Mechanisms underlying the acid leaching process for $\text{LiNi}_{0.6}\text{Co}_{0.2}\text{Mn}_{0.2}\text{O}_2$ with and without H_2O_2 †

Kazuhiko Mukai, * Yasuhiro Takatani and Takamasa Nonaka

Digesting lithium insertion materials in acid solutions is succeeded by into today's discovery and developments of lithium-ion batteries (LIBs), and has recently received significant attention as a leaching process for recycling spent LIBs. To explore more effective and eco-friendly leaching conditions, we elucidated the reaction mechanisms underlying the dissolution of $\text{LiNi}_{0.6}\text{Co}_{0.2}\text{Mn}_{0.2}\text{O}_2$ (NCM622) into an HNO_3 solution with or without H_2O_2 . Without H_2O_2 , delithiated NCM622 powder remained even after 24 h, whereas, with H_2O_2 , NCM622 completely dissolved into the solution within 3 h. X-Ray diffraction patterns, transmission electron microscopy, and X-ray Raman spectroscopy all indicated that the residual NCM622 powder maintained the initial Li composition during the entire leaching process with H_2O_2 . However, soft X-ray absorption spectroscopy, which provides information on the electronic and oxidation states of a surface, revealed the presence of a delithiated NCM622 phase. Hence, successive oxidation and dissolution reactions on the surface occur during the leaching process with H_2O_2 , enabling the rapid and complete dissolution of NCM622. The results of leaching with an eco-friendly organic acid are also presented, along with comparative leaching experiments with other positive electrode materials. These insights into the dissolution of lithium insertion materials in acid solutions could pave the way to more effective and eco-friendly acid leaching and solvent extraction processes.

1 Introduction

State-of-the-art technology and knowledge are not always established only on brand-new information. Confucius, an ancient Chinese thinker, preached the importance of attempting to discover new things by scrutinizing the past.¹ Lithium-ion batteries (LIBs), which are essential for the information and communication devices that our society relies on, have reached a stage of maturation; thus, re-examining existing knowledge is required to further develop LIBs.²

Conventional LIBs are based on a reversible electrochemical reaction, wherein Li^+ ions move back and forth between positive and negative electrodes. This is called a topotactic reaction, which originated from a discovery by Goodenough and coworkers in 1980. They found that Li^+ ions could be extracted from LiCoO_2 with a layered structure in a nonaqueous electrolyte through the following reaction:^{3,4}

Then, in 1981, Hunter proposed applying LiMn_2O_4 with a spinel structure to LIBs by examining a residual compound after digesting LiMn_2O_4 in several acid solutions such as HNO_3 and H_2SO_4 .⁵ Specifically, this chemical reaction is represented by

where $\lambda\text{-MnO}_2$ also adopts a spinel structure that provides three-dimensional channels for Li ion migration, and l and s stand for liquid and solid phases, respectively.⁵ Eqn (2) can be understood as a disproportionation reaction:

Substituting LiCoO_2 into eqn (2), the electrochemical reaction in eqn (1) becomes

Eqn (2) and (4) correspond to the electrochemical oxidation reactions in LIB, although the interface of the LiCoO_2 particles should be continuously renewed to proceed the chemical oxidation reaction. Particularly for layered LiNiO_2 , an insertion of H^+ ions as well as the chemical oxidation reaction occur due to a partial structural change in oxygen packing sequence;

i.e., from a cubic-closed packing to a hexagonal-closed packing.^{6–8} Details of differences between the electrochemical and chemical oxidation reactions have remained a subject of debate.

As the demand for LIBs has expanded rapidly, sustainable and green recycling technologies for spent LIBs are increasingly required to make efficient use of limited metal sources.^{9,10} Such technologies inevitably involve pyrometallurgy, which consists of acid leaching (digestion) and solvent extraction processes.^{11–13} Acid leaching agents include HNO₃, H₂SO₄, HCl, and several organic acids,^{11–13} which are almost the same as those in Hunter's original experiments.⁵ A typical acid leaching reaction for LiCoO₂ can be described by¹³

which differs from the chemical reaction in eqn (4). Meanwhile, although H₂O₂ is regarded as a reducing agent,^{11–13} to our best knowledge, the reaction mechanisms in which it participates during the acid leaching process—in other words, the roles of H₂O₂—have remained unclear.

We thus revisited this overlooked issue with LIBs by employing modern analysis methods such as high-angle annular dark field scanning transmission electron microscopy (HAADF-STEM), X-ray Raman spectroscopy (XRS), and soft X-ray absorption spectroscopy (XAS). XRS utilizes the inelastic scattering of hard X-rays, providing information equivalent to that of soft XAS under the dipole approximation.^{14–16} Because hard X-rays penetrate deeper, XRS conveys information on X-ray absorption edges in the bulk material, whereas soft XAS provides surface information (within ~50 nm). We selected LiNi_{0.6}Co_{0.2}Mn_{0.2}O₂ (NCM622) as a model because of its increasing popularity as a positive electrode material for high-energy-density LIBs.^{17–21} Then, we examined the particle morphologies, crystal structures, electronic states, and electrochemical properties of NCM622 during the HNO₃ leaching process with and without H₂O₂ and compared the reaction schemes between the two conditions. An in-depth understanding of the dissolution of NCM622 into an HNO₃ solution could unveil the appropriate conditions for effective and eco-friendly acid leaching and solvent extraction processes. Consequently, we revealed the consecutive reactions of oxidation and dissolution on the surface of NCM622 with H₂O₂.

