# Effect of microhydration on the aromatic charge resonance interaction: the case of the pyrrole dimer cation†

Dashjargal Arildii,<sup>a</sup> Yoshiteru Matsumoto<sup>b</sup> and Otto Dopfer<sup>b</sup>  <sup>★ac</sup>

Charge resonance (CR) interactions between aromatic molecules are amongst the strongest intermolecular forces and responsible for many phenomena in chemistry and biology. Microhydration of an aromatic radical dimer cation allows investigation of the strong effects of stepwise solvation on the charge distribution and strength of the CR. We characterise herein the microhydration process of the pyrrole dimer cation ( $\text{Py}_2^+$ ), a prototypical aromatic homodimer with a strong CR. The NH and OH stretch vibrations ( $\nu_{\text{NH/OH}}$ ) of mass-selected bare and colder Ar-tagged hydrated clusters of  $\text{Py}_2^+$ ,  $\text{Py}_2^+(\text{H}_2\text{O})_n\text{Ar}_m$  ( $n \leq 3$ ,  $m \leq 1$ ), recorded by infrared photodissociation (IRPD) spectroscopy provide detailed insight into the preferred cluster growth and strengths of the various intermolecular interactions by comparison to dispersion-corrected density functional theory calculations. The analysis of systematic frequency shifts, structural parameters, binding energies, and charge distributions allows for a quantitative evaluation of the drastic effects of stepwise hydration on the strength and symmetry of the aromatic CR, the strengths of the various hydrogen bonds (H-bonds), and the competition between slightly noncooperative interior ion hydration and strongly cooperative formation of a H-bonded solvent network. The most stable  $\text{Py}_2^+\text{H}_2\text{O}$  structure exhibits a strong  $\text{NH}\cdots\text{O}$  ionic H-bond of  $\text{H}_2\text{O}$  to the antiparallel stacked  $\text{Py}_2^+(\text{a})$  core, thereby breaking the symmetry of the CR.  $\text{Py}_2^+(\text{H}_2\text{O})_2$  prefers a highly symmetric  $\text{C}_{2h}$  structure with two equivalent  $\text{NH}\cdots\text{O}$  H-bonds of  $\text{Py}_2^+(\text{a})$  and an optimised CR. Starting from  $n = 3$ , clusters with a parallel configuration,  $\text{Py}_2^+(\text{p})$ , are more stable than those with  $\text{Py}_2^+(\text{a})$ , further highlighting the strong impact of (micro-)solvation on the structural motif of the aromatic CR. The spectral and computational data demonstrate a linear correlation of  $\nu_{\text{NH}}$  of the free Py unit with its partial charge, illustrating that IR spectroscopy is a powerful tool for probing the charge distribution in aromatic CR cluster cations. Comparison of  $\text{Py}_2^+(\text{H}_2\text{O})_n$  with neutral  $\text{Py}_2(\text{H}_2\text{O})_n$  and  $\text{Py}^+(\text{H}_2\text{O})_n$  reveals the impact of the magnitude of positive charge and the number of acidic proton donors on the structure of the microhydration shell and strength of the various competing intermolecular bonds.

## 1. Introduction

Intermolecular interactions involving aromatic  $\pi$  electrons are highly relevant for a large number of chemical and biological phenomena.<sup>1–9</sup> One of the most common interactions between aromatic molecules is  $\pi$ – $\pi$  stacking, a weak interaction mostly based on London dispersion forces. Such  $\pi$ – $\pi$  stacking is well-known to stabilise the DNA double-strand and to contribute to protein folding.<sup>10–12</sup> In structural chemistry,  $\pi$ – $\pi$  stacking often

determines the geometry of supramolecules and the properties of solid or liquid crystals.<sup>13–15</sup> In addition,  $\pi$  hydrogen bonds ( $\pi$  H-bonds) such as  $\text{CH}\cdots\pi$  bonds are important weak interactions involving aromatic molecules.<sup>16–20</sup> In contrast to these weak interactions, the charge resonance (CR) interaction in charged aromatic dimers is amongst the strongest intermolecular forces, with a strength of around  $100 \text{ kJ mol}^{-1}$ .<sup>21–23</sup> The CR interaction plays an important role for structure, energetics, and dynamics of intermolecular and intramolecular hole transport in stacked conjugated biological and organic semiconductor materials.<sup>24–31</sup>

The CR in aromatic dimer cations ( $\text{AB}^+$ ) is formed by sharing the positive charge generated by removing a single  $\pi$  electron. This CR gives rise to two electronic states described by

$$\psi_+ = c_1\phi(\text{A}^+)\phi(\text{B}) + c_2\phi(\text{A})\phi(\text{B}^+)$$

$$\psi_- = c_2\phi(\text{A}^+)\phi(\text{B}) - c_1\phi(\text{A})\phi(\text{B}^+)$$

whereby  $\psi_+$  is the stabilised ground electronic state and  $\psi_-$  is the repulsive excited electronic state.<sup>32</sup> The splitting between the two states  $\psi_{\pm}$  is typically of the order of  $\sim 1$  eV and gives rise to a strongly allowed optical transition in the near-IR range ( $\sim 1000$  nm). In general, the splitting between these two electronic states depends strongly on the difference in the ionisation energies ( $\Delta IE$ ) of A and B, whereby the CR becomes stronger, the smaller  $\Delta IE$  and thus is strongest for homodimer cations,  $A_2^+$  (i.e.,  $A = B$  and  $c_1 = c_2$ ).<sup>23,33</sup>

CR interactions were first detected in the condensed phase by electron spin resonance<sup>34–36</sup> and optical absorption spectroscopy.<sup>37–40</sup> However, these experiments suffer from environmental perturbations such as solvent and counter ions. In the gas phase, the binding energies of several isolated aromatic homo- and heterodimers were measured by mass spectrometric techniques.<sup>41–43</sup> The spectra of the electronic CR transitions recorded for the aromatic homodimers of benzene,<sup>44–47</sup> naphthalene,<sup>48–50</sup> toluene,<sup>51</sup> pyrene,<sup>52</sup> and several heterodimers<sup>32,51,53</sup> have proven that the splitting between the two electronic states  $\psi_{\pm}$  depends on the size and  $\Delta IE$  of the two monomer units. The strength of the CR interaction is controlled by the charge distribution on the respective monomers.<sup>32,51,53</sup> However, the electronic CR bands observed by optical absorption in the spectral range around 1 eV are too broad even in the gas phase due to their transitions into the repulsive  $\psi_-$  state, preventing a precise estimation of the partial charge distribution on the interacting monomers. To circumvent this problem, we previously demonstrated an efficient spectroscopic method to estimate the charge distribution in isolated aromatic  $A_2^+$  and  $AB^+$  dimers by monitoring their vibrational transitions in the ground state ( $\psi_+$ ) utilising infrared photodissociation spectroscopy (IRPD).<sup>23</sup> This study concentrated on the pyrrole dimer cation ( $Py_2^+$ ), its clusters, and related heterodimers because of its strong CR interaction and the high sensitivity of the NH stretch frequency ( $\nu_{NH}$ ) of Py ( $C_4H_5N$ ) to its partial charge.<sup>23</sup> Besides being a fundamental building block of many important biomolecules such as porphyrins, amino acids, proteins, and DNA bases, Py has a single isolated, uncoupled, and strongly IR-active NH stretch oscillator, whose frequency is indeed rather sensitive to the charge state of  $Py^q$  (e.g.,  $\nu_{NH} = 3531$  and  $3447$   $cm^{-1}$  for  $q_{Py} = 0$  and  $1e$ ).<sup>54,55</sup> The latter property differs from that of bare aromatic hydrocarbons, such as benzene and related polycyclic aromatic hydrocarbons, whose CH stretch frequencies ( $\nu_{CH}$ ) are less sensitive to charges and have weaker IR oscillator strengths in the cation ground state. Furthermore, often strong anharmonic or vibronic couplings further complicate the CH stretch range in these hydrocarbons (e.g., Fermi resonances in  $C_6H_6$  and  $C_6H_4Cl_2^+$  or Jahn–Teller effect in  $C_6H_6^+$ ).<sup>45,53,56–60</sup>

Because Py has an acidic NH group and aromatic  $\pi$  electrons, neutral  $Py_2$  dimer forms a weak  $NH \cdots \pi$  H-bond,<sup>61–63</sup> with an interaction energy of  $0.07$  eV.<sup>64</sup> Its T-shaped structure has been confirmed by microwave,<sup>64</sup> IR,<sup>63,65</sup> and Raman spectroscopy,<sup>65</sup> as well as quantum chemical calculations.<sup>61,66</sup>  $Py_2^+$  radical cations formed in a supersonic plasma expansion based on electron ionisation (EI) have a stacked sandwich structure stabilised by a strong CR interaction ( $1.01$  eV), which

has been characterised by IRPD and quantum chemical calculations.<sup>23</sup> Further analysis of IRPD spectra of cold  $Py_2^+$  dimers tagged with Ar or  $N_2$  reveals that the antiparallel  $Py_2^+(a)$  isomer with  $C_{2h}$  symmetry is significantly more stable than the parallel  $Py_2^+(p)$  local minimum with  $C_s$  symmetry (by around  $10$   $kJ\ mol^{-1}$ ) and thus dominates the population in the plasma expansion.<sup>67</sup> A minor population of hot  $Py_2^+$  ions ( $<15\%$ ) has been attributed to H-bonded clusters produced by intramolecular H-transfer and subsequent ring-opening reactions.<sup>67</sup> The presence of these high-energy isomers has been inferred from additional transitions observed in the IRPD spectrum of hot  $Py_2^+$  ions, which are absent in spectra recorded for cold  $Py_2^+Ar_n$  clusters.<sup>67</sup> These additional transitions have also been observed in the IRPD spectra of  $Py_2^+$  ions generated by VUV ionisation of neutral  $Py_n$  clusters but interpreted by isomers, in which the two heterocyclic units are connected by a chemical C–C or C–N bond.<sup>68,69</sup> However, as the IR spectra computed for these chemically-bonded isomers are not compatible with the measured IRPD spectra of  $Py_2^+$  for both EI<sup>67</sup> and VUV<sup>68</sup> generation, we currently prefer an assignment to H-bonded rather than chemically-bonded isomers.<sup>67</sup>

