# An excimer process induced a turn-on fluorescent probe for detection of ultra-low concentration of mercury ions†

Shujing Fang,<sup>a</sup> K. M. K. Swamy,<sup>b</sup> Wen-Yan Zan,<sup>c</sup> Juyoung Yoon<sup>\*b</sup> and  
Shudi Liu<sup>\*a</sup>

The accumulation of mercury pollution in plants can induce severe injury to human beings. It is a great challenge to monitor ultra-low concentrations of mercury in complicated matrixes. In this study, we successfully developed a strategy via  $\text{Hg}^{2+}$ -triggered naphthalene-based fluorescent **probe 1**, which formed excimer that subsequently emitted fluorescence for the successful detection of ultra-low concentrations of  $\text{Hg}^{2+}$ . The coordination of N and S atoms with  $\text{Hg}^{2+}$  facilitated the formation of excimer from the naphthalene-conjugated planes that were in sufficiently close proximity. Suppression of C=N bond rotation also induced the chelation-enhanced fluorescence (CHEF) effect, and the cumulative result of these effects was obvious fluorescent enhancement. Compared with **probe 2**, the other key factor for detection of  $\text{Hg}^{2+}$  is that the electrons of the hydroxyl group can easily transfer to a naphthalene moiety, resulting in an augmented  $\pi$ -electron density that enhanced the  $\pi$ - $\pi$  stacking of the naphthalene-conjugated excimer. After detailed spectral studies and mechanism discussions, it was realized that **probe 1** was able to detect ultra-low concentrations of  $\text{Hg}^{2+}$  in PBS buffer solution. The detection limit was calculated to be 1.98 nM. On account of the excellent performances, the probe was successfully applied in monitoring  $\text{Hg}^{2+}$  in water and pea sprouts with the potential for application as an advanced warning of contamination.

## Introduction

Mercury is widely distributed in the natural environment and exists in various forms. Volcanic eruptions, seismic activity, geological exploitation, gold mining, and oil refining are always accompanied by mercury contamination. The average mercury concentration was calculated to be more than  $100 \text{ mg kg}^{-1}$  in industrial and mining areas, which is higher than the background value of  $0.4 \text{ mg kg}^{-1}$ .<sup>1</sup> Potential leakage risks also originate from a variety of supplies used on a daily basis, ranging from preservatives in vaccines, dental consumables, thermometers, and high-pressure mercury lamps.<sup>2,3</sup> Mercury exposure is prevalent in daily life through inhaled air, drinking water, and food. Mercury does not degrade, and because it continuously accumulates in biological systems, the potential

risk for contamination appears to be very serious and deserves adequate attention.<sup>4,5</sup>

Quantitative and qualitative measurements are necessary to accurately assess mercury pollution.<sup>6,7</sup> Efficient methods for mercury detection should be highly sensitive and selective to distinguish mercury from complicated matrixes. Commonly used methods are colorimetric analysis, atomic absorption spectrometry, and gas chromatography-mass spectrometry.<sup>8</sup> However, these methods require sophisticated procedures and expensive instruments, and they are not suitable for real-time *in situ* visual detection. In this respect, fluorescent probes have become powerful monitoring tools due to their excellent properties, such as small size, easy modification, high selectivity and sensitivity, perfect solubility and biocompatibility, non-invasiveness, and real-time *in situ* detection with high spatial and temporal resolution.<sup>9–14</sup>

Hundreds of fluorescent probes have been designed and used for  $\text{Hg}^{2+}$  monitoring based on diverse detection mechanisms.<sup>15–22</sup> However, excimer formation-induced fluorescent changes for  $\text{Hg}^{2+}$  are rare. Intramolecular or intermolecular excimers are mainly constructed with increased  $\pi$ - $\pi$  electron stacking by fixing two or more planar chromophores at close distances. Besides, excimers can form in concentrated solutions

that induce the interaction of neighboring molecules.<sup>23,24</sup> Excimer-based fluorescent probes can provide built-in self-calibration for signal correction according to modulated monomer and excimer emission.<sup>25–27</sup>

The conformations of polycyclic aromatic hydrocarbons such as naphthalene, anthracene, naphthalimide, perylene, pyrene, and analogous derivatives are easily modulated with varying optical properties,<sup>28–38</sup> although certain disadvantages such as the solubility and short emission wavelength more or less limit their biological application.<sup>39,40</sup> In addition, sensitive detection of  $\text{Hg}^{2+}$  directly in aqueous solutions is difficult due to the pronounced hydration effects of  $\text{Hg}^{2+}$ . Amongst these aromatic fluorophores, naphthalene provides an excellent platform for functionalized design of fluorescent probes that will recognize specific substrates.<sup>41–44</sup> Facile modification of hydrophilic groups is essential to increase water solubility. Because of obvious advantages such as stable optical properties and selectivity, it is feasible for widespread development in different domains.