2 Experimental

2.1 Characterization

NCM622 powder was purchased from Hosen Corp. and characterized by synchrotron radiation X-ray diffraction (XRD), electrochemical charge and discharge tests, inductively coupled plasma atomic emission spectroscopy (ICP-AES; ICPS-8100, Shimadzu), scanning electron microscopy (SEM; SU3500, Hitachi High-Technologies), and transmission electron microscopy (TEM; JEM-2100F, JEOL). Approximately 2 mg of NCM622 was packed into a borosilicate glass capillary with a diameter of

0.3 mm (W. Müller Glas Technik) and exposed to X-rays for 10 min. Its XRD pattern was recorded at the BL5S2 beamline at Aichi Synchrotron Radiation Center (Aichi SR) using a two-dimensional (2D) detector (PILATUS 100 K, Dectris). The X-ray wavelength (λ) was determined to be 0.8000(2) Å using a silicon standard (NIST 640d). The Rietveld analysis was conducted using RIETAN-FP software,²² and the crystal structure was drawn schematically using VESTA software.²³

The TEM specimens were prepared using a dual-beam focused ion beam scanning microscope (Helios, FEI) with Ga ions at accelerating voltages from 2 to 40 kV. High-resolution TEM images were obtained at 200 kV using an objective lens with Cs = 0.5 mm. Energy dispersive X-ray spectroscopy (EDS) was conducted to clarify elemental distributions in the TEM specimens. HAADF-STEM images were recorded with a convergence semi-angle of 29 mrad and a collection angle of 75–200 mrad.

LiNi_{0.88}Co_{0.09}Al_{0.03}O₂ (NCA) and LiCoO₂ (LCO) powders were also purchased from Hosen Corp. and NiO, Co₃O₄, and MnO₂ powders were provided by FUJIFILM Wako Pure Chemical.

2.2 Electrochemical measurements

Electrochemical reactivity was examined in a Li cell using an electrolyte consisting of 1 M LiPF₆ dissolved in a mixture of ethylene carbonate (EC) and diethylene carbonate (DEC) (EC/DEC = 1/1 by volume, Kishida Chemical). Different working electrodes were prepared by two methods, *i.e.*, a wet process using polyvinylidene fluoride (PVdF; KF#1120, Kureha) and a dry process using polytetrafluoroethylene (PTFE; Sigma-Aldrich). For the wet-processed NCM622, NCA, and LCO electrodes, a black slurry containing one of these three active materials along with acetylene black (AB; HS-100, Denka), PVdF, and *N*-methyl-2-pyrrolidone (Nacalai Tesque) was cast onto an Al foil (thickness = 20 μm), dried under vacuum at 120 °C for 12 h, and finally cut into a disc with a diameter of 16 mm. The weight ratio of active material/AB/PVdF was 88/6/6. For the dry-processed NCM622, N₂₄, N + H_{0.5}, and N + H₁ electrodes, 75 wt% active material (~10 mg), 20 wt% AB, and 5 wt% PTFE were pressed onto an Al mesh current collector (diameter = 10 mm). The N₂₄, N + H_{0.5}, and N + H₁ samples are described in the next section. Lithium cells were fabricated in an Ar-filled glovebox (DBO-2BLKP, Miwa Mfg) by pressing a Li metal sheet onto a stainless steel plate (diameter = 19 mm), which was utilized as a counter electrode. Two sheets of a polypropylene membrane with a thickness of 25 μm (Tonen-General Sekiyu) were used as the separator. Charge and discharge tests were performed at a current of 0.3 mA ($\approx 0.15 \text{ mA cm}^{-2}$) for the wet-processed electrodes and 0.1 mA ($\approx 0.13 \text{ mA cm}^{-2}$) for the dry-processed ones. The voltage range was 3.0–4.4 V, and the environmental temperature of the cells was 25 °C.

2.3 HNO₃ leaching with or without H₂O₂

One gram of the NCM622 powder was immersed in 50 ml of a 1 M HNO₃ solution (FUJIFILM Wako Pure Chemical), and then stirred for 0.25, 0.5, 0.75, 1, 1.5, 2, 3, 4, 8, or 24 h at room

^a Li/Ni/Co/Mn ratios in the liquid (l) phase are provided for N_1, N_4, N_24, and N + H_1.

temperature (RT; ~22 °C). These samples are hereafter labelled “N” for nitric acid and suffixes indicating their leaching time in hours, *i.e.*, N_0.25, N_0.5, *etc.* (Table 1). We employed HNO₃ as a leaching acid by considering its strong oxidizing power compared to those for H₂SO₄ and HCl. In addition, 1 g of the NCM622 powder was immersed in a 1 M HNO₃ solution including H₂O₂ of 1 ml (purity ~30 wt%, FUJIFILM Wako Pure Chemical), and then stirred for 0.25, 0.5, 0.63, 0.75, 1, 1.5, 1.75, 2, 3, 4, 8, or 24 h at RT. These samples are hereafter labeled “N + H” indicating immersion in both nitric acid (N) and hydrogen peroxide (H) with similar suffixes indicating their stirring time in hours, *i.e.*, N + H_0.25, N + H_0.5, *etc.* (Table 1).

After the treatment, each sample was filtered and dried at 40 °C for 24 h, except for the completely dissolved samples. For the residual powders, the Li/Ni/Co/Mn ratios were determined by ICP-AES analyses, and their crystal structure was examined by synchrotron XRD measurements at the BL5S2 beamline at Aichi SR. The experimental procedure for the XRD measurements was the same as that for the pristine NCM622 sample.

Only for N_1, N_4, N_24, and N + H_1 samples, the Li/Ni/Co/Mn ratios in the liquid phase were determined by ICP-AES. TEM analyses were conducted on the N_24 and N + H_1 samples.

For comparison with NCM622, 1 g each of NCA, LCO, NiO, Co₃O₄, and MnO₂ powders were separately immersed in 50 ml of a 1 M HNO₃ solution at RT for 24 h with or without H₂O₂. Moreover, 1 g each of NCM622, NCA, or LCO was separately immersed in 50 ml of 1 M citric acid (C₆H₈O₇, FUJIFILM Wako Pure Chemical) with H₂O₂ for 24 h at RT.