$Py_2^+(a)$  is an ideal prototypical model to characterise in detail the aromatic CR interaction by IR spectroscopy of its bound  $\psi_+(^2A_u)$  ground electronic state.<sup>23</sup> First, its small five-membered ring causes the CR interaction to be very strong, in particular, stronger than any ionic  $NH \cdots N$  H-bond or  $NH \cdots \pi$  cation– $\pi$  interaction.<sup>67</sup> Moreover, the frequency of its rather isolated and strongly IR-active  $\nu_{NH}$  mode provides a rather sensitive measure of the partial positive charge located on Py, which thus can precisely be measured by high-resolution IR spectroscopy.<sup>23</sup> For example, the symmetric  $Py_2^+(a)$  dimer with a partial charge of  $q_{Py} = 0.5e$  on each Py unit has its  $\nu_{NH}$  ( $3480$   $cm^{-1}$ ) midway between those of Py ( $3531$   $cm^{-1}$ ) and  $Py^+$  ( $3447$   $cm^{-1}$ ).<sup>23</sup> Indeed, we established a linear relation between  $\nu_{NH}$  and  $q_{Py}$  expressed as  $\nu_{NH}(q_{Py})/cm^{-1} = -83.8\ q_{Py}/e + 3527.8$ .<sup>23</sup> This linear correlation derived from data for Py,  $Py^+$ , and  $Py_2^+$  ( $q_{Py}/e = 0, 1.0$ , and  $0.5$ ) was shown to hold for related clusters, in which the symmetry of  $Py_2^+$  is reduced either by solvation (e.g.,  $Py_2^+N_2$ ) or by substitution of functional groups (e.g., by replacing one Py by *N*-methyl-Py, NMPy).<sup>23</sup> In both heterodimers ( $Py-PyN_2$ ,  $Py-NMPy$ ), the IE of the aromatic binding partner is lowered compared to Py, leading to an asymmetric charge distribution in  $[Py-PyN_2]^+$  and  $[Py-NMPy]^+$  with  $q_{Py} < 0.5e$  and thus a blueshift in the free  $\nu_{NH}$  of the remaining Py unit.<sup>23</sup> In  $Py_2^+N_2$ ,  $N_2$  binds *via* an  $NH \cdots N$  H-bond to one of the free acidic NH groups of  $Py_2^+(a)$ .<sup>23,67</sup> Therefore, stronger bases like  $H_2O$  are expected to act as better H-bond acceptors with a larger reduction in symmetry of the geometric structure, the charge distribution, and thus the CR.

Herein, we characterise the microhydration process of  $Py_2^+$  using IRPD of mass-selected  $Py_2^+(H_2O)_nAr_m$  clusters ( $n \leq 3$ ,  $m \leq 1$ ) in the CH, NH, and OH stretch ranges ( $\nu_{CH/NH/OH}$ ). Ar-tagging is applied to generate clusters with lower internal energy and to reduce the effective dissociation energy, leading to higher-resolution spectra and larger photodissociation efficiency.<sup>7</sup> Complementary dispersion-corrected density functional theory (DFT) calculations at the B3LYP-D3/aug-cc-pVTZ

level are employed to assign the measured IRPD spectra and to analyse the observed intermolecular interactions. The present study is motivated by the following main reasons. First, stepwise microhydration of  $\text{Py}_2^+$  enables the investigation of breaking and restoring the symmetry of the CR interaction. Because  $\text{H}_2\text{O}$  has a significantly higher proton affinity than  $\text{N}_2$  ( $\text{PA} = 691$  vs.  $494 \text{ kJ mol}^{-1}$ ),<sup>70</sup> it forms a much stronger  $\text{NH} \cdots \text{O}$  ionic H-bond and thus causes a larger perturbation of the CR due to the larger difference in the IE of Py and  $\text{PyH}_2\text{O}$  (computed herein as  $\text{IE} = 8.09$  and  $7.06 \text{ eV}$ , respectively, *vide infra*). In addition, the magnitude of symmetry breaking can also be controlled by the degree of hydration ( $n$ ). For example, the linear H-bonded  $(\text{H}_2\text{O})_2$  is an even stronger H-bond acceptor than a single  $\text{H}_2\text{O}$  ligand, because of its larger PA ( $808 \text{ kJ mol}^{-1}$ ),<sup>71</sup> causing a larger perturbation of the CR in  $\text{Py}_2^+$ . Hence, we can address for the first time in detail the correlation between the CR in stacked  $\pi$ - $\pi$  dimers and the strength of its H-bonds to the (dipolar) solvent molecules. In passing, we note that also only a few spectroscopic studies have been reported on the solvation effects of the related  $\sigma$ - $\sigma$ <sup>72,73</sup> and  $\sigma$ - $\pi$ <sup>74</sup> hemibonded dimer cation systems which reveal the dependence of the stability of the  $\sigma$ - $\sigma$  and  $\sigma$ - $\pi$  hemibonds upon solvation with various ligands. Second, microhydration of  $\text{Py}_2^+$  is expected to show different hydration motifs than those of the neutral and cationic  $\text{Py}^{(+)}$  monomers, because  $\text{Py}_2^+$  offers two acidic NH groups as H-bond donors and an intermediate charge state ( $0.5e$  for each Py unit). Hence, we can follow the evolution of the  $\text{Py}_n(\text{H}_2\text{O})_m$  cluster network (structure and interaction strength) as a function of (i) charge and (ii) number of available acidic proton donors in (aromatic solute)-(dipolar solvent) systems. Previous studies reveal that  $\text{PyH}_2\text{O}^{20,55,75-79}$  and  $\text{Py}^+\text{H}_2\text{O}^{54}$  form conventional  $\sigma$ -type  $\text{NH} \cdots \text{O}$  H-bonds, whereby the H-bond in the cation is much stronger than in the neutral ( $65.1$  vs.  $17.6 \text{ kJ mol}^{-1}$ ), mainly due to the additional electrostatic and induction forces of the excess charge (charge-dipole and charge-induced dipole).<sup>54,80</sup> Moreover, we have recently reported the hydration motif of  $\text{Py}^+(\text{H}_2\text{O})_2$ , in which the linear  $(\text{H}_2\text{O})_2$  chain is directly H-bonded to the NH group of  $\text{Py}^+$ .<sup>80</sup> Strong cooperativity of the nonadditive induction forces make the  $\text{NH} \cdots \text{O}$  and  $\text{OH} \cdots \text{O}$  H-bonds in the  $\text{Py}^+(\text{H}_2\text{O})_2$  trimer much stronger than those in the respective  $\text{Py}^+\text{H}_2\text{O}$  and  $(\text{H}_2\text{O})_2$  dimers. In contrast to  $\text{Py}^+$ ,  $\text{Py}_2^+$  has the potential to develop at least two principally different and competing H-bonding motifs in  $\text{Py}_2^+(\text{H}_2\text{O})_2$ , such that either a  $(\text{H}_2\text{O})_2$  chain is H-bonded to one NH group (*i.e.*, formation of a H-bonded solvent network) or two single  $\text{H}_2\text{O}$  molecules are H-bonded to each NH group (*i.e.*, interior ion solvation). Third, it is possible that the hydration process may change the preferred orientation of the two NH groups in  $\pi$ -stacked  $\text{Py}_2^+$  from anti-parallel (a) to parallel (p) and thus modify the structural motif, symmetry, and strength of the CR interaction. Our previous B3LYP-D3 calculations suggest that the  $\text{Py}_2^+(\text{p})$  local minimum is less stable than the  $\text{Py}_2^+(\text{a})$  global minimum by only  $7.5 \text{ kJ mol}^{-1}$ .<sup>67</sup> As this energy difference is much smaller than typical monohydration energies of aromatic ions with an  $\text{NH} \cdots \text{O}$  ionic H-bond ( $\sim 50 \text{ kJ mol}^{-1}$ ),<sup>80-83</sup> stepwise hydration may indeed be able to induce a  $\text{Py}_2^+(\text{a}) \rightarrow \text{Py}_2^+(\text{p})$  transition of the

CR core ion at a critical size ( $n_c$ ). Because  $\text{Py}_2^+(\text{p})$  offers the possibility of forming cyclic hydration motifs in  $\text{Py}_2^+(\text{p})(\text{H}_2\text{O})_n$  clusters with one additional H-bond as compared to  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_n$ , such a  $\text{Py}_2^+(\text{a}) \rightarrow \text{Py}_2^+(\text{p})$  switch in the preferred structural CR motif may indeed occur upon progressive hydration.

## 2. Experimental and computational details

IRPD spectra of mass-selected  $\text{Py}_2^+(\text{H}_2\text{O})_n\text{Ar}_m$  cluster cations ( $n = 1-3$ ,  $m = 0-1$ ) are measured in a tandem quadrupole mass spectrometer coupled to an EI source and an octupole ion guide.<sup>9,84</sup> Cluster cations are produced in a pulsed supersonic plasma expansion of Py (Sigma-Aldrich, >98%, heated to  $50^\circ\text{C}$ ) seeded in Ar carrier gas. Hydrated cluster cations are generated by adding distilled  $\text{H}_2\text{O}$  into the gas inlet system. In general, ionic clusters are formed by electron (and/or chemical) ionisation (EI) of Py close to the nozzle orifice and subsequent three-body aggregation reactions. Hydrated clusters may also be produced by EI of neutral  $\text{Py}_{p \geq 2}(\text{H}_2\text{O})_{q \geq n}$  clusters and subsequent fragmentation into  $\text{Py}_2^+(\text{H}_2\text{O})_n$ . The cluster cations of interest are selected by the first quadrupole mass filter and irradiated in the adjacent octupole with a tunable IR laser pulse ( $\nu_{\text{IR}}$ ) generated by an optical parametric oscillator and amplifier (OPO/OPA) pumped by a Q-switched nanosecond Nd:YAG laser. The IR radiation is characterised by a pulse energy of 2–5 mJ, a bandwidth of  $<2 \text{ cm}^{-1}$ , and a repetition rate of 10 Hz. The IR laser frequency is calibrated to better than  $1 \text{ cm}^{-1}$  using a wavemeter. Resonant vibrational excitation induces the loss of the most weakly bonded ligand, *i.e.*, either  $\text{H}_2\text{O}$  or Ar. The generated fragment ions are selected by the second quadrupole mass filter and monitored by a Daly detector as a function of  $\nu_{\text{IR}}$  to obtain the IRPD action spectrum of the parent cluster. The ion source is triggered at twice the laser frequency to subtract the metastable decay background from the total fragment ion signal to extract the laser-induced fragmentation signal. All IRPD spectra are normalised for frequency-dependent variations in the IR photon flux measured by a pyroelectric detector. The peak widths of the vibrational transitions observed in the IRPD spectra are mainly caused by unresolved rotational structure, sequence hot bands involving inter- and intramolecular modes, and possibly contributions of several isomers. In addition to laser-induced dissociation (IRPD and LID), low-energy collision-induced dissociation (CID) experiments are performed in the octupole ion guide to confirm the composition of the mass-selected parent clusters. For the latter mass spectra, the octupole is filled with  $\text{N}_2$  gas or air ( $10^{-5}$  mbar) resulting in collisions with 10 eV energy in the laboratory frame. The respective CID and LID spectra of the mass-selected parent clusters are shown in Fig. S1 in ESI.†