In this study, two fluorescent probes (1 and 2) were successfully synthesized by modifying mercaptoethylamine on a naphthalene fluorophore. The thiol and Schiff base moieties in **probe 1** drive the affinity coordination between S, N, and  $\text{Hg}^{2+}$ , triggering the fluorophores to be situated in sufficiently close proximity to yield excimer. The C=N group acting as a molecular rotor was restricted, and the inhibited isomerization mechanism induced turn-on fluorescence in the presence of  $\text{Hg}^{2+}$ .<sup>45,46</sup> Lone pairs of electrons of hydroxyl groups transferred to the naphthalene moiety, which also resulted in an augmented  $\pi$ -electron density that triggered  $\pi$ - $\pi$  electron stacking. These interactions further tuned the emissions from monomer to excimer simultaneously, with obvious fluorescence enhancement.

Combining the solubility advantages of hydroxyl and thiol groups, this probe exhibited turn-on emission in the presence of ultra-low concentrations of  $\text{Hg}^{2+}$  in PBS buffer solution. The spectral spectroscopies were investigated involving sensitivity and selectivity testing, and the detection mechanism was identified by mass spectra. **probe 1** was finally applied for monitoring real water samples and imaging the roots of pea sprouts.

## Results and discussion

### Spectral studies of probe 1

**probe 1** and **probe 2** were synthesized using the following procedures (Scheme 1) and were fully characterized by NMR and MS spectra, which appears in the ESI† (Fig. S1–S6). Having obtained **probe 1**, fluorescence spectral studies were performed for  $\text{Hg}^{2+}$  monitoring in different solutions. The fluorescence emission remained stable in organic solvents, including DMF, DMSO, THF,  $\text{CH}_2\text{Cl}_2$ ,  $\text{C}_2\text{H}_5\text{OH}$ , and  $\text{CH}_3\text{OH}$  (Fig. S7, ESI†), while a slight fluctuation was exhibited in PBS buffer solution (Fig. 1). The phenomenon was ascribed to the self-assembly process of **probe 1** in PBS buffer to form an excimer with the

Scheme 1 Synthesis routes for **probe 1** and **probe 2**.