2.4 Soft XAS

Soft XAS was performed on pristine NCM622, N_24, N + H_1, and electrochemically delithiated NCM622 at the BL1N2 beamline at Aichi SR. This beamline covers K-edge measurements from B to Si, L-edge measurements for 3d transition metals, and M-edge measurements for lanthanoids.²⁴ For the pristine NCM622, N_24, and N + H_1 samples, a composite sheet (3 mm × 3 mm) consisting of 95 wt% of each sample and 5 wt% PVdF was attached onto an XAS sample holder using

carbon tape. The electrochemically delithiated NCM622 samples were prepared by charging at a current of 0.3 mA. The Li composition in NCM622, namely x in $\text{Li}_x\text{Ni}_{0.6}\text{Co}_{0.2}\text{Mn}_{0.2}\text{O}_2$, was 0.92, 0.82, or 0.72. X-Ray absorption near-edge structure (XANES) spectra for the Ni L-edge, Co L-edge, Mn L-edge, and O K-edge were recorded in total-electron-yield mode and were normalized using the Au 4f spectrum.

2.5 XRS

To characterize the pristine NCM622, N_24, and N + H_1 samples, XRS was conducted at the Toyota beamline (BL33XU) at SPring-8. Approximately 0.1 g of each sample was pressed into a pellet with a diameter of 10 mm and a thickness of ~ 0.5 mm, which was then placed on Kapton tape (thickness = 25 μm , Dupont). Each sample was exposed to hard X-rays for at least for 14 h by tilting the sample to the incident X-rays (angle = 5°). Fig. S1 (ESI[†]) shows photographs of the experimental setup at the beamline. The experimental setup and procedures for XRS measurements have been described elsewhere.^{14,15}

3 Results and discussion

3.1 Characterization of pristine NCM622

Before moving on to the results of HNO_3 leaching, we briefly describe the characteristics of the present NCM622. As shown in Fig. 1a, the XRD pattern of pristine NCM622 can be assigned to a regular layered structure with the $R\bar{3}m$ space group, in

Table 2 Structural parameters of pristine NCM622, N_24, and N + H_1 as determined by the Rietveld analysis

Sample	Phase	Atom	Wyckoff position	g	x	y	z	B_{iso} (\AA^2)
Pristine NCM622		Li	3b		1.0	0	0.5	1.0

Fig. 1 (a) Rietveld analysis of the XRD pattern for the pristine NCM622 sample and (b) charge and discharge curves of the NCM622/Li cell operated at a current of 0.3 mA (≈ 0.15 mA cm^{-2}) in the range of 3.0–4.4 V. The layered structure of NCM622 is shown schematically in the inset of (a). Red lines in (b) indicate the charge and discharge curves for the first cycle, and blue dashed lines indicate the stable voltage range for the aqueous solution vs. Li^+/Li electrode, i.e., 3.0–4.2 V.

which Li^+ ions occupy the octahedral 3b site and Ni/Co/Mn ions occupy the octahedral 3a site in a cubic close-packed O^{2-} array. Table 2 summarizes the structural parameters, such as the atomic positions and lattice parameters of the a_h - and c_h -axes. Fig. 1b shows the charge and discharge curves of the NCM622/Li cell operated at a current of 0.3 mA. The rechargeable capacity (Q_{recha}) of ~ 190 mA h g^{-1} is obtained in the range of 3.0–4.4 V, where the theoretical capacity is calculated to be 276.5 mA h g^{-1} by assuming a one-electron transfer. The structural and electrochemical properties of pristine NCM622 are similar to those previously reported for NCM622.^{17,18}

3.2 w and particle morphology

Fig. 2a and b show the weight fraction (w) after HNO_3 leaching without and with H_2O_2 , respectively. Without H_2O_2 , w decreases almost linearly from 100% at 0 h to 61% at 8 h and then levels off at $\sim 60\%$ for the rest of the 24 h experiment. The blue line in Fig. 2a represents the theoretical w (= 47%) based on the disproportionation reaction for NCM622:^{5–8}

where $\text{M} = \text{Ni}_{0.6}\text{Co}_{0.2}\text{Mn}_{0.2}$. The difference in w between the observed and theoretical values is caused by the limited voltage range of the aqueous solution. As shown in Fig. 1b, the aqueous HNO_3 solution is only stable in the range between 3.0 and ~ 4.2 V vs. Li^+/Li , restricting further delithiation above 4.2 V. The Li composition in NCM622 at 4.2 V is expected to be 0.31 by including the initial irreversible capacity, which is similar to

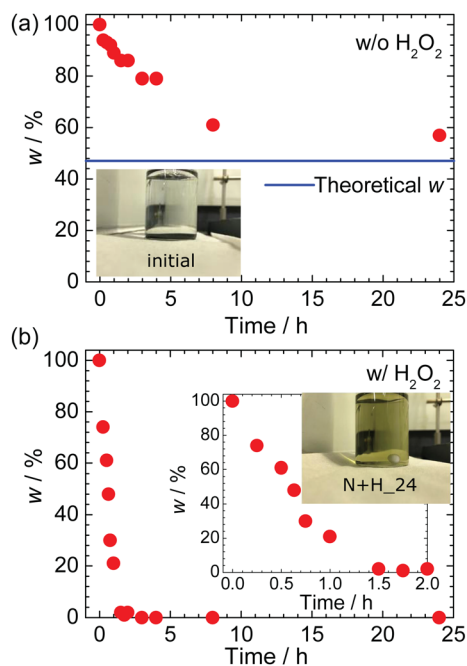

Fig. 2 Weight fraction w as a function of the HNO_3 leaching time (a) without H_2O_2 and (b) with H_2O_2 . Under both conditions, the solutions are initially colorless and transparent [inset of (a)]. The blue line in (a) represents the theoretical w ($= 47\%$) based on eqn (6). The insets in (b) show an enlargement of the time dependence of w and a photograph of N + H₂₄.

the actual Li composition ($= 0.26$) of N₂₄ as determined by the ICP-AES analysis (see Table 1).