Quantum chemical calculations are carried out at the dispersion-corrected B3LYP-D3/aug-cc-pVTZ level to determine the structural, energetic, vibrational, and electronic properties of the investigated cluster cations.<sup>85-89</sup> This level of calculation has provided reliable results in our previous studies of related

pyrrole cluster ions.<sup>23,54,67,80</sup> Harmonic vibrational frequencies are scaled by factors of 0.9619 for NH and CH stretch vibrations and 0.9631 for OH stretch vibrations to optimise the agreement with the measured frequencies of bare Py and H<sub>2</sub>O ( $\nu_{\text{NH}} = 3531 \text{ cm}^{-1}$ ,  $\nu_{1/3} = 3657/3756 \text{ cm}^{-1}$ ), respectively.<sup>63,80,90</sup> Inter-molecular interaction energies ( $D_0$ ) and relative energies ( $E_0$ ) are corrected for zero-point vibrational energy. Relative free energies ( $G_0$ ) are calculated at 298 K. The counterpoise procedure for correcting energies for basis set superposition error is not included because such corrections are expected to be 1% or less for the large basis set employed, as has been shown for related microhydrated aromatic cluster cations.<sup>82,91</sup> The natural charge distributions on each molecular component and the donor-acceptor interaction energies ( $E^{(2)}$ ) describing the strengths of H-bonds are obtained employing the natural bond orbital (NBO) analysis.<sup>92</sup> Anharmonic vibrational calculations are carried out at the lower B3LYP-D3/aug-cc-pVDZ level to reduce computational costs and at the PBE0/aug-cc-pVDZ level to evaluate the dependence on the DFT functional.<sup>85,93</sup> The reliability of the results obtained at the reduced basis set and the different DFT functional is evaluated by comparing the harmonic frequencies of each method to the frequencies obtained at the B3LYP-D3/aug-cc-pVTZ level. Harmonic vibrational frequencies calculated at the B3LYP-D3/aug-cc-pVDZ level are scaled by factors of 0.9628 for  $\nu_{\text{CH/NH}}$  and 0.9621 for  $\nu_{\text{OH}}$  and at the PBE0/aug-cc-pVDZ level by factors of 0.9522 for  $\nu_{\text{CH/NH}}$  and 0.9474 for  $\nu_{\text{OH}}$ . Vertical CR transition energies are obtained from time-dependent DFT (TD-DFT) calculations at the B3LYP-D3<sup>85</sup> level for the optimised ground state geometry and compared with results from the B3PW91-D3,<sup>94</sup> CAM-B3LYP-D3,<sup>95</sup> and M06-2X<sup>96</sup> functionals using the aug-cc-pVTZ basis set. The evaluation of the strengths of the intermolecular H-bonds is facilitated by the noncovalent interaction (NCI) approach.<sup>97–99</sup> This method is based on the analysis of the electron densities ( $\rho$ ) and their reduced density gradients (RDG),  $s(\rho)$ , and therefore highlights the interactions in the low-density region.<sup>99</sup> The NCI analysis provides an index based on a plot of  $s(\rho)$  in the area in which  $s(\rho)$  is close to its minima of  $\rho$ . The final visualisation is then obtained by plotting RDG against  $\rho$  oriented by the sign of the second eigenvalue  $\lambda_2$  of the Hessian matrix,  $\rho^* = \text{sign}(\lambda_2)\rho$ .<sup>100,101</sup> The plotted NCI surfaces cover the range  $-0.05 < \rho^* < 0.0 \text{ a.u.}$ , with an isosurface value of 0.3 a.u. The NCI color code uses blue surfaces for attractive interactions (negative  $\lambda_2$ ), green surfaces for weak van der Waals contacts ( $\lambda_2$  near 0), and red surfaces for repulsive interactions (positive  $\lambda_2$ ). Cartesian coordinates of all considered isomers and their corresponding energies are provided in ESI†

### 3. Results and discussion

#### 3.1. Overview of IRPD spectra of $\text{Py}_2^+(\text{H}_2\text{O})_n$

Fig. 1 compares the IRPD spectra of  $\text{Py}_2^+(\text{H}_2\text{O})_n$  with  $n = 1–3$  measured in the H<sub>2</sub>O loss channel. For comparison, the previously reported IRPD spectra of  $\text{Py}^+\text{Ar}$  and  $\text{Py}_2^+$  measured in the Ar and Py loss channels, respectively, are included as well.<sup>54,67</sup>

Fig. 1 IRPD spectra of  $\text{Py}_2^+(\text{H}_2\text{O})_n$  with  $n = 0–3$  (and  $\text{Py}^+\text{Ar}$  for comparison)<sup>54</sup> recorded in the CH, NH, and OH stretch range. The positions, width, and assignments of the observed transitions are compiled in Table S1 (ESI†).

The positions and widths of the bands observed are listed in Table S1 (ESI†) along with the suggested vibrational and isomer assignments. The spectral range investigated ( $2600–3800 \text{ cm}^{-1}$  for  $\text{Py}_2^+(\text{H}_2\text{O})_n$  with  $n = 1–2$  and  $3000–3800$  for  $n = 3$ ) covers the free and bound OH and NH stretch bands of the H<sub>2</sub>O ligands and the  $\text{Py}_2^+$  cation, as well as the aromatic CH stretch modes of  $\text{Py}_2^+$ . The IRPD spectra in Fig. 1 exhibit systematic shifts in the OH and NH stretch bands as a function of cluster size and composition, providing detailed information about the stepwise microhydration process around  $\text{Py}_2^+$ . The free OH stretch range ( $3600–3800 \text{ cm}^{-1}$ ) contains the symmetric and antisymmetric OH stretch bands of H<sub>2</sub>O ligands acting as single/double acceptors ( $\nu_1$  and  $\nu_3$ , B and A) and the free OH stretch bands of H<sub>2</sub>O ligands acting as single/double acceptor and single donor ( $\nu_{\text{OH}}^f$ , C). The corresponding H-bonded OH stretch modes of H<sub>2</sub>O involved as an H-bond donor occur near  $3400 \text{ cm}^{-1}$  ( $\nu_{\text{OH}}^b$ , D). The free NH stretch of  $\text{Py}_2^+$  occurs near  $3500 \text{ cm}^{-1}$  ( $\nu_{\text{NH}}^f$ , E), while the H-bonded NH stretch shifts strongly to the red down to  $3000–3300 \text{ cm}^{-1}$  upon hydration ( $\nu_{\text{NH}}^b$ , F, F1). Peak G observed at  $\sim 3130 \text{ cm}^{-1}$  in all spectra is assigned to the aromatic CH stretch vibrations ( $\nu_{\text{CH}}$ ) of  $\text{Py}_2^+$ . Bands X, Y, and Y' cannot arise from fundamentals of  $\text{Py}_2^+(\text{H}_2\text{O})_n$  clusters with  $\pi$ -stacked  $\text{Py}_2^+(\text{a/p})$  cores and are attributed at this initial stage to either overtone and/or combination bands or transitions of other minor

isomers.<sup>102,103</sup> The pronounced broad peak F\* in the IRPD spectrum of  $\text{Py}_2^+$  has been assigned in our previous study to  $\nu_{\text{NH}}^{\text{b}}$  of a minor population of H-bonded isomers,  $\text{Py}_2(\text{CC/OC})^+$ .<sup>67</sup> Its absence in the IRPD spectra of  $\text{Py}_2^+(\text{H}_2\text{O})_n$  and their Ar-tagged clusters indicates that these isomers are below the detection limit for the hydrated clusters. In the following sections, the structures of the microhydrated  $\text{Py}_2^+$  clusters are identified by comparing the measured IRPD spectra with linear IR absorption spectra computed for low-energy isomers. The IRPD spectra of their Ar-tagged clusters are also considered because their lower temperature yields narrower bands in the IRPD spectra, which provide more precise vibrational assignments.