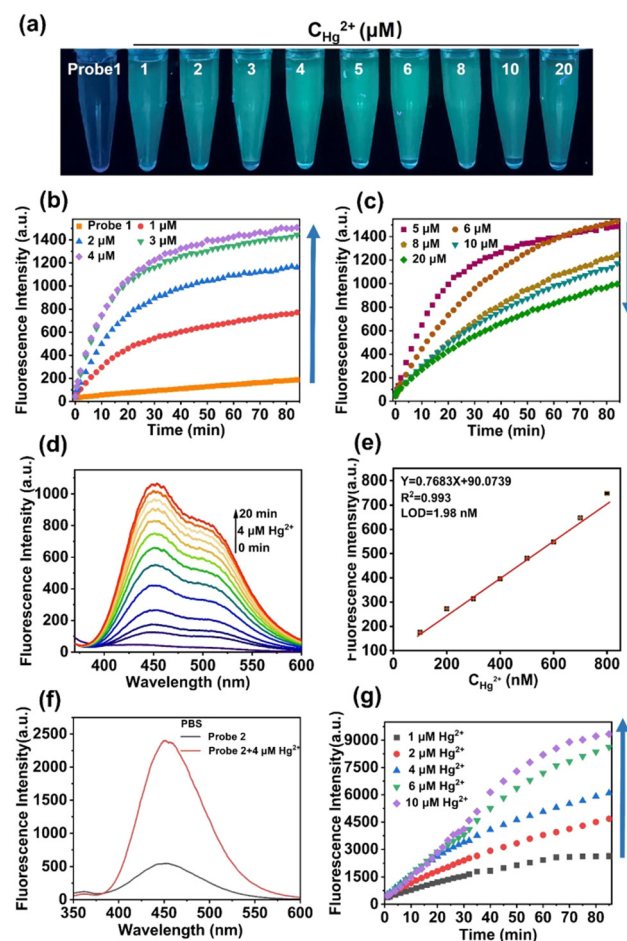

Fig. 1 Spectral studies of **probe 1** and **probe 2** with  $\text{Hg}^{2+}$ . (a) Fluorescence photographs of **probe 1** with different concentrations of  $\text{Hg}^{2+}$  under 365 nm UV light irradiation. (b) and (c) Time-dependent and concentration-dependent fluorescence spectra of **probe 1** (10  $\mu\text{M}$ ) in the presence of 1  $\mu\text{M}$ , 2  $\mu\text{M}$ , 3  $\mu\text{M}$ , 4  $\mu\text{M}$ , 5  $\mu\text{M}$ , 6  $\mu\text{M}$ , 8  $\mu\text{M}$ , 10  $\mu\text{M}$ , and 20  $\mu\text{M}$  of  $\text{Hg}^{2+}$  in PBS buffer solution. (d) Time-dependent fluorescence spectra of **probe 1** (10  $\mu\text{M}$ ) in the presence of  $\text{Hg}^{2+}$  (4  $\mu\text{M}$ ) in PBS buffer solution. (e) The curve of  $F_{450}$  versus  $\text{Hg}^{2+}$  concentration in the range of 100 to 800 nM, indicating a good linear relationship. (f) The fluorescent response of **probe 2** (10  $\mu\text{M}$ ) with  $\text{Hg}^{2+}$  (4  $\mu\text{M}$ ) in PBS buffer solution. (g) Time-dependent and concentration-dependent fluorescence spectra of **probe 2** (10  $\mu\text{M}$ ) in the presence of 1  $\mu\text{M}$ , 2  $\mu\text{M}$ , 4  $\mu\text{M}$ , 6  $\mu\text{M}$ , and 10  $\mu\text{M}$  of  $\text{Hg}^{2+}$  in PBS buffer solution.

assistance of hydrogen bonds of sulfhydryl and hydroxyl groups, which was suggested by mass spectrum (Fig. S3, ESI†).

After addition of  $\text{Hg}^{2+}$ , an obvious fluorescent enhancement was observed in PBS buffer solution because of the coordination of **probe 1** with  $\text{Hg}^{2+}$  that triggered the aggregation and excimer formation for fluorescence enhancement, and the ratio of fluorescence intensity in the presence and absence of  $\text{Hg}^{2+}$  was about 10.4-fold. The fluorescence intensity was nearly unchanged in other solutions (Fig. S7h, ESI†). In comparison, there was greater dispersion of coordination compounds in organic solvents, which prevented aggregation as compared to that in PBS buffer solution, and resulted in no fluorescence change. The detection procedures can also be conducted under different pH values, ranging from 5.8 to 8.0 (Fig. S8, ESI†).

The time-dependent and concentration-dependent fluorescence responses of **probe 1** in the presence of  $\text{Hg}^{2+}$  were determined (Fig. 1a–d). The fluorescence intensity dramatically increased upon addition of  $\text{Hg}^{2+}$  at the first 4  $\mu\text{M}$ . Along with extended time (Fig. 1b), and then decreased with increasing

concentrations from 5  $\mu\text{M}$  to 20  $\mu\text{M}$  (Fig. 1c). Moreover, visible colorimetric detection was applied under 365-nm excitation with the same tendency. The color changed from colorless to deep green as the concentration of  $\text{Hg}^{2+}$  increased from 1  $\mu\text{M}$  to 4  $\mu\text{M}$ , whereas it weakened to light green from 5  $\mu\text{M}$  to 20  $\mu\text{M}$  (Fig. 1a). The fluorescence intensity attained equilibrium as the time reached about 30 min (Fig. 1b). The detailed fluorescent spectral changes exhibited by **probe 1** with  $\text{Hg}^{2+}$  (4  $\mu\text{M}$ ) were also recorded (Fig. 1d). The fluorescence intensities at 450 nm exhibited a strong linear correlation with  $\text{Hg}^{2+}$  in the concentration range from 100 nM to 800 nM (Fig. 1e).

