{1920} \right) + \dots \quad (48)$$

That is, the curvature felt by lattice II from the one at lattice I

becomes effectively reduced by an amount  $-\kappa_I \left( \frac{l^2 \tau^2}{24} - \frac{l^4 \tau^4}{1920} \right)$ .

The overall energy penalty per length  $l$  can then be written as the average over the two sub-lattices, with  $K_{\text{tor}}$  given by eqn (6), and evaluates to

$$E_{\text{tot}} = \frac{1}{2}(E_I + E_{II}) = \frac{1}{2} \left( \frac{1}{2} K_{\text{tor}} (\delta \kappa_I)^2 + \frac{1}{2} K_{\text{tor}} (\delta \kappa_{II})^2 \right) \\ \simeq \frac{1}{4} K_{\text{tor}} \left( 2(\delta \kappa_I)^2 + \kappa_I^2 \left( \frac{l^2 \tau^2}{24} \right)^2 + 2(\delta \kappa_I) \kappa_I \left( \frac{l^2 \tau^2}{24} \right) + \dots \right)$$

with  $\delta \kappa_i = \kappa_{\text{tor}} - \kappa_i$ .

Dropping the index  $I$  and rearranging,

$$E_{\text{tot}} = \underbrace{\frac{K_{\text{tor}}}{2} (\kappa_{\text{tor}} - \kappa)^2}_{\text{Bending}} + \underbrace{\frac{1}{4} \frac{K_{\text{tor}}}{24^2} \kappa^2 (l\tau)^4 + \frac{K_{\text{tor}}}{2} \cdot (\kappa_{\text{tor}} - \kappa) \cdot \kappa \cdot \frac{(l\tau)^2}{24}}_{\text{Torsion-bend coupling}},$$

we see that there is a classical bending energy term followed by an unusual torsion-bend coupling. Overall the energy is positive definite and has a minimum for  $\kappa = \kappa_{\text{tor}}$  and  $\tau = 0$  as seen from the form

$$E_{\text{tot}} = \frac{1}{4} K_{\text{tor}} (\kappa_{\text{tor}} - \kappa)^2 + \frac{1}{4} K_{\text{tor}} \left( (\kappa_{\text{tor}} - \kappa) + \kappa \frac{l^2 \tau^2}{24} \right)^2 \quad (49)$$

given in the main manuscript.

The torsion-bend coupling suggests an unusual mechanics: (i) for optimal curvature  $\kappa = \kappa_{\text{tor}}$  the torsional term has a weak quartic stiffness  $O(\tau^4)$  indicating some flexibility in this degree of freedom. (ii) For curvature larger than optimal, *i.e.* for  $\kappa_{\text{tor}} - \kappa < 0$ , a torsion (of any sign) is favorable, given by

$$\tau_{\pm} = \pm \frac{1}{l} \sqrt{24} \sqrt{1 - \frac{\kappa_{\text{tor}}}{\kappa}}, \quad (50)$$

as already stated in the main text. (iii) For curvature smaller than optimal,  $\kappa_{\text{tor}} - \kappa > 0$ , the torsion experiences a quadratic stiffness term  $\frac{K_{\text{tor}} (\kappa_{\text{tor}} - \kappa) \cdot \kappa l^2}{48} \cdot \tau^2$  in leading order, forcing it strongly towards the  $\tau = 0$  state.

Overall this indicates some highly unusual spatial dynamics of the toro-elastic state, very much different from usual semi-flexible filaments. Note that case (ii), *i.e.* larger curvature than  $\kappa_{\text{tor}}$ , is the one that should be relevant for a virus in a mucus environment, where glycan ligands cause additional tensile stresses, leading to increased curvatures.