### 3.2. $\text{Py}_{1/2}^+$ and $(\text{H}_2\text{O})_{1/2}$

Before considering the  $\text{Py}_2^+(\text{H}_2\text{O})_n$  clusters, we briefly review the available knowledge on the  $\text{Py}_{1/2}^+$  and  $(\text{H}_2\text{O})_{1/2}$  subunits relevant to the current study. The structures of Py and  $\text{Py}^+$  in their  $^1\text{A}_1$  and  $^2\text{A}_2$  electronic ground states are planar ( $\text{C}_{2v}$ ), and the N–H bond length increases by 7 mÅ from  $r_{\text{NH}} = 1.0031$  to  $1.0102$  Å upon ionisation from the  $\pi(\text{a}_2)$  HOMO orbital (Fig. 2). This geometry change results in a large calculated redshift from  $3531$  to  $3459$   $\text{cm}^{-1}$  ( $\Delta\nu_{\text{NH}}^{\text{f}} = -72$   $\text{cm}^{-1}$ ), which compares favourably with the measured values of  $3531$  and  $3447$   $\text{cm}^{-1}$  ( $\Delta\nu_{\text{NH}}^{\text{f}} = -84$   $\text{cm}^{-1}$ ), respectively.<sup>54,63</sup> The IRPD spectrum of  $\text{Py}^+\text{Ar}$  shown in Fig. 1 exhibits two bands E and F at  $3450$  and  $3423$   $\text{cm}^{-1}$  assigned to  $\nu_{\text{NH}}^{\text{f}}$  of  $\pi$ -bonded  $\text{Py}^+\text{Ar}(\pi)$  and  $\nu_{\text{NH}}^{\text{b}}$  of H-bonded of  $\text{Py}^+\text{Ar}(\text{H})$ , respectively.<sup>54</sup> Because the  $\pi$ -bonded local minimum with  $D_0 = 6.6$   $\text{kJ mol}^{-1}$  shows a computed  $\nu_{\text{NH}}^{\text{f}}$  blueshift of only  $3$   $\text{cm}^{-1}$  from that of bare  $\text{Py}^+$  ( $3459$  vs.  $3462$   $\text{cm}^{-1}$ ), an accurate experimental value can be estimated for bare  $\text{Py}^+$  as  $\nu_{\text{NH}}^{\text{f}} = 3447$   $\text{cm}^{-1}$ .<sup>54</sup> The formation of the  $\text{NH} \cdots \text{Ar}$  H-bond in the planar  $\text{Py}^+\text{Ar}(\text{H})$  global minimum ( $\text{C}_{2v}$ ) with  $D_0 =$

$9.4$   $\text{kJ mol}^{-1}$  and  $R_e = 2.470$  Å causes a larger redshift measured as  $\Delta\nu_{\text{NH}}^{\text{b}} = -50$   $\text{cm}^{-1}$ .

Because of the CR, the positive charge in  $\text{Py}_2^+(\text{a})$  is equally shared between the two equivalent Py units and both N–H bond lengths and NH stretch frequencies of  $\text{Py}_2^+$  are intermediate between those of Py and  $\text{Py}^+$  (Fig. 2).<sup>23</sup> Indeed, for the  $\text{Py}_2^+(\text{a})$  global minimum,  $r_{\text{NH}} = 1.0061$  Å is close to the average of Py and  $\text{Py}^+$  ( $r_{\text{NH}} = 1.0031$  and  $1.0102$  Å). As a result, the calculated frequencies of the antisymmetric IR-active and symmetric IR-forbidden NH stretch modes,  $\nu_{\text{NH}}^{\text{f}} = 3500$  and  $3501$   $\text{cm}^{-1}$ , are midway between those of Py and  $\text{Py}^+$  computed as  $\nu_{\text{NH}}^{\text{f}} = 3531$  and  $3459$   $\text{cm}^{-1}$ . These computational predictions agree well with band E observed at  $\nu_{\text{NH}}^{\text{f}} = 3479$   $\text{cm}^{-1}$  in the IRPD spectrum of  $\text{Py}_2^+$  (Fig. 1), which is also midway between those of Py and  $\text{Py}^+$  observed at  $\nu_{\text{NH}}^{\text{f}} = 3531$  and  $3447$   $\text{cm}^{-1}$ .<sup>23,67</sup> The slightly less stable  $\text{Py}_2^+(\text{p})$  local minimum structure with a parallel orientation of the two NH groups (Fig. 2) has two IR-active NH stretch modes calculated as  $\nu_{\text{NH}}^{\text{f}} = 3499$  and  $3510$   $\text{cm}^{-1}$  with a splitting of  $11$   $\text{cm}^{-1}$  (Table S2, ESI†). As these frequencies are similar to those of the  $\text{Py}_2^+(\text{a})$  global minimum, one cannot exclude the contribution of  $\text{Py}_2^+(\text{p})$  to band E in the IRPD of bare  $\text{Py}_2^+$  because its width ( $19$   $\text{cm}^{-1}$ ) is much larger than the  $\nu_{\text{NH}}^{\text{f}}$  shifts and splittings for the  $\text{Py}_2^+(\text{a/p})$  rotamers.<sup>67</sup> However, from the energetic point of view, the  $\text{Py}_2^+$  population will be dominated by  $\text{Py}_2^+(\text{a})$  because it is more stable than  $\text{Py}_2^+(\text{p})$  by  $7.5$   $\text{kJ mol}^{-1}$  (B3LYP-D3). Indeed, in our recent study on the internal energy dependence of the formation of  $\text{Py}_2^+$  in our EI source, the higher-resolution IRPD spectra of cold  $\text{Py}_2^+\text{L}_n$  clusters tagged with  $\text{L} = \text{Ar}$  and  $\text{N}_2$  suggest that the population of  $\text{Py}_2^+(\text{p})$  is at most 15% of the  $\pi$ -stacked  $\text{Py}_2^+$  dimers.<sup>67</sup> The high rotational barriers ( $V_b$ ) for  $\text{a} \rightarrow \text{p}$  and  $\text{p} \rightarrow \text{a}$  isomerisation computed at different computational levels suggest that the  $\text{Py}_2^+(\text{a/p})$  isomers are kinetically trapped in their potential well rather than isomerising between each other. Therefore, the estimated  $\text{Py}_2^+(\text{p})$  abundance using a Boltzmann distribution based on  $\Delta E_0(\text{B3LYP-D3}) = 7.5$   $\text{kJ mol}^{-1}$  is 17% at 298 K, which is compatible with the experiment ( $\leq 15\%$ ). In the same study, we assigned the additional bands at  $2888$  (X) and  $3028$  (F\*)  $\text{cm}^{-1}$  observed in the IRPD spectrum of bare  $\text{Py}_2^+$  (but not in  $\text{Py}_2^+\text{L}_n$ ) to a Fermi doublet ( $2\nu_{\text{NH}}^{\text{b}}$  and  $\nu_{\text{NH}}^{\text{b}}$ ) of a minor population (10%) of H-bonded  $\text{Py}_2(\text{OC})^+$  isomers containing one open-cycle (OC) Py unit. The latter dimers are characterized by an  $\text{NH} \cdots \text{N}$  ionic H-bond between  $\text{Py}^+$  and a neutral noncyclic Py isomer formed by H-migration and subsequent ring opening in the EI source.<sup>67</sup>

The calculated O–H bond parameters of  $\text{H}_2\text{O}$  in its  $^1\text{A}_1$  ground state ( $r_{\text{OH}} = 0.9618$  Å,  $\nu_1 = 3657$   $\text{cm}^{-1}$ ,  $\nu_3 = 3756$   $\text{cm}^{-1}$ ) agree well with the experimental data ( $0.9578$  Å,  $3657$  and  $3756$   $\text{cm}^{-1}$ ).<sup>90</sup> Our computed  $(\text{H}_2\text{O})_2$  equilibrium geometry has the known *trans*-linear H-bonded structure (Fig. 2), with an  $\text{O} \cdots \text{O}$  distance ( $r_{\text{OO}} = 2.909$  Å) and an angle of the acceptor  $\text{H}_2\text{O}$  axis with respect to  $r_{\text{OO}}$  ( $59.1^\circ$ ) consistent with corresponding experimental values ( $2.98$  Å,  $58^\circ$ ).<sup>104</sup> The four calculated OH stretch frequencies of the  $\text{H}_2\text{O}$  acceptor ( $\nu_{1/3} = 3652/3747$   $\text{cm}^{-1}$ ) and donor ( $\nu_{\text{OH}}^{\text{b/f}} = 3540/3728$   $\text{cm}^{-1}$ ) are also close to their experimental data ( $\nu_{1/3} = 3654/3746$   $\text{cm}^{-1}$ ,  $\nu_{\text{OH}}^{\text{b/f}} = 3601/3735$   $\text{cm}^{-1}$ ), respectively.<sup>105–107</sup> The H-bond strength computed

Fig. 2 Structures of (a)  $\text{Py}^+$ , (b)  $\text{H}_2\text{O}$  and  $(\text{H}_2\text{O})_2$ , (c)  $\text{Py}_2^+(\text{a})$ , and (d)  $\text{Py}_2^+(\text{p})$  obtained at the B3LYP-D3/aug-cc-pVTZ level. Selected intra- and intermolecular bond lengths (in Å) are given in black and red, respectively. Values in dark red indicate NBO charges (in units of  $e$ ). The dissociation energies ( $D_0$ , in parentheses) are given in  $\text{kJ mol}^{-1}$ .

as  $D_0 = 13.0 \text{ kJ mol}^{-1}$  compares again favourably with the experimental determination of  $D_0 = 13.2 \pm 0.1 \text{ kJ mol}^{-1}$  ( $1105 \pm 10 \text{ cm}^{-1}$ ),<sup>108</sup> illustrating that the chosen B3LYP-D3 level reliably describes the  $\text{H}_2\text{O} \cdots \text{H}_2\text{O}$  interaction. The IEs of  $(\text{H}_2\text{O})_n$  calculated at the B3LYP-D3 level (12.60 and 10.73 eV for  $n = 1$  and 2) are much higher than the IEs of both Py (8.09 eV) and  $\text{Py}_2$  (7.22 eV), indicating that the positive charge is mostly located on  $\text{Py}_2$  rather than on the  $\text{H}_2\text{O}$  ligands, which justifies the notation of  $\text{Py}_2^+(\text{H}_2\text{O})_n$ . These calculated IEs are close to available experimental values (IE = 12.615, 11.21, 8.207 for  $\text{H}_2\text{O}$ ,  $(\text{H}_2\text{O})_2$ , Py, respectively).<sup>109–113</sup>