The limit of detection (LOD) was calculated to be 1.98 nM, which was greatly improved compared with the reported fluorescent probes in Table S1 (ESI†). The quantum yields of **probe 1** and **probe 1**- $\text{Hg}^{2+}$  were calculated to be 4.1% and 8.2%, respectively (Fig. S9a, ESI†). The quantitative fluorescence lifetimes of **probe 1** and **probe 1**- $\text{Hg}^{2+}$  were 1.6631 and 1.6698,

Fig. 2 The coordination mechanisms between probes 1 and 2 with  $\text{Hg}^{2+}$ . (a) and (b) Schematic diagrams of the excimer formation process of **probe 1** and **probe 2** with  $\text{Hg}^{2+}$ . (c) and (d) Mass spectra of the **probe 1**- $\text{Hg}^{2+}$  (2:1) complex and **probe 2**- $\text{Hg}^{2+}$  (2:1) complex. (e) Mass spectra of the **probe 1**- $\text{Hg}^{2+}$  (1:2) complex ( $m/z$  468.25 was assigned to a 1:1 complex,  $m/z$  663.25 was assigned to a 2:1 complex, and  $m/z$  1092.23 was assigned to a 2:1+1:1 complex). (f) The mass spectrum of the **probe 2**- $\text{Hg}^{2+}$  (1:2) complex ( $m/z$  482.29 was assigned to a 1:1 complex,  $m/z$  691.30 was assigned to a 2:1 complex, and  $m/z$  1134.29 was assigned to a 2:1+1:1 complex).

respectively (Fig. S10a and b, ESI†). UV-Vis spectra in the absence and presence of  $\text{Hg}^{2+}$  were also obtained using an absorption band at 320 nm increased over time (Fig. S11, ESI†).

The fluorescent changes of **probe 1** towards  $\text{Hg}^{2+}$  is a puzzling phenomenon and may be related to the reason for the high sensitivity of **probe 1** for ultra-low concentration detection of  $\text{Hg}^{2+}$ . To elucidate this phenomenon, contrast **probe 2** was synthesized for comparison. Parallel fluorescent and UV-Vis spectra experiments with **probe 2** were carried out, and  $\text{Hg}^{2+}$  detection was feasible in PBS solution (Fig. S12 and S13, ESI† and Fig. 1f). The time-dependent and concentration-dependent fluorescence responses of **probe 2** in the presence of  $\text{Hg}^{2+}$  were then determined.

As shown in Fig. 1g, the fluorescent intensity of **probe 2** in response to  $\text{Hg}^{2+}$  was enhanced as the concentration of  $\text{Hg}^{2+}$  increased and over extended time. The quantum yields of **probe 2** and **probe 2**- $\text{Hg}^{2+}$  were calculated to be 10.9% and 17.6%, respectively (Fig. S9b, ESI†). The quantitative fluorescence lifetimes of **probe 2** and **probe 2**- $\text{Hg}^{2+}$  were 5.3900 and 6.2103, respectively (Fig. S10c and d, ESI†). However, this was different from the fluorescent trends of **probe 1** (Fig. 1b and c).

Hence, mass spectroscopy was further performed to clarify the response mechanism. According to the spectral studies, the fluorescence intensity of **probe 1** and  $\text{Hg}^{2+}$  reached the maximum with a concentration ratio of 2:1 (Fig. 1b). Therefore, the electrospray ionization-mass spectrometry (ESI-MS) spectra of the probe- $\text{Hg}^{2+}$  coordinated complexes with a ratio of 2:1 were measured. As shown in Fig. 2, the coordination mode of **probe 1** and **probe 2** with  $\text{Hg}^{2+}$  was confirmed to be 2:1, as suggested by their values of  $m/z$  663.22 and 691.29, respectively (Fig. 2c and d).

In this case, the complexes of **probe 1**- $\text{Hg}^{2+}$  and **probe 2**- $\text{Hg}^{2+}$  mainly existed in a 2:1 ratio, and both of them were formed as excimer. However, when the probes and  $\text{Hg}^{2+}$  were mixed at the ratio of 1:2 (Fig. 2e and f), new peaks at 1092.23 and 1134.29 appeared for the **probe 1**- $\text{Hg}^{2+}$  and **probe 2**- $\text{Hg}^{2+}$  complexes, respectively. Different ratios of the probe- $\text{Hg}^{2+}$  complexes were formed, and the excimer would be destroyed as the concentration of  $\text{Hg}^{2+}$  increased. **probe 1** and **probe 2** exhibited the same trends in the mass spectra of their complexes. All the results indicated that  $\text{Hg}^{2+}$  possessed the ability to trigger naphthalene-based fluorescent probes so they would form excimer and subsequently emit fluorescence, but this does not adequately explain the changes in fluorescence.