As shown in Fig. 2b, the w value with H_2O_2 rapidly decreases to $\sim 0\%$ within 1.5 h, implying that the NCM622 powder completely dissolved into the aqueous solution, as evidenced by the yellow appearance of N + H₂₄ in the inset. Thus, the presence of H_2O_2 in the acid solution drastically changes the leaching process for NCM622. In addition, the Li/Ni/Co/Mn ratio of the liquid (l) phase differs between the two processes;

namely, as listed in Table 1, twice as much Li was leached without H_2O_2 .

We next investigated the particle morphology and size for the residual NCM622 powders after HNO_3 leaching with or without H_2O_2 . Fig. 3a–d show SEM images of the pristine NCM622, N₁, N₈, and N₂₄ samples leached without H_2O_2 , and Fig. 3e–h show the corresponding enlarged SEM images. The pristine NCM622 powders form spherical secondary particles (diameter = 10–30 μm) consisting of non-uniform primary particles with sizes of 1–3 μm . The spherical secondary particles seem to be increasingly broken as the leaching proceeded, whereas the primary particles seem to have maintained their original particle morphology and size.

Fig. 4a–d show SEM images of the pristine NCM622, N + H_{0.5}, N + H₁, and N + H₂₄ samples (with H_2O_2), with corresponding enlargements in Fig. 4e–h. Note that the SEM images in Fig. 4a and e are identical to those of Fig. 3a and e. As in the case without H_2O_2 , the spherical secondary particles broke as leaching proceeded, but they did so much more rapidly than those leached without H_2O_2 . Furthermore, some primary particles exhibit a flake-like morphology and a smaller particle size ($\sim 1 \mu\text{m}$).

3.3 Crystal structure for residual powders

3.3.1 Macrostructure determined by the XRD measurements. Fig. 5a–c shows selected Rietveld analysis results after leaching without H_2O_2 , *i.e.*, N₁, N₈, and N₂₄. Fig. S2 (ESI[†]) shows the Rietveld analysis results for N_{0.25}, N_{0.5}, and N_{0.75}, and Fig. S3 (ESI[†]) shows those for N₂, N₃, and N₄. The structural parameters are detailed in Tables S1 and S2 (ESI[†]), and those of only N₂₄ are listed in Table 2.

The XRD pattern of N₁ can be indexed as a single phase of the layered structure with the $R\bar{3}m$ space group, as for pristine NCM622. Their lattice parameters were calculated to be $a_h = 2.8629(1) \text{ \AA}$ and $c_h = 14.249(1) \text{ \AA}$, which differ slightly from the initial values (Table 1). The single-phase layered structure

Fig. 4 SEM images of residual NCM622 powders after HNO_3 leaching with H_2O_2 : (a) pristine NCM622, (b) N + $\text{H}_{0.5}$, (c) N + H_1 , and (d) N + H_2 . (e)–(h) Corresponding enlarged SEM images of (a)–(d). Note that (a) and (e) are identical to Fig. 3a and e.

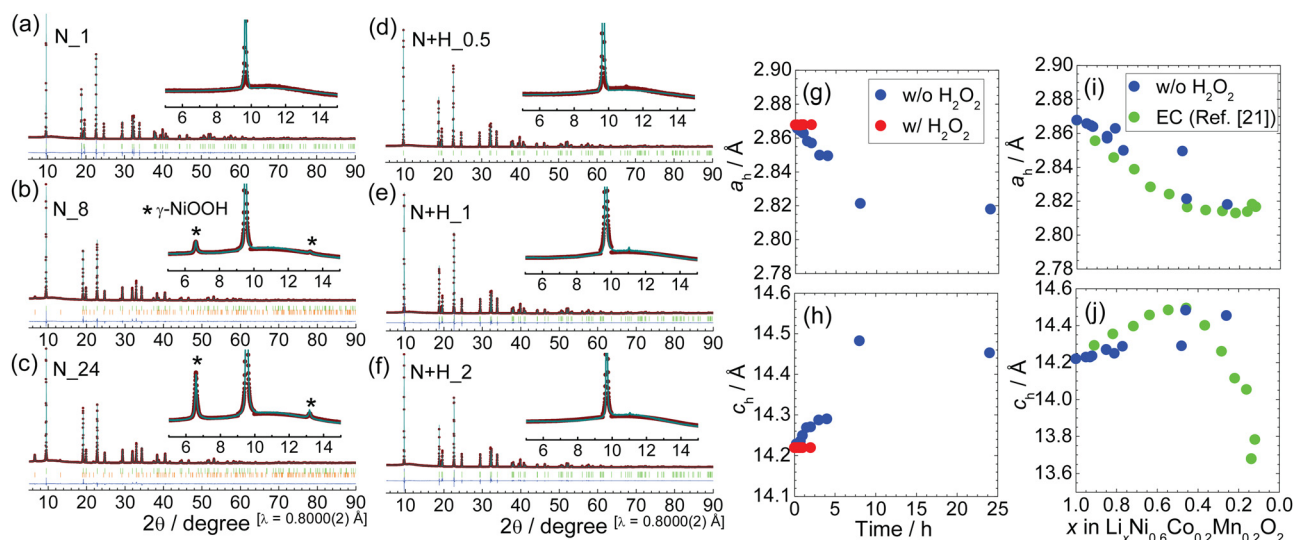

Fig. 5 Rietveld analysis results after HNO_3 leaching with or without H_2O_2 : (a) N_1 , (b) N_8 , (c) N_{24} , (d) N + $\text{H}_{0.5}$, (e) N + H_1 , and (f) N + H_2 . The diffraction peaks indicated by * can be assigned to $\gamma\text{-NiOOH}$. (g) a_h and (h) c_h as a function of leaching time. Comparison between (i) a_h and (j) c_h values after HNO_3 leaching without H_2O_2 and those after electrochemical (EC) delithiation taken from our previous report.¹⁸