### 3.3. $\text{Py}_2^+\text{H}_2\text{O}$

Based on the two stacked  $\text{Py}_2^+(\text{a/p})$  minima, several low-energy  $\text{Py}_2^+\text{H}_2\text{O}$  structures are obtained, and the four most stable ones,  $\text{Py}_2^+(\text{a/p})\text{H}_2\text{O}$  (I and II), are shown in Fig. 3 and Fig. S2 (ESI†). Their computed IR spectra are compared in Fig. 4 and Fig. S3 (ESI†) to the IRPD spectra recorded for  $\text{Py}_2^+\text{H}_2\text{O}$  and  $\text{Py}_2^+\text{H}_2\text{OAr}$ . In the most stable structure,  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}$  (I),  $\text{H}_2\text{O}$  is attached to  $\text{Py}_2^+(\text{a})$  via a nearly linear  $\text{NH} \cdots \text{O}$  H-bond, a binding motif similar to the  $\text{NH} \cdots \text{N}$  H-bond reported previously for  $\text{Py}_2^+(\text{a})\text{N}_2$ .<sup>54,67</sup> The H-bond in  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}$  (I) is substantially weaker than that in  $\text{Py}_2^+\text{H}_2\text{O}$  (H)<sup>54</sup> ( $R_{\text{NH} \cdots \text{O}} = 1.809 \text{ vs. } 1.704 \text{ \AA}$ ,  $D_0 = 46.3 \text{ vs. } 65.1 \text{ kJ mol}^{-1}$ ,  $E^{(2)} = 30.0 \text{ vs. } 46.4 \text{ kJ mol}^{-1}$ ), because of the strongly reduced charge on the proton-donor Py molecule upon attachment of the second Py unit (from 1.0 to 0.5e). As a result of the weaker H-bond, the charge transfer to  $\text{H}_2\text{O}$  is smaller ( $q_{\text{H}_2\text{O}} = 0.033 \text{ vs. } 0.051e$ ). The N–H donor bond becomes less elongated ( $r_{\text{NH}} = 1.0219 \text{ vs. } 1.0363 \text{ \AA}$ ,  $\Delta r_{\text{NH}} = 16 \text{ vs. } 26 \text{ m\AA}$ ), leading to a smaller redshift in  $\nu_{\text{NH}}^b$  ( $\Delta \nu_{\text{NH}}^b = -278 \text{ vs. } -455 \text{ cm}^{-1}$ ,  $\nu_{\text{NH}}^b = 3223 \text{ vs. } 3004 \text{ cm}^{-1}$ ). The free N–H bond of the second Py unit contracts slightly upon monohydration (1.0057 vs. 1.0061  $\text{\AA}$ ), resulting in an observed blueshift of  $6 \text{ cm}^{-1}$  ( $\nu_{\text{NH}}^f = 3506$

Fig. 4 IRPD spectra of  $\text{Py}_2^+\text{H}_2\text{OAr}_n$  ( $n = 0-1$ ) recorded in the CH, NH, and OH stretch range are compared to linear IR absorption spectra calculated for  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}$  (I and II) and  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}$  (I)Ar(I and II) at the B3LYP-D3/aug-cc-pVTZ level (Tables S1 and S3, ESI†).

vs.  $3500 \text{ cm}^{-1}$ ). Monohydration completely decouples the two NH stretch oscillators of  $\text{Py}_2^+(\text{a})$ , and the free NH stretch is a pure local

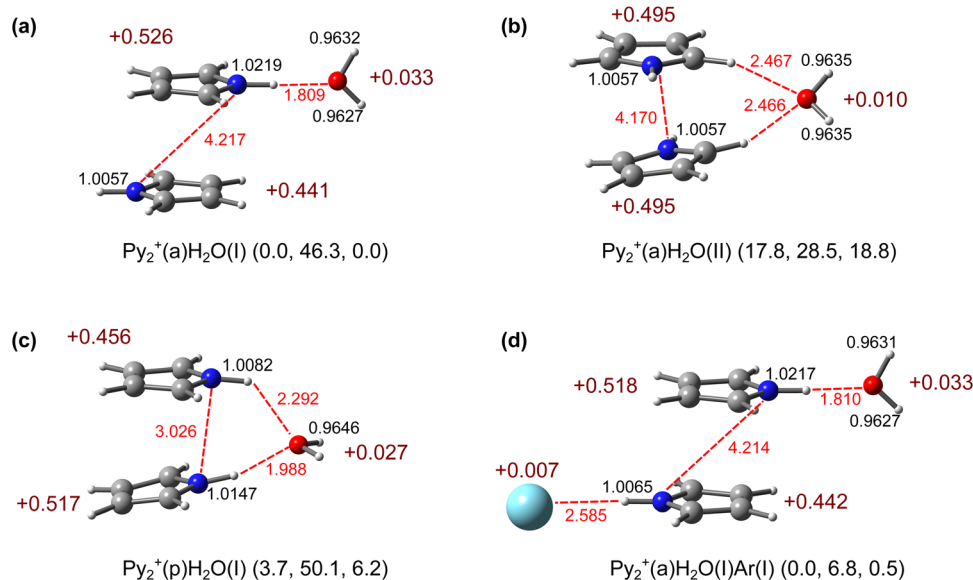

Fig. 3 Structures of (a) and (b)  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}$  (I and II), (c)  $\text{Py}_2^+(\text{p})\text{H}_2\text{O}$  (I), and (d)  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}$  (I)Ar(I) obtained at the B3LYP-D3/aug-cc-pVTZ level. Selected intra- and intermolecular bond lengths (in  $\text{\AA}$ ) are given in black and red, respectively. Values in dark red indicate NBO charges (in units of  $e$ ). Energies in parentheses are the relative energy, the dissociation energy of the most weakly bonded ligand, and the relative Gibbs free energy at 298 K ( $E_0$ ,  $D_0$ , and  $G_0$  in  $\text{kJ mol}^{-1}$ ).

mode of the free Py unit. Its partial charge is smaller than that on the H-bonded Py molecule ( $q_{\text{Py}} = 0.441$  vs.  $0.526e$ ), which may be rationalised by the lower ionisation energy of  $\text{PyH}_2\text{O}$  as compared to Py (calculated as  $\text{IE} = 7.60$  vs.  $8.09$  eV). This asymmetry in the  $\text{Py}_2^+(\text{a})$  charge distribution reduces the strength of the CR (vide infra). According to the  $q_{\text{Py}}-\nu_{\text{NH}}^{\text{f}}$  relation, the lower charge is fully consistent with the blueshift of  $\nu_{\text{NH}}^{\text{f}}$ . As in  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$  the H-bond to  $\text{H}_2\text{O}$  is weaker than that in  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{H})$ , the O–H bonds in  $\text{H}_2\text{O}$  are less elongated ( $r_{\text{OH}} = 0.9632/0.9627$  vs.  $0.9636$  Å) and the computed OH stretch frequencies are correspondingly higher ( $\nu_{1/3} = 3651/3739$  vs.  $3643/3729$   $\text{cm}^{-1}$ ).

$\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{II})$  is the second most stable isomer with a  $\text{Py}_2^+(\text{a})$  core. Its  $C_2$  symmetric structure has a bifurcated  $\text{CH}\cdots\text{O}$  H-bond of  $\text{H}_2\text{O}$  to two CH groups of the two Py units, with  $R_{\text{CH}\cdots\text{O}} = 2.467$  Å and  $D_0 = 28.5$   $\text{kJ mol}^{-1}$ . It is substantially less stable than the global minimum by  $17.8$   $\text{kJ mol}^{-1}$ , because the two  $\text{CH}\cdots\text{O}$  H-bonds are much weaker than the single  $\text{NH}\cdots\text{O}$  H-bond, resulting in a smaller charge transfer to  $\text{H}_2\text{O}$  ( $q_{\text{H}_2\text{O}} = 0.010$  vs.  $0.033e$ ). The remaining charge on  $\text{Py}_2^+$  is shared symmetrically (leading to an optimised and fully developed CR) but somewhat lower than in bare  $\text{Py}_2^+$  ( $q_{\text{Py}} = 0.495$  vs.  $0.500e$ ) due to the minor charge transfer to  $\text{H}_2\text{O}$ . In line with the  $q_{\text{Py}}-\nu_{\text{NH}}^{\text{f}}$  relation, the N–H bonds are slightly shorter ( $1.0057$  vs.  $1.0061$  Å), leading to a calculated blueshift of  $5$   $\text{cm}^{-1}$  for the two  $\nu_{\text{NH}}^{\text{f}}$  frequencies (Table S3, ESI†).

The most stable isomer with a  $\text{Py}_2^+(\text{p})$  core,  $\text{Py}_2^+(\text{p})\text{H}_2\text{O}(\text{I})$ , shown in Fig. 3 features an asymmetric bifurcated nonlinear H-bond of  $\text{H}_2\text{O}$  (double acceptor) to both available NH donor groups ( $R_{\text{NH}\cdots\text{O}} = 1.988$  and  $2.292$  Å) and thus the highest  $\text{H}_2\text{O}$  dissociation energy ( $D_0 = 50.1$   $\text{kJ mol}^{-1}$ ), although the individual  $\text{NH}\cdots\text{O}$  H-bonds are much weaker than in  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$ . Hence, its energy gap to the  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$  global minimum is reduced to only  $3.7$   $\text{kJ mol}^{-1}$ . The two Py units are not equivalent, and the relatively free Py unit carries less positive charge than the more strongly H-bonded bottom one ( $q_{\text{Py}} = 0.456$  vs.  $0.517e$ ). The weaker H-bond is strongly nonlinear and gives rise to an almost free  $\nu_{\text{NH}}$  ( $E^{(2)} = 4.4$   $\text{kJ mol}^{-1}$ ), while the stronger H-bond is more linear ( $E^{(2)} = 17.6$   $\text{kJ mol}^{-1}$ ). As both NH groups are involved in H-bonding, we cannot readily apply the  $q_{\text{Py}}-\nu_{\text{NH}}^{\text{f}}$  relation. The weaker H-bonded N–H bond is less elongated than the more strongly H-bonded one ( $r_{\text{NH}} = 1.0082$  and  $1.0147$  Å), which results in two redshifted and strongly IR-active  $\nu_{\text{NH}}^{\text{b}}$  modes at  $3339$  and  $3466$   $\text{cm}^{-1}$ , respectively (Table S4, ESI†). To enable bifurcated H-bonding, the  $\text{H}_2\text{O}$  plane has to rotate by  $90^\circ$  providing direct access to both lone pairs of the O atom. In this way,  $\text{H}_2\text{O}$  attachment strongly reduces the distance between the two Py rings ( $R_{\text{N}\cdots\text{N}} = 3.026$  vs.  $4.217$  Å). Due to the charge transfer to  $\text{H}_2\text{O}$  ( $q_{\text{H}_2\text{O}} = 0.027e$ ), the O–H bonds become longer ( $r_{\text{OH}} = 0.9646$  Å) and the OH stretch frequencies are redshifted compared to  $\text{H}_2\text{O}$  ( $\nu_{1/3} = 3632/3713$  vs.  $3657/3756$   $\text{cm}^{-1}$ ). In contrast to  $\text{Py}_2^+(\text{p})\text{H}_2\text{O}(\text{I})$ ,  $\text{Py}_2^+(\text{p})\text{H}_2\text{O}(\text{II})$  has a single  $\text{NH}\cdots\text{O}$  H-bond to the top Py unit. The geometric, energetic, and vibrational parameters of this  $\text{NH}\cdots\text{O}$  H-bond are quite similar to those in  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$ , indicating that internal rotation of the free Py unit by  $180^\circ$  has only a small impact on the remote monohydration motif and interaction