For structural analysis of the two probes, the only difference was in their different substituted groups—the hydroxyl group and methoxyl group. The Hammett substituent constants provide direct evidence of the higher electron-donating abilities of the hydroxyl group (−0.37) as compared to the methoxyl group (−0.27).<sup>47</sup> In **probe 1**, the lone pair of electrons in the hydroxyl group was intensively transferred to the naphthalene moiety, resulting in an augmented  $\pi$ -electron density that triggered the  $\pi$ - $\pi$  electron stacking of the naphthalene conjugation and further facilitated the coordination of N and S atoms with  $\text{Hg}^{2+}$ . The enhancement of the fluorescence intensity was attributed to the formation of excimer with the extensive

conjugated plane of naphthalene, as well as the rotation suppression of the C=N bond and the chelation enhanced fluorescence (CHEF) effect.

Density functional theory (DFT) studies were carried out to elucidate the possible mechanism. **probe 2** exhibited a higher energy gap between the HOMO–LUMO orbitals than **probe 1**, which was unfavorable for coordination with mercury ions due to its lower reactivity (Fig. S14a, ESI†). We also investigated the electron loss abilities of the naphthalene portion in two probes (Fig. S14b and Table S2, ESI†). The results (loss of 0.18442e in **probe 1** and loss of 0.18695e in **probe 2**) proved that the methoxyl group impeded the electron transfer to naphthalene, which is unfavorable for the formation of excimer. Besides, the lack of a hydrogen bond in the  $\pi$ - $\pi$  stacking mode of **probe 2** directly weakened the stacking ability (Fig. S14c, ESI†). Therefore, the methoxyl group impeded the electron transfer to naphthalene and then weakened the  $\pi$ - $\pi$  electron stacking, which is unfavorable for the formation of excimer. Moreover, the hydrogens in **probe 1** were shifted to a field that was higher than that of **probe 2** (Fig. S1 and S4, ESI†), which was derived from the stronger  $\pi$ - $\pi$  stacking that increased the charge densities and further weakened the vibration of hydrogen. Based on these studies, it was determined that **probe 1** is more sensitive to low concentrations of  $\text{Hg}^{2+}$  in aqueous solutions, which is beneficial for bilateral fixation by hydrogen bond and mercury coordination to facilitate excimer formation as well as lone pair electrons to enhance the  $\pi$ - $\pi$  electron stacking of the naphthalene conjugation.

To obtain insight into the fluorescent performance in a complicated matrix, selectivity studies were investigated in the presence of interfering metal ions (100  $\mu\text{M}$ ), including  $\text{Cu}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Fe}^{3+}$ ,  $\text{Fe}^{2+}$ ,  $\text{Cd}^{2+}$ ,  $\text{K}^+$ ,  $\text{Cr}^{3+}$ ,  $\text{Ba}^{2+}$ ,  $\text{Na}^+$ ,  $\text{Mn}^{2+}$ ,  $\text{Co}^{2+}$ ,  $\text{Ca}^{2+}$ ,  $\text{Ni}^{2+}$ ,  $\text{Al}^{3+}$ ,  $\text{Cu}^+$ ,  $\text{Zn}^{2+}$ , and  $\text{Ag}^+$ . As shown in Fig. 3, colorimetric detection under a 365-nm UV lamp was performed. **probe 1** (10  $\mu\text{M}$ ) was pre-introduced in PBS solution, and there