with $R\bar{3}m$ was maintained for the first 4 h of leaching (Fig. S2 and S3, ESI[†]), although the a_h and c_h values varied with the leaching time (Table 1). However, the XRD patterns of N_8 and N_{24} can be assigned to a mixture of the aforementioned layered structure and $\gamma\text{-NiOOH}$ with the $R\bar{3}m$ space group; the $\gamma\text{-NiOOH}$ phase has been reported in Ni-MH batteries²⁵ and electrocatalysts for the oxygen evolution reaction.²⁶ The c_h value of $\gamma\text{-NiOOH}$ is more than 20 Å, indicating that it can accommodate H_3O^+ and/or water molecules between the MO_2 layers. The weight fractions of $\gamma\text{-NiOOH}$ in N_8 and N_{24} were determined to be 1.3 and 3.2%, respectively (Table 2 and Table S2, ESI[†]).

Fig. 5d–f shows selected Rietveld analysis results after leaching with H_2O_2 , i.e., N + $\text{H}_{0.5}$, N + H_1 , and N + H_2 ,

and Fig. S4 (ESI[†]) shows those of N + $\text{H}_{0.25}$, N + $\text{H}_{0.63}$, and N + $\text{H}_{0.75}$. The XRD patterns of all the samples are similar to those of pristine NCM622. For instance, the XRD pattern of N + H_1 is assigned to a single-phase layered structure with the $R\bar{3}m$ space group and $a_h = 2.8679(1)$ Å and $c_h = 14.219(1)$ Å (Table 2). Table S3 (ESI[†]) lists the structural parameters of the other samples.

To clarify the differences in a_h and c_h with and without H_2O_2 , their leaching time dependences are illustrated in Fig. 5g and h. The a_h value without H_2O_2 decreased from 2.8677(1) Å at 0 h to ~ 2.82 Å at 8 h, while the c_h value increased from 14.219(1) Å to ~ 14.5 Å at the same time points. The decrease (increase) in a_h (c_h) resembles the change in a_h (c_h) upon the charge reaction.¹⁸ As listed in Table 1, the ICP-AES analysis

confirmed that the Li composition decreased as leaching proceeded. By contrast, the a_h and c_h values with H_2O_2 were almost constant, regardless of the leaching time, suggesting that Li^+ ions are not effectively extracted from the NCM622 lattice. Indeed, the Li composition of N + H_1 was found to be 0.97 according to ICP-AES (Table 1).

Fig. 5(i) and (j) compare the a_h and c_h values as a function of x in $Li_xNi_{0.6}Co_{0.2}Mn_{0.2}O_2$ between the chemical (without H_2O_2) and electrochemical oxidation¹⁸ reactions. The two trends are similar, but the a_h and c_h values without H_2O_2 are more scattered, particularly at $x \leq 0.5$, meaning an inhomogeneous Li composition in the particles. The origin of these differences is the dissolution reaction in the chemical oxidation process, as understood by eqn (6). The crystal structure also differs between chemically and electrochemically reacted samples of $LiNiO_2$.^{6,7}

3.3.2 Microstructure determined by the TEM analyses. The microstructure and elemental distributions were analyzed by TEM, including HAADF-STEM and EDS. Fig. 6a shows the HAADF-STEM image of pristine NCM622, and Fig. 6a1–a5 show the corresponding enlarged HAADF-STEM image and EDS mappings of Ni, Co, Mn, and O. The primary particles of pristine NCM622 adhere to each other, as observed in the SEM image (Fig. 3e and 4e), and the distributions of the four detected elements are homogeneous in the primary particles. In contrast, the primary particles of N_24 are isolated from each other and consist of many thin layers with a thickness of ~ 5 nm (Fig. 6b and b1). Moreover, Ni, Co, Mn, and O are inhomogeneously distributed among the thin layers; specifically, they appear depleted in the darker layers (Fig. 6b1–b5). As shown in Fig. 6c and c1–c5, N + H_1 appears similar to

pristine NCM622, except for the size and distribution of primary particles.

To elucidate the microstructure of N_24, two-dimensional fast Fourier transform (FFT) patterns were examined in various regions. Fig. 7a and b show the TEM and corresponding HAADF-STEM images of N_24 to illustrate the striped layers. As shown in Fig. 7c, the enlarged FFT pattern obtained from the total (T) region of Fig. 7a consists of diffraction spots indicated by blue and green circles and streaks along the $[001]$ direction. This FFT pattern is viewed from the $[100]$ or $[110]$ direction. The diffraction spots indicated by blue and green circles come from regions R1 and R3 in Fig. 7a, respectively (Fig. 7d and f). Surprisingly, the diffraction patterns from R1 and R3 are rotated by 60° with respect to each other, according to the assignments of blue and green diffraction spots. For instance, the two blue circles in R1 are assigned to 012 and $01\bar{1}$. As shown in Fig. 7e, streaks rather than distinct spots are observed from R3, suggesting a low-crystallinity in this region. The original FFT patterns for T, R1, R2, and R3 are shown in Fig. S5a–d (ESI†). Based on the TEM analyses, N_24 is composed of several phases, although the XRD analysis indicated a single phase with a layered structure (except for γ -NiOOH).