strength. As a result, the IR spectra predicted for  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$  and  $\text{Py}_2^+(\text{p})\text{H}_2\text{O}(\text{II})$  are very similar, too. The largest difference in both structures refers to the free N–H bond, which is shorter in  $\text{Py}_2^+(\text{p})\text{H}_2\text{O}(\text{II})$  leading to a higher  $\nu_{\text{NH}}^{\text{f}}$  ( $r_{\text{NH}} = 1.0048$  vs.  $1.0057$  Å,  $\nu_{\text{NH}}^{\text{f}} = 3517$  vs.  $3506$   $\text{cm}^{-1}$ ), consistent with the modified CR, which is less asymmetric ( $0.485/0.483$  vs.  $0.526/0.441e$ ).

Next, we briefly consider the predicted effects of Ar tagging on the properties of  $\text{Py}_2^+\text{H}_2\text{O}$  by taking the example of the most stable  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$  isomer (Fig. 3 and Fig. S4, ESI†). All considered Ar-tagged clusters have similar dissociation energies of  $D_0 = 4.2$ – $6.8$   $\text{kJ mol}^{-1}$ , which are consistent with the experimentally determined Ar binding energy.<sup>67</sup> Because the Ar binding energy is very low compared to  $\sim 100$  and  $\sim 50$   $\text{kJ mol}^{-1}$  for the much stronger  $\text{Py}\cdots\text{Py}$  and  $\text{Py}_2^+\cdots\text{H}_2\text{O}$  interactions, respectively, the effects of Ar tagging are minor and thus we discuss only the two most stable Ar isomers,  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})\text{Ar}(\text{I})$  and  $\text{II}$ ). They have slightly different N–H and O–H bond lengths because Ar affects their H-bonds in a different fashion. The  $\text{NH}\cdots\text{Ar}$  H-bond of Ar to the free Py unit in  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})\text{Ar}(\text{I})$  induces an N–H bond elongation by  $0.8$  mÅ to  $1.0065$  Å, resulting in a slight redshift of  $\nu_{\text{NH}}^{\text{f}}$  from  $3506$  to  $3494$   $\text{cm}^{-1}$  (Table S1, ESI†). In  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})\text{Ar}(\text{II})$ , Ar forms an  $\text{OH}\cdots\text{Ar}$  H-bond to the  $\text{H}_2\text{O}$  ligand and interacts weakly with two adjacent CH groups. Its proton donor N–H bond is longer by  $0.8$  mÅ than in  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})\text{Ar}(\text{I})$  ( $1.0225$  vs.  $1.0217$  Å), as  $\text{H}_2\text{OAr}$  has a larger PA than  $\text{H}_2\text{O}$ , which leads to a slight redshift in  $\nu_{\text{NH}}^{\text{b}}$  from  $3226$  to  $3212$   $\text{cm}^{-1}$  (Table S3, ESI†). For the structures, binding energies, and IR spectra of the  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})\text{Ar}(\text{III–V})$  and  $\text{Py}_2^+(\text{p})\text{H}_2\text{O}(\text{I})\text{Ar}(\text{I})$  isomers, the reader is referred to Fig. S2–S4 and Tables S3 and S4 (ESI†).

The IRPD spectra of  $\text{Py}_2^+\text{H}_2\text{O}$  and  $\text{Py}_2^+\text{H}_2\text{OAr}$  are compared in Fig. 4 to the IR spectra computed for the  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I and II})$  and  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})\text{Ar}(\text{I and II})$  isomers. The positions and widths of the transitions observed are listed in Table S1 (ESI†) along with vibrational and isomer assignments. The IRPD spectrum of  $\text{Py}_2^+\text{H}_2\text{O}$  exhibits ten main transitions A, A', B, B', E, F, F', G, Y, and Y' at  $3725$ ,  $3705$ ,  $3639$ ,  $3605$ ,  $3492$ ,  $3228$ ,  $3282$ ,  $3134$ ,  $3006$ , and  $3175$   $\text{cm}^{-1}$  with widths of  $13$ – $58$   $\text{cm}^{-1}$ . The IRPD spectrum of  $\text{Py}_2^+\text{H}_2\text{OAr}$  shows corresponding, but better resolved, transitions at  $3727$ ,  $3706$ ,  $3642$ ,  $3607$ ,  $3488$ ,  $3210$ ,  $3274$ ,  $3133$ ,  $3010$ , and  $3175$   $\text{cm}^{-1}$ , respectively, with similar intensity ratios but much smaller widths ( $4$ – $28$   $\text{cm}^{-1}$ ), because the lower binding energy leads to colder clusters. The small shifts of  $\leq 10$   $\text{cm}^{-1}$  imply that Ar tagging has indeed little impact on the  $\text{Py}_2^+\text{H}_2\text{O}$  structure and resulting IR spectrum apart from the substantially improved spectral resolution. An even colder IRPD spectrum of  $\text{Py}_2^+\text{H}_2\text{OAr}$  measured in the range of  $3100$ – $3800$   $\text{cm}^{-1}$  exhibits only six main transitions (A, B, E, F, G, and Y' at  $3727$ ,  $3642$ ,  $3489$ ,  $3213$ ,  $3141$ , and  $3178$   $\text{cm}^{-1}$ ) with even narrower widths and the absence of the minor peaks A', B', and F' present in the IRPD spectra of  $\text{Py}_2^+\text{H}_2\text{O}$  and  $\text{Py}_2^+\text{H}_2\text{OAr}$  recorded under warmer conditions. This difference suggests a minor contribution of less stable isomers that are responsible for A', B', and F'. The colder IRPD spectrum of  $\text{Py}_2^+\text{H}_2\text{OAr}$  also shows that the most abundant and thus most stable isomer can be probed by tagging under the coldest

conditions. The major transitions in the IRPD spectra of  $\text{Py}_2^+\text{H}_2\text{O}(\text{Ar})$  can be explained by the most stable  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$  isomer. Indeed, good agreement is observed between measured and computed IR spectra concerning both the positions and relative intensities of the vibrational transitions. Bands A and B of  $\text{Py}_2^+\text{H}_2\text{O}$  at 3725 and 3639  $\text{cm}^{-1}$  correspond well with the predicted transitions of  $\nu_3 = 3739$  and  $\nu_1 = 3651$   $\text{cm}^{-1}$ . Band E at 3492  $\text{cm}^{-1}$  can be assigned to  $\nu_{\text{NH}}^{\text{f}}$  predicted at 3506  $\text{cm}^{-1}$ . Its modest blueshift of 13  $\text{cm}^{-1}$  upon monohydration from 3479 to 3492  $\text{cm}^{-1}$  is well reproduced by the calculations (from 3500 to 3506  $\text{cm}^{-1}$ ). The intense band F at 3228  $\text{cm}^{-1}$  is readily assigned to  $\nu_{\text{NH}}^{\text{b}}$  predicted at 3223  $\text{cm}^{-1}$ . Its blue-shaded band contour confirms the assignment to a proton-donor stretch vibration, consistent with the strong  $\text{NH}\cdots\text{O}$  ionic H-bond.<sup>54,80,81,114</sup> This band shows again drastic narrowing and a small redshift ( $-18$   $\text{cm}^{-1}$ ) as a result of cooling by Ar tagging.<sup>54,80–82</sup> Band G observed at 3134  $\text{cm}^{-1}$  is attributed to the eight unresolved and nearly degenerate  $\nu_{\text{CH}}$  modes with a predicted spread of only 24  $\text{cm}^{-1}$ . The colder IRPD spectrum of  $\text{Py}_2^+\text{H}_2\text{OAr}$  exhibits only the major peaks A, B, E, F, G, and Y' assigned to  $\text{Py}_2^+\text{H}_2\text{O}(\text{I})\text{Ar}(\text{I})$ . Therefore, the absent minor peaks A', B', and F' observed in the IRPD spectrum of  $\text{Py}_2^+\text{H}_2\text{O}$  and warmer  $\text{Py}_2^+\text{H}_2\text{OAr}$  must come from a higher-energy isomer. Although the substantially less stable  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{II})$  can at first glance be excluded as a major carrier of the spectrum because of its high relative energy ( $E_0 = 17.8$   $\text{kJ mol}^{-1}$ ) and the lack of the intense  $\nu_{\text{NH}}^{\text{b}}$  transition (band F), it can be still considered as a candidate for the minor contribution from its predicted (scaled) harmonic frequencies (vide infra). Next,  $\text{Py}_2^+(\text{p})\text{H}_2\text{O}(\text{I})$  can be excluded as the predominant carrier (Fig. S3a, ESI†) because of the lack of its intense  $\nu_{\text{NH}}^{\text{b}}$  band predicted at 3339  $\text{cm}^{-1}$  in the observed IRPD spectrum although its relative energy is higher by only 3.7  $\text{kJ mol}^{-1}$  compared to  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$ . However, the predicted harmonic  $\nu_{1/3}$  of  $\text{Py}_2^+(\text{p})\text{H}_2\text{O}(\text{I})$  are lower than those of  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$  (3651/3713 vs. 3651/3739) and  $\nu_{\text{NH}}^{\text{b}}$  is higher (3339 vs. 3223  $\text{cm}^{-1}$ ), indicating that  $\text{Py}_2^+(\text{p})\text{H}_2\text{O}(\text{I})$  may contribute to the minor peaks A', B', and F'. The slightly less stable  $\text{Py}_2^+(\text{p})\text{H}_2\text{O}(\text{II})$  isomer will not be considered any further because of the close similarity of its predicted spectrum to that of the assigned  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$  global minimum. Although the scaled harmonic spectra of  $\text{Py}_2^+(\text{a/p})\text{H}_2\text{O}(\text{I})$  explain most of the peaks (A–G), none of the structures can explain peaks Y and Y'. Therefore, we consider anharmonic calculations for  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$  conducted at the reduced B3LYP-D3/aug-cc-pVDZ level (Fig. S3b, ESI†). These calculations suggest an assignment of band Y to the NH bend overtone ( $2\beta_{\text{NH}}$ ) of the  $\text{N-H}\cdots\text{O}$  H-bonded Py unit, which gains intensity *via* Fermi resonance with the nearby and strongly IR-active  $\nu_{\text{NH}}^{\text{b}}$  fundamental.<sup>82,102,103,115</sup> Shoulder Y' may be assigned to the OH bend overtone ( $2\beta_{\text{OH}}$ ) of  $\text{H}_2\text{O}$ .<sup>116–119</sup> Although the B3LYP-D3/aug-cc-pVDZ level explains the anharmonicity of  $\text{Py}_2^+(\text{a})$  well, it overestimates the anharmonicity of  $\nu_{1/3}$  of  $\text{NH}\cdots\text{O}$  H-bonded  $\text{H}_2\text{O}$ . Therefore, we also consider the PBE0/aug-cc-pVDZ level to support our anharmonic predictions. Fig. S3b (ESI†) shows the reliability of the PBE0/aug-cc-pVDZ level by comparison to the harmonic and anharmonic spectra calculated at the B3LYP-D3/aug-cc-pV(D/T)Z levels. The