Fig. 3 (a) Fluorescence photograph of **probe 1** with different metal ions under 365-nm UV light irradiation. (b) Fluorescence spectra of **probe 1** with  $\text{Hg}^{2+}$  (4  $\mu\text{M}$ ) and other different metal ions (100  $\mu\text{M}$ ) in PBS buffer solution. (c) Relevant column diagram for selectivity studies of fluorescence **probe 1** with different metal ions (black bars, 0: **probe 1**, 1–18:  $\text{Cu}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Fe}^{3+}$ ,  $\text{Fe}^{2+}$ ,  $\text{Cd}^{2+}$ ,  $\text{K}^+$ ,  $\text{Cr}^{3+}$ ,  $\text{Ba}^{2+}$ ,  $\text{Na}^+$ ,  $\text{Mn}^{2+}$ ,  $\text{Co}^{2+}$ ,  $\text{Ca}^{2+}$ ,  $\text{Ni}^{2+}$ ,  $\text{Zn}^{2+}$ ,  $\text{Al}^{3+}$ ,  $\text{Cu}^+$ ,  $\text{Ag}^+$ , and  $\text{Hg}^{2+}$ ) and following the addition of  $\text{Hg}^{2+}$  (red bars) in PBS buffer solution (10 mM, pH 7.4). ( $\lambda_{\text{ex}}$  = 320 nm,  $\lambda_{\text{em}}$  = 450 nm).

were no obvious fluorescence color changes upon addition of these interfering metal ions except for  $\text{Ag}^+$  and  $\text{Hg}^{2+}$ . A slight green color and weak enhancement was exhibited after addition of  $\text{Ag}^+$ , as shown in (Fig. S15, ESI<sup>†</sup>), whereas a significant color transformation from colorless to deep green emerged upon addition of  $\text{Hg}^{2+}$ . The fluorescence intensities were further compared with each other, as shown in Fig. 3b and c, and only  $\text{Hg}^{2+}$  induced obvious emission enhancement (black bars), which increased to different extents in the presence of interfering metal ions (red bars). Therefore, **probe 1** exhibited high selectivity and sensitivity for the detection of  $\text{Hg}^{2+}$  in PBS buffer solution.

### Determination of $\text{Hg}^{2+}$ in real water samples

Having confirmed the excellent performances of the probes, **probe 1** was selected and then applied to evaluate the applicability of detection in real water samples, including tap water, ultrapure water, and lake water. As presented in Table 1, the determination of  $\text{Hg}^{2+}$  at ultra-low concentrations was conducted according to the standard addition method, and the recovery rates ranged from 91% to 108%. Therefore, **probe 1** can be effectively applied to measure  $\text{Hg}^{2+}$  in environmental water samples.

### Imaging of $\text{Hg}^{2+}$ in pea sprouts

As mentioned above, mercury can accumulate in the food chain, and plants are a key link because they act as repositories for mercury from the soil. Detection of  $\text{Hg}^{2+}$  in plants not only enables visualization of mercury distribution and bioaccumulation in plants, but also facilitates the use of effective methods to avoid mercury damage. Hence, pea sprouts were employed as a plant model for fluorescent imaging. Four-day-old pea sprouts were incubated with **probe 1** for 12 hours, and then incubated with mercury for another 12 hours. The longitudinal and transverse root sections were then imaged under a 10x objective lens. Fig. 4 shows that the fluorescent emissions were quite weak when the tissues were only incubated with **probe 1**. Once  $\text{Hg}^{2+}$  was added, it was transferred into the plant tissues through plant veins and exhibited bright fluorescent emission. The results indicate that **probe 1** was capable of visualization imaging of mercury in plants.

Table 1 Determination of  $\text{Hg}^{2+}$  in real water samples

Sample	Added (nM)	Found (nM) and RSD ( $n = 3$ )	Recovery (%)
Tap water	0	Not detected	—
	200	$215.58 \pm 0.97$	108
	500	$540.29 \pm 0.23$	108
	800	$810.27 \pm 0.40$	101
Ultrapure water	0	Not detected	—
	200	$210.27 \pm 1.36$	105
	500	$464.81 \pm 0.31$	93
	800	$744.51 \pm 0.06$	93
Lake water	0	Not detected	—
	200	$181.20 \pm 0.29$	91
	500	$507.00 \pm 0.61$	101
	800	$791.92 \pm 0.29$	99

## Experimental

### Materials and instruments

All chemical reagents were analytical grade and purchased from commercial sources, and were used without further purification. Fluorescent probes were characterized by NMR and ESI-MS spectra using a Bruker AVANCE IIIITM 500 spectrometer and a Thermo LCQ Fleet mass spectrometer, respectively. Fluorescent spectral studies were recorded on a fluorescence spectrophotometer (HITACHI F-4700). The mechanisms of probe coordination with  $\text{Hg}^{2+}$  were confirmed by mass spectra. Fluorescence imaging of slices of pea sprouts was obtained using an Olympus fluorescent microscope (FluoView FV1000). DFT calculations were carried out by the Gaussian 16 program packages. All structures were fully optimized at the M06-2X+GD3/def2-TZVP level. Natural atomic charges were generated using the NBO 6.0 program.