3.4 Electronic structure for residual powders

Fig. 8a–d show the XANES spectra of pristine NCM622, N_24, and N + H_1 for the O K-edge, Ni L-edge, Co L-edge, and Mn L-edge, and Fig. S6a–d (ESI†) shows the corresponding enlarged XANES spectra. The O K-edge spectrum of pristine NCM622 indicates at least four peaks at 529.7, 533.8, 539.1, and 541.9 eV. The first two are regarded as a pre-edge of the O K-edge spectrum, which has been understood as hybridization

Fig. 6 HAADF-STEM images and EDS mappings of (a) pristine NCM622, (b) N_24, and (c) N + H_1. (a1)–(c1) Enlarged HAADF-STEM images and (a2)–(c5) EDS mappings of Ni, Co, Mn, and O corresponding to (a)–(c).

Fig. 7 (a) TEM and (b) corresponding enlarged HAADF-STEM images of N₂₄. Enlarged FFT patterns obtained in the [100] or [110] direction from (c) the total area in (a) and from the regions in (a) labeled (d) R1, (e) R2, and (f) R3.

between the 3d orbital of a transition metal and the O 2p orbital.^{27–29} The latter two peaks are attributed to hybridization between 4s and p orbitals of a transition metal and the O 2p orbital.^{27–29} Meanwhile, in the O K-edge XANES spectrum of N₂₄, the pre-edge peak at ~530 eV is enlarged, while the pre-edge peak at ~534 eV has disappeared or appears rounded and has shifted to a lower photon energy. Moreover, the peak at ~540 eV is weakened in this spectrum. However, the O K-edge

XANES spectrum of N + H₁ seems to have features of both pristine NCM622 and N₂₄ in terms of the enlarged pre-edge peak at ~530 eV and the weakened peak at ~540 eV. This indicates that the surface of N + H₁ is partially delithiated, although XRD measurements showed that its *a_h* and *c_h* values were very similar to those of pristine NCM622. Nonetheless, the XANES spectra for the Ni L-edge, Co L-edge, and Mn L-edge also support this conclusion (Fig. 8b–d). For instance, the Ni L-edge XANES spectra show four peaks at ~852.3, 854.4, 869.3, and 870.6 eV, two of which are shifted to higher photon energies for N₂₄ and N + H₁. Additionally, as shown in Fig. S6c (ESI[†]), the peak at ~780 eV in the Co L-edge XANES spectrum shifts to higher photon energies in the order of N₂₄ and N + H₁, suggesting higher oxidation states than those of the initial pristine NCM622 material. Note that the L-edge XANES peaks for Ni, Co, and Mn more directly reflect electronic structures near the Fermi level than their corresponding K-edge XANES peaks.³⁰

Soft XAS was also performed on electrochemically delithiated NCM622 samples. Fig. 8e shows the charge and discharge curves of three independent NCM622/Li cells, confirming homogeneous and reproducible electrochemical reactions. The *x* values in Li_{*x*}Ni_{0.6}Co_{0.2}Mn_{0.2}O₂ were calculated to be 0.92, 0.82, and 0.72 by assuming 100% Coulombic efficiency. Fig. 8f and g show the O K-edge and Ni L-edge XANES spectra of the *x* = 0.92, 0.82, and 0.72 samples. However, the O K-edge XANES spectra of the electrochemically delithiated samples diverging from those of N₂₄ and N + H₁, indicating that