anharmonic frequencies of  $\text{Py}_2^+(\text{a/p})\text{H}_2\text{O}(\text{I})$  calculated at the PBE0/aug-cc-pVDZ level are again in good agreement with our assignment.

The higher-resolved IRPD spectra of the colder Ar-tagged ions reveal small additional bands under certain experimental conditions, indicating the minor presence of higher-energy isomers. These may arise from different  $\text{Py}_2^+\text{H}_2\text{O}$  isomers or different Ar tagging sites of the major assigned  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$  core. Band E observed at 3489  $\text{cm}^{-1}$  and assigned to  $\nu_{\text{NH}}^{\text{f}}$  of  $\text{Py}_2^+\text{H}_2\text{OAr}$  in the cold spectrum is redshifted by 3  $\text{cm}^{-1}$  from that of  $\text{Py}_2^+\text{H}_2\text{O}$  (3492  $\text{cm}^{-1}$ ), suggesting that Ar is attached to the free NH group of  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$  in the major  $\text{Py}_2^+\text{H}_2\text{OAr}$  isomer, with a computed redshift of 13  $\text{cm}^{-1}$ . The other four  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})\text{Ar}(\text{II–V})$  isomers, in which Ar does not bind to the NH group, do not reproduce this  $\nu_{\text{NH}}^{\text{f}}$  redshift (Fig. S4 and Table S3, ESI†). The somewhat warmer  $\text{Py}_2^+\text{H}_2\text{OAr}$  spectrum in Fig. 4 shows additional small bands A', B', and F' at 3706, 3607, and 3274  $\text{cm}^{-1}$ , which are similar to those of the bare  $\text{Py}_2^+\text{H}_2\text{O}$  spectrum at 3705, 3605, and 3282  $\text{cm}^{-1}$ , indicating a small contribution of  $\text{Py}_2^+(\text{p})\text{H}_2\text{O}(\text{I})\text{Ar}$ . The observed redshift in F' from 3282 to 3274  $\text{cm}^{-1}$  suggests that the Ar may bind to the NH group of  $\text{Py}_2^+(\text{p})\text{H}_2\text{O}(\text{I})$  as shown in Fig. S2 and S3 (ESI†). The abundance of  $\text{Py}_2^+(\text{p})\text{H}_2\text{O}(\text{I})\text{Ar}(\text{I})$  is estimated to be below 25% when considering its computed  $\nu_{\text{NH}}^{\text{b}}$  intensity (Fig. S3e, ESI†). The IRPD spectrum of colder  $\text{Py}_2^+\text{H}_2\text{OAr}$  exhibits sharp bands with no splitting in the range of  $\nu_{1/3}$ , revealing the sole presence of  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$ , while the other high-energy isomers are below the detection limit of 5% by considering the signal-to-noise ratio of peak F ( $\nu_{\text{NH}}^{\text{b}}$ ).

### 3.4. $\text{Py}_2^+(\text{H}_2\text{O})_2$

Our B3LYP-D3 calculations yield seven dihydrated isomers with a  $\text{Py}_2^+(\text{a})$  core,  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I–VII})$  (Fig. 5 and Fig. S5, ESI†). These can be divided into two groups depending on whether two individual  $\text{H}_2\text{O}$  ligands or an H-bonded  $(\text{H}_2\text{O})_2$  dimer are attached to  $\text{Py}_2^+(\text{a})$ . In the highly-symmetric global minimum ( $C_{2h}$ ),  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$ , which belongs to the first group, two individual  $\text{H}_2\text{O}$  ligands form equivalent  $\text{NH}\cdots\text{O}$  H-bonds to the two available acidic NH groups of  $\text{Py}_2^+(\text{a})$ . The next two isomers II and III belong to the second group, in which a  $(\text{H}_2\text{O})_2$  dimer chain is attached to one of the NH groups either with or without a second  $\text{CH}\cdots\text{O}$  contact, respectively, while the other NH group remains free. The latter structure is similar to that of  $\text{Py}^+(\text{H}_2\text{O})_2$  reported previously.<sup>80</sup> The relative energies calculated for isomers I–III are  $E_0 = 0.0, 5.0$ , and 5.5  $\text{kJ mol}^{-1}$ , and their relative free energies amount to  $G_0 = 0.0, 11.1$ , and 8.2  $\text{kJ mol}^{-1}$ , respectively. The energy gap between I and both II and III increases significantly with temperature due to the reduced entropy contribution for the less flexible isomers II and III resulting from the structural constraints of the  $(\text{H}_2\text{O})_2$  unit. From the energetics, I–III are expected to dominate the  $\text{Py}_2^+(\text{H}_2\text{O})_2$  population in the molecular beam. The other isomers IV–VII, which also feature  $\text{NH}\cdots\text{O}$  and  $\text{CH}\cdots\text{O}$  H-bonds, are substantially higher in energy ( $E_0 = 8.5\text{--}37.2$  and  $G_0 = 15.4\text{--}40.6$   $\text{kJ mol}^{-1}$ ) and thus not considered in detail further.

The  $\text{NH}\cdots\text{O}$  H-bonds in the dihydrated  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$  global minimum are slightly weaker than that of the related

Fig. 5 Structures of  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_n$  with  $n = 2$  (a)–(c) and  $n = 3$  (d)–(g) obtained at the B3LYP-D3/aug-cc-pVTZ level. Selected intra- and intermolecular bond lengths (in Å) are given in black and red, respectively. Values in dark red indicate NBO charges (in units of  $e$ ). Energies in parentheses indicate the relative energy, the dissociation energy of the most weakly bonded ligand, and the relative Gibbs free energy at 298 K ( $E_0$ ,  $D_0$ , and  $G_0$  in  $\text{kJ mol}^{-1}$ ).

monohydrated  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$  isomer ( $R_{\text{NH}\cdots\text{O}} = 1.826$  vs.  $1.809$  Å,  $D_0 = 44.2$  vs.  $46.3$   $\text{kJ mol}^{-1}$ ,  $E^{(2)} = 37.7$  vs.  $30.0$   $\text{kJ mol}^{-1}$ ), with a smaller perturbation of the N–H proton donor bond ( $r_{\text{NH}} = 1.0202$  vs.  $1.0219$  Å,  $\nu_{\text{NH}}^b = 3247$  vs.  $3223$   $\text{cm}^{-1}$ ). This is the result of the slightly noncooperative three-body induction forces for interior ion solvation with individual ligands due to extended delocalisation of the positive charge. The asymmetric CR in  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$  becomes symmetric again in  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$  ( $q_{\text{Py}} = 0.526/0.441$  vs.  $0.461/0.461e$ ). Although the individual

H-bonds are weaker, the charge transfer to the  $\text{H}_2\text{O}$  ligands is increased in  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$  ( $q_{\text{H}_2\text{O}} = 0.039$  vs.  $0.033e$ ) because of the restored symmetry and optimised CR interaction.

Both  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{II})$  and  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{III})$  local minima have a similar solvent configuration with one free NH group and one NH group solvated by  $(\text{H}_2\text{O})_2$ , resulting in a similar charge distribution. Their major difference is that the terminal  $\text{H}_2\text{O}$  in II has an additional weak  $\text{CH}\cdots\text{O}$  contact with  $\text{Py}_2^+(\text{a})$ , forming a four-membered cyclic ring. This additional H-bond causes, however,