### Spectral analysis

The spectral analysis was conducted in phosphate-buffered saline (PBS, 10 mM, pH 7.4). The stock solutions of probes (10 mM and 1 mM) were prepared using analytically pure dimethyl sulfoxide (DMSO) and stored at 4 °C, and then diluted to a working concentration (10  $\mu\text{M}$ , 0.1% DMSO) with PBS buffer solution. Deionized water was used to prepare 10 mM individual stock solutions of  $\text{Cu}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Fe}^{3+}$ ,  $\text{Fe}^{2+}$ ,  $\text{Cd}^{2+}$ ,  $\text{K}^+$ ,  $\text{Cr}^{3+}$ ,  $\text{Ba}^{2+}$ ,  $\text{Na}^+$ ,  $\text{Mn}^{2+}$ ,  $\text{Co}^{2+}$ ,  $\text{Ca}^{2+}$ ,  $\text{Ni}^{2+}$ ,  $\text{Al}^{3+}$ ,  $\text{Cu}^+$ ,  $\text{Zn}^{2+}$ ,  $\text{Ag}^+$ , and  $\text{Hg}^{2+}$ . Selective and competitive experiments of **probe 1** (10  $\mu\text{M}$ ) in the presence of  $\text{Hg}^{2+}$  (4  $\mu\text{M}$ ) and with potential interference (100  $\mu\text{M}$ ) were conducted in PBS buffer solution after 60 minutes. The lake water, tap water, and ultrapure water were mixed with PBS buffer solution (1:19, v/v) and then assessed with working concentrations of **probe 1** (10  $\mu\text{M}$ ) and  $\text{Hg}^{2+}$  (0 to 800 nM).

### Preparation of the slices of pea sprouts

Pea seeds were sterilized with ethanol and cultured in ultrapure water medium at room temperature. Roots of four-day-old pea sprouts were incubated with **probe 1** (10  $\mu\text{M}$ ) for 12 hours and  $\text{Hg}^{2+}$  (20  $\mu\text{M}$ ) for 12 hours in cascade. After thoroughly washing with ultrapure water, the roots (mature zone) were embedded in 4% low melting point agarose. Longitudinal and transverse cutting was implemented using a vibrating microtome (VT1200S, Leica), and the roots were cut into semi-thin sections of 100- $\mu\text{m}$  thickness. The sections were placed on microscope slides, infiltrated with PBS, and then covered with a coverslip. Fluorescence imaging for slices of pea sprouts in longitudinal and transverse cutting forms was performed, and the sprouts were observed under an Olympus fluorescence microscope with a 10x objective lens. The excitation wavelength was at 405 nm, and the collecting wavelengths were from 400 to 500 nm.

### Synthesis of probe 1

In a 50-mL round-bottomed flask, 6-hydroxy-2-naphthaldehyde (172 mg, 1 mmol) and mercaptoethylamine (77 mg, 1 mmol) were dissolved in 5 mL anhydrous ethanol under stirring, and then refluxed for 30 min. The reaction progress was monitored

**Fig. 4** Fluorescence imaging of **probe 1** for  $\text{Hg}^{2+}$  determination in pea sprouts. (A) Photograph of a pea sprout and schematic diagrams of root slices. (B) Fluorescence imaging of cross-section slices of pea sprouts. (a) Blank group. (b) Slices of pea sprouts incubated with **probe 1** ( $10\ \mu\text{M}$ ) for 12 h. (c) Slices of pea sprouts incubated with **probe 1** ( $10\ \mu\text{M}$ ) for 12 h and then treated with  $\text{Hg}^{2+}$  ( $20\ \mu\text{M}$ ) for 12 h. (C) Fluorescence imaging of longitudinal slices of pea sprouts. (d) Blank group. (e) Slices of pea sprouts incubated with **probe 1** ( $10\ \mu\text{M}$ ) for 12 h. (f) Slices of pea sprouts incubated with **probe 1** ( $10\ \mu\text{M}$ ) for 12 h and then treated with  $\text{Hg}^{2+}$  ( $20\ \mu\text{M}$ ) for 12 h. Scale bars =  $200\ \mu\text{m}$  ( $\lambda_{\text{ex}} = 405\ \text{nm}$ ,  $\lambda_{\text{em}} = 400\text{--}500\ \text{nm}$ ).