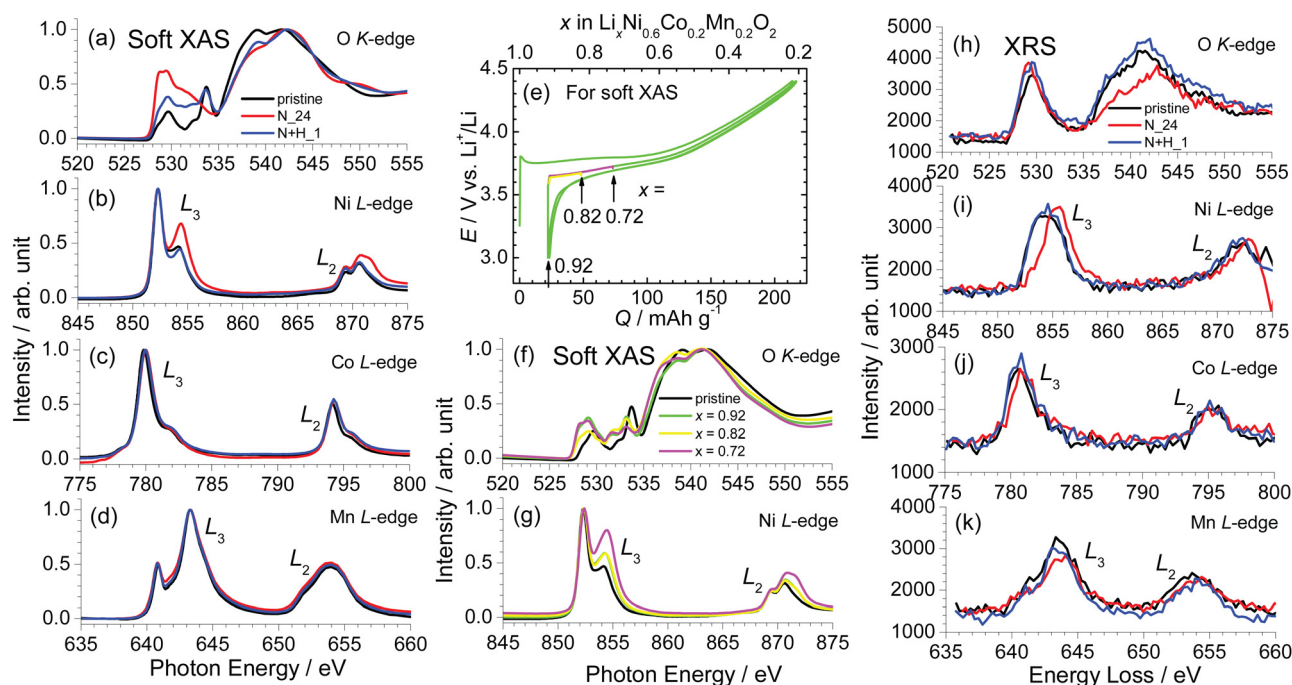

Fig. 8 XANES spectra of pristine NCM622, N₂₄, and N + H₁: (a) O K-edge, (b) Ni L-edge, (c) Co L-edge, and (d) Mn L-edge. (e) Charge and discharge curves of the NCM622/Li cells for preparing electrochemically delithiated NCM622 samples for soft XAS. The *x* value in Li_{*x*}Ni_{0.6}Co_{0.2}Mn_{0.2}O₂ was calculated to be 0.92, 0.82, or 0.72 by assuming 100% Coulombic efficiency. XANES spectra of the electrochemically delithiated NCM622 samples with *x* = 0.92, 0.82, and 0.72: (f) O K-edge and (g) Ni L-edge. XRS results for pristine NCM622, N₂₄, and N + H₁: (h) O K-edge, (i) Ni L-edge, (j) Co L-edge, and (k) Mn L-edge.

electrochemical delithiation essentially differs from chemical delithiation. However, the shift to higher photon energies in the Ni L-edge XANES spectra is similar to the results of chemical delithiation, supporting the existence of a small amount of delithiated phase on the surface of N + H₁.

In contrast to soft XAS, XRS is related to the electronic structures of the bulk (*i.e.*, the whole sample). Fig. 8h–k shows the XRS results corresponding to O K-edge, Ni L-edge, Co L-edge, and Mn L-edge XANES spectra, respectively, for pristine NCM622, N₂₄, and N + H₁. The spectrum of pristine NCM622 exhibits two peaks at ~530 and 541 eV, but the latter peak is weakened and shifted to ~542.5 eV for N₂₄. The shifts to higher energy losses also occur in the peaks at ~844, 780.5, and 643 eV, indicating higher oxidation states in N₂₄. In the case of N + H₁, the results of XRS resemble those of pristine NCM622, suggesting that N + H₁ maintains its initial oxidation state, *i.e.*, the initial Li composition in the bulk. The soft XAS and XRS results of the L-edge of Ni, Co, and Mn atoms have never been compared for any NCM materials, although comparison between soft XAS and XRS was performed for Li_xMn₂O₄ with $x \leq 1$.³¹

3.5 Electrochemical properties of residual powders

To further clarify the surface and bulk states of N₂₄ and N + H₁, their electrochemical properties were evaluated using dry-processed electrodes, which we employed to avoid any undesired changes during mixing with the conventional PVdF + NMP solution and drying at a high temperature (120 °C). Recently, this dry process using PTFE has received considerable attention as a new way to prepare electrodes because it decreases CO₂ emissions.³² Fig. 9a–d shows the charge and discharge curves of the Li cells with pristine NCM622, N₂₄, N + H_{0.5}, and N + H₁ operated at a current of 0.1 mA at 25 °C. The pristine NCM622 indicates a steady Q_{recha} of ~190 mA h g⁻¹ in the range of 3.0–4.4 V, which is consistent with the results of a Li cell with the PVdF binder (Fig. 1b). N₂₄ is delithiated from the initial state, as evidenced by the open-circuit voltage before the cycling test (= 3.992 V) and charge capacity (Q_{cha}) at the first cycle. The Q_{cha} and discharge capacity decreases with each cycle, forming a plateau at ~3.5 V during the discharge reaction. This electrochemical reactivity suggests that the bulk structure of N₂₄ is quite different from that of the electrochemically delithiated NCM622 sample. Meanwhile, the electrochemical properties of N + H_{0.5} and N + H₁ are similar to that of pristine NCM622, except for the large voltage increase to ~4.0 V during the initial charge reaction and slightly lower Q_{recha} . The large voltage increase is related to the decomposition of the electrolyte originating from H₂O molecules on the surface of N + H_{0.5} or N + H₁. The Q_{recha} values of N + H_{0.5} and N + H₁ are ~180 and 170 mA h g⁻¹, respectively. These results imply that the surface states of N + H_{0.5} and N + H₁ differ from that of pristine NCM622 (Fig. 10).

3.6 Reaction mechanisms during the leaching process

Based on the above results, we illustrate the reaction mechanisms underlying the HNO₃ leaching processes with and without H₂O₂. In the leaching process without H₂O₂, almost half of the

Fig. 9 Charge and discharge curves of the Li cells with (a) pristine NCM622, (b) N₂₄, (c) N + H_{0.5}, and (d) N + H₁ operated at a current of 0.1 mA at 25 °C. All the electrodes were prepared by the dry process. Red lines indicate the charge and discharge curves for the first cycle.

Fig. 10 Schematics of the reaction mechanisms during the HNO₃ leaching process (a) without H₂O₂ and (b) with H₂O₂. For both processes, the particle size of NCM622 decreased as the reaction proceeded, but the Li composition in NCM622 (x) differed between the two processes; specifically, it decreased to 0.26 after 24 h in (a), whereas it remained at ~1 in (b), except for at the surface ($x < 1$).

NCM622 dissolved into the HNO₃ solution, while the rest of it remained in the solution in the delithiated state ($x = 0.28$ for N₂₄). According to TEM, soft XAS, and electrochemical analyses, this chemically delithiated NCM622 differed from its electrochemically delithiated counterpart in terms of its

structural and compositional homogeneity. The Li content in the liquid phase was twice as high as the initial composition, whereas the Ni/Co/Mn ratios in the solid and liquid phases remained at approximately 0.6/0.2/0.2 (Table 1). Hence, the ideal overall reaction during the leaching process without H₂O₂ can be described by eqn (6).