by thin-layer chromatography (TLC). At the end of the reaction, the crude product was filtered to obtain a white solid (**probe 1**) with a yield of 58%.  $^1\text{H}$  NMR (500 MHz,  $\text{DMSO-d}_6$ )  $\delta$  9.75 (s, 1H), 7.81 (s, 1H), 7.72 (d,  $J = 8.7\ \text{Hz}$ , 1H), 7.65 (d,  $J = 8.6\ \text{Hz}$ , 1H), 7.47 (dd,  $J = 8.6, 1.6\ \text{Hz}$ , 1H), 7.16–6.99 (m, 2H), 5.58 (s, 1H), 3.52 (ddd,  $J = 11.4, 5.1, 3.4\ \text{Hz}$ , 1H), 3.08–2.81 (m, 3H).  $^{13}\text{C}$  NMR (126 MHz,  $\text{DMSO-d}_6$ )  $\delta$  155.48, 134.86, 134.13, 129.35, 127.19, 126.13, 125.77, 125.41, 118.84, 108.61, 73.43, 52.88, 36.31. ESI-MS  $[\text{C}_{13}\text{H}_{13}\text{NOS}]^+$ , calcd. 231.07, found  $[\text{M}+1]^+$ : 232.19.

### Synthesis of probe 2

In a 50-mL round-bottomed flask, 6-methoxy-2-naphthaldehyde (186 mg, 1 mmol) and mercaptoethylamine (116 mg, 1.5 mmol) were dissolved in 5 mL anhydrous ethanol under stirring, and then refluxed for 30 min. The reaction was monitored by TLC. At the end of the reaction, the crude product was filtered to obtain a white solid (**probe 2**) with a yield of 60%.  $^1\text{H}$  NMR (500 MHz,  $\text{DMSO-d}_6$ )  $\delta$  7.88 (s, 1H), 7.83–7.73 (m, 2H), 7.54 (dd,  $J = 8.5, 1.7\ \text{Hz}$ , 1H), 7.30 (d,  $J = 2.4\ \text{Hz}$ , 1H), 7.16 (dd,  $J = 8.9, 2.6\ \text{Hz}$ , 1H), 5.61 (s, 1H), 3.87 (s, 3H), 3.57–3.44 (m, 1H), 3.11–2.85 (m, 3H).  $^{13}\text{C}$  NMR (126 MHz,  $\text{DMSO-d}_6$ )  $\delta$  157.37, 135.94, 133.81, 129.31, 127.99, 126.78, 126.04, 125.34, 118.78, 105.84, 73.28, 55.19, 52.87, 36.34. ESI-MS  $[\text{C}_{14}\text{H}_{15}\text{NOS}]^+$ , calcd. 245.34, found  $[\text{M}+1]^+$ : 246.22.

## Conclusions

In summary, we successfully constructed naphthalene-based fluorescent **probe 1** for detection of ultra-low concentrations of mercury. We synthesized contrast **probe 2** to use fluorescence and mass spectra to deeply study the response mechanism,

which can be ascribed to three key factors. First, the sulfhydryl and  $\text{C}=\text{N}$  group of the Schiff base were responsible for the coordination between probes and  $\text{Hg}^{2+}$ , which was conducive to inducing excimer formation and then subsequent turn-on fluorescence emission. Second, the hydroxyl group of **probe 1** formed an intermolecular hydrogen bond, but this could not occur in **probe 2**. The bilateral fixation by hydrogen bond and coordination further enhanced the stability of the excimer. Third, the key factor for fluorescence enhancement of **probe 1** was speed, because the lone pair of electrons of the hydroxyl group could easily transfer to the naphthalene moiety, resulting in an augmented  $\pi$ -electron density that further enhanced the  $\pi$ - $\pi$  electron stacking. For these reasons, **probe 1** is more sensitive to low concentrations of  $\text{Hg}^{2+}$  in aqueous solutions, with a calculated detection limit of 1.98 nM. Hence, **probe 1** was successfully applied to detect  $\text{Hg}^{2+}$  in water samples and pea sprouts. This holds significant importance for the determination of mercury contamination and bioaccumulation, with potential application for contamination warning in advance.