In the leaching process with H₂O₂, NCM622 completely dissolved into the solution within 3 h. The Ni/Co/Mn ratio in the liquid phase (= 0.6/0.2/0.2) was similar to that in the case without H₂O₂, but the Li composition in the liquid phase was only ~1. Thus, the ideal overall reaction is represented by

However, as revealed by the soft XAS and electrochemical analyses, the surface of NCM622 was slightly delithiated from the initial state ($x < 1$). Therefore, successive reactions of oxidation and dissolution occurred on the NCM622 surface during the leaching process with H₂O₂. In other words, the small amount of delithiation reaction played a crucial role in the rapid and complete dissolution of NCM622. The delithiation reaction with H₂O₂ is expected to be similar to eqn (6), although details are currently unclear.

To further support these mechanisms, HNO₃ leaching experiments were also performed on NiO, Co₃O₄, and MnO₂ with and without H₂O₂. As shown in Fig. S7 (ESI[†]), the w values are ~100% for all the samples without H₂O₂. On the other hand, with H₂O₂, the w values are also ~100% for NiO and Co₃O₄ but not for MnO₂. Thus, the delithiation reaction of NCM622, namely, the oxidation of transition metals, promotes subsequent reduction and/or decomposition of the NCM622 surface, enabling successive oxidation and dissolution reactions. Notably, these experiments were performed at RT, which is a more moderate temperature than that for the conventional industrial procedure.^{11–13}

3.7 Comparison with NCA and LCO

Finally, we compared our results to those of other positive electrode materials and investigated a more eco-friendly leaching process. Fig. 11a shows the results of HNO₃ leaching without H₂O₂ for NCA and LCO as well as NCM622. Similar to NCM633, NCA and LCO have a layered structure with the *R*3*m* space group.¹⁸ The w values for NCA and LCO were 51.1 and 60.4%, respectively, indicating a similar dissolution reaction for NCM622 as described by eqn (6). The difference in w between the three positive electrode materials originates from the difference in their electrochemical properties. According to the charge curves for NCM622, NCA, and LCO in Fig. 11b, the x values in Li _{x} MO₂ are 0.41, 0.34, and 0.48, respectively, where M is Ni_{0.6}Co_{0.2}Mn_{0.2}, Ni_{0.88}Co_{0.09}Al_{0.03}, or Co. The HNO₃ solution is unstable above ~4.2 V vs. Li⁺/Li at RT; thus, below 4.2 V, the further extraction of Li ions and the dissolution of the materials are both restricted to x .

In the HNO₃ leaching process with H₂O₂, all the NCA and LCO powder dissolved, as shown in the inset of Fig. 11b, and

Fig. 11 (a) Results of HNO₃ leaching for NCM622, NCA, and LCO without H₂O₂. (b) Charge curves of the Li cells with NCM622, NCA, and LCO, which were normalized as a function of x in Li _{x} MO₂ with M = Ni_{0.6}Co_{0.2}Mn_{0.2}, Ni_{0.88}Co_{0.09}Al_{0.03}, or Co. Photographs of the HNO₃ leaching experiments for NCA and LCO with H₂O₂ (right). (c) Results of the citric acid leaching for NCM622, NCA, and LCO with H₂O₂.

their solutions appeared green and red, respectively. This suggests that the yellow appearance of the NCM622 solution was a mixture of green from Ni and red from Co.

To reduce the environmental load, organic acids are preferable over inorganic acids such as HNO₃ and H₂SO₄. Fig. 11c shows the results using citric acid with H₂O₂ to leach NCM622, NCA, and LCO. The w values for NCM822 and LCO were 1.4 and 5.4%, respectively, indicating the possibility of complete dissolution under more eco-friendly conditions. However, w for NCA was limited to 46.0%, implying that even a small amount of Al ions (0.03) impedes the dissolution of NCA. This relates to the fact that the solubility of Al³⁺ significantly decreases in the neutral solution.³³

4 Conclusion

We elucidated the reaction mechanisms underlying the HNO₃ leaching process for NCM622 with or without H₂O₂. In the leaching process without H₂O₂, w approached ~60% after 24 h. The a_h and c_h values of residual NCM622 powder changed with the leaching time or Li composition (x), similar to those of electrochemically delithiated NCM622 compounds. However, this residual NCM622 powder differed from electrochemically delithiated compounds in terms of the microscopic crystal and electronic structures. A small amount of the γ -NiOOH phase existed in N_8 and N_24 (reaching a maximum of 3.2 wt%). Furthermore, EDS mappings and HAADF-STEM images clarified the compositional and structural inhomogeneities in N_24. Surprisingly, N_24 consisted of different-oriented layers, which are rotated by 60° with respect to each other. Owing to such inhomogeneities, the charge and discharge profiles of N_24

drastically changed with respect to those of the initial NCM622; a plateau appeared at ~ 3.5 V, and Q_{recha} decreased with each cycle.

In the leaching process with H_2O_2 , the NCM622 powder completely dissolved into the solution within 3 h. The spherical secondary particles were broken within 1 h, and the average size of the primary particles decreased as leaching proceeded further. The a_{h} and c_{h} values in the middle of the leaching process were similar to those of the initial NCM622, indicating that x in NCM622 is 1. The XRS results, which reveal the electronic structures of the bulk, were consistent with the XRD measurements. However, soft XAS, which corresponds to the electronic structures of the surface, revealed a delithiated phase on the surface of N + H₁ according to the O K-edge, Ni L-edge, Co L-edge, and Mn L-edge XANES spectra. Hence, sequential oxidation (delithiation) and dissolution (decomposition) reactions occurred during the leaching process with H_2O_2 , enabling complete dissolution within 3 h.

We also investigated the leaching process for NCA and LCO powders, which also dissolved into the HNO_3 solution with H_2O_2 , whereas approximately half of the LCO remained in the citric acid solution with H_2O_2 . Even a small amount of Al ions (0.03) impeded the dissolution of NCA under mild acidic conditions. Thus, we must pay particular attention to the chemical composition of positive electrode materials under eco-friendly leaching conditions.