strain on the other H-bonds which become weaker in II compared to III, so that the net energy gain by increasing the size of the H-bonded network is only 0.5 kJ mol<sup>-1</sup>. The intermolecular Py<sup>+</sup>⋯H<sub>2</sub>O and H<sub>2</sub>O⋯H<sub>2</sub>O distances in isomer II are longer than in III, and the N–H proton donor bond elongates less ( $r_{\text{NH}} = 1.0283$  vs. 1.0308 Å,  $\nu_{\text{NH}}^{\text{b}} = 3107$  vs. 3068 cm<sup>-1</sup>) due to the weakened NH⋯O H-bond. As (H<sub>2</sub>O)<sub>2</sub> is attached to Py<sub>2</sub><sup>+</sup> in II and III, the resulting NH⋯O H-bond is much stronger than in I ( $R = 1.742$  and 1.720 vs. 1.826 Å), because of the higher PA of (H<sub>2</sub>O)<sub>2</sub> compared to H<sub>2</sub>O and the enhanced charge transfer to the solvent ( $q_{\text{H}_2\text{O}} = 0.050$  and 0.059 vs. 0.039e). As a result, the elongation of the N–H proton donor bond is larger ( $r_{\text{NH}} = 1.0283$  and 1.308 vs. 1.0202 Å), causing larger NH stretch redshifts ( $\nu_{\text{NH}}^{\text{b}} = 3107$  and 3068 vs. 3247 cm<sup>-1</sup>). The same PA argument explains the stronger NH⋯O H-bond in dihydrated Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub>(III) compared to that in monohydrated Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)(I). The high cooperativity of three-body induction forces typical for H-bonded solvent networks also strongly strengthens the H-bond of (H<sub>2</sub>O)<sub>2</sub> (Fig. 2) by the presence of the positive charge of the nearby Py<sub>2</sub><sup>+</sup> ion ( $R = 1.773$  vs. 1.946 Å,  $D_0 = 38.8$  vs. 13.0 kJ mol<sup>-1</sup>). Nonetheless, these H-bonds are in Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub>(III) with a Py<sub>2</sub><sup>+</sup>(a) core substantially weaker than those in Py<sup>+</sup>(H<sub>2</sub>O)<sub>2</sub>(I) with a Py<sup>+</sup> core ( $R_{\text{NH} \cdots \text{O}} = 1.720$  vs. 1.609 Å,  $R_{\text{OH} \cdots \text{O}} = 1.773$  vs. 1.732 Å) due to the increased charge delocalisation arising from the CR ( $q_{\text{Py}} = 0.528$  vs. 0.926e). The free NH group of Py<sub>2</sub><sup>+</sup>(a) becomes progressively less acidic with mono- and dihydration ( $r_{\text{NH}} = 1.0061, 1.0057, 1.0054$  Å for  $n = 0-2$ ), resulting in small incremental blueshifts of  $\nu_{\text{NH}}^{\text{f}}$  as  $n$  increases from 0 to 2 (3500, 3506, and 3510 cm<sup>-1</sup>).

Before comparing the computed IR spectra to the IRPD spectra, we briefly discuss the effects of Ar tagging on the structure and energy of Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub> (Fig. S6, ESI†), with particular focus on the Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub>(I) global minimum with C<sub>2h</sub> symmetry. The three most stable Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub>(I)Ar(I–III) isomers have Ar binding energies of  $D_0 = 6.7, 4.3$ , and 3.2 kJ mol<sup>-1</sup>. In the most stable Ar(I) isomer, Ar binds to the OH group of H<sub>2</sub>O and one CH group of Py. In the Ar(II) isomer, Ar interacts with the  $\pi$  electron ring of Py and thus has the least perturbation on the structure and IR spectrum of Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub>. In Ar(III), Ar forms a linear OH⋯Ar H-bond to one of the H<sub>2</sub>O ligands, which causes redshifts of 7 and 5 cm<sup>-1</sup> in  $\nu_3$  and  $\nu_1$  of Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub>(I), respectively. In Ar complexes of the higher-energy isomer Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub>(II), Ar preferentially binds to the free NH group, resulting in its slight elongation of 0.2 mÅ. Nevertheless,  $\nu_{\text{NH}}^{\text{f}}$  redshifts by only 2 cm<sup>-1</sup> (3508 vs. 3510 cm<sup>-1</sup>). In Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub>(III)Ar(I), Ar is part of a four-membered ring with OH⋯Ar⋯HC bonds, whereas in isoenergetic Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub>(III)Ar(II), Ar binds to the free NH group of Py and elongates its N–H bond by 0.7 mÅ, resulting in a slight redshift of  $\nu_{\text{NH}}^{\text{f}}$  by 8 cm<sup>-1</sup> (from 3508 to 3500 cm<sup>-1</sup>). At higher temperature, Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub>(III)Ar(II) is more favourable than Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub>(III)Ar(I) due to entropy ( $G_0 = 2.4$  vs. 10.3 kJ mol<sup>-1</sup>). For the structures, binding energies, and IR spectra of the less stable Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub>(IV–VI)Ar isomers, the reader is referred to Fig. S6 and Table S5 (ESI†). As expected from the weak Ar interaction energies ( $D_0 \leq 7$  kJ mol<sup>-1</sup>), the overall impact of Ar tagging on the computed IR spectra (<10 cm<sup>-1</sup>) and energetic order is very minor for all considered Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub> isomers and thus not considered in detail further.

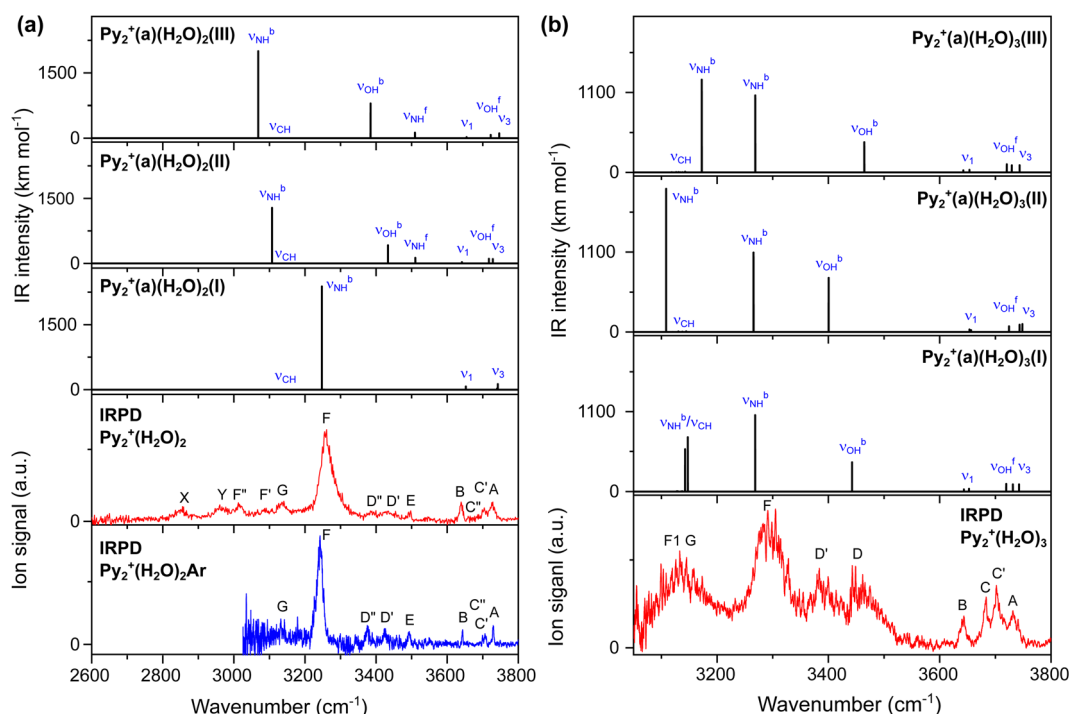

Fig. 6 IRPD spectra of (a) Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub>Ar<sub>n</sub> ( $n = 0-1$ ) and (b) Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>3</sub> recorded in the CH, NH, and OH stretch range are compared to the linear IR absorption spectra calculated for Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>n</sub>(I–III) ( $n = 2-3$ ) at the B3LYP-D3/aug-cc-pVTZ level (Tables S1, S5, and S7, ESI†).

The IRPD spectra of  $\text{Py}_2^+(\text{H}_2\text{O})_2$  and  $\text{Py}_2^+(\text{H}_2\text{O})_2\text{Ar}$  are compared in Fig. 6 to the IR spectra computed for the three most stable isomers  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I-III})$  with a  $\text{Py}_2^+(\text{a})$  core. The positions and widths of the transitions observed are listed in Table S1 (ESI<sup>†</sup>), along with vibrational and isomer assignments. The IRPD spectrum of  $\text{Py}_2^+(\text{H}_2\text{O})_2$  exhibits 13 major transitions at 3726 (A), 3639 (B), 3703 (C'), 3684 (C''), 3430 (D'), 3388 (D''), 3493 (E), 3260 (F), 3093 (F'), 3014 (F''), 3136 (G), 2852 (X), and 2967 (Y)  $\text{cm}^{-1}$ , with widths of 12–64  $\text{cm}^{-1}$ . The IRPD spectrum of  $\text{Py}_2^+(\text{H}_2\text{O})_2\text{Ar}$  recorded in a smaller spectral range has corresponding transitions at 3730 (A), 3643 (B), 3706 (C'), 3700 (C''), 3424 (D'), 3376 (D''), 3493 (E), 3242 (F), and 3135 (G)  $\text{cm}^{-1}$ , respectively, with similar intensity ratios but much smaller widths (3–19  $\text{cm}^{-1}$ ). Ar tagging shifts of those peaks are less than 18  $\text{cm}^{-1}$  and on average only 7  $\text{cm}^{-1}$ . Thus, Ar tagging has essentially no impact on the intermolecular structure and vibrational signatures of the observed  $\text{Py}_2^+(\text{H}_2\text{O})_2$  isomers. As  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2$  has only six NH/OH stretch oscillators ( $2\nu_{\text{NH}}$ ,  $4\nu_{\text{OH}}$ ), a single isomer cannot explain all observed features detected in this spectral range. Therefore, several isomers need to be considered. The major three bands A, B, and F observed for  $\text{Py}_2^+(\text{H}_2\text{O})_2$  and  $\text{Py}_2^+(\text{H}_2\text{O})_2\text{Ar}$  are fully reproduced by the most stable isomer of  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$  concerning both band positions and relative intensities. The most intense and strongly blueshifted band F is readily assigned to  $\nu_{\text{NH}}^{\text{b}}$ , while the weak bands A and B are assigned to  $\nu_3$  and  $\nu_1$ , respectively. Because of  $C_{2h}$  symmetry of  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$ , only three out of the six OH/NH stretch fundamentals are IR-active, namely the out-of-phase linear combinations of  $\nu_{\text{NH}}^{\text{b}}$ ,  $\nu_1$ , and  $\nu_3$ . Band G at 3136  $\text{cm}^{-1}$  assigned to  $\nu_{\text{CH}}$  is not sensitive to isomeric structure. Band E at 3493  $\text{cm}^{-1}$  is close to  $\nu_{\text{NH}}^{\text{f}}$  of  $\text{Py}_2^+$  and well reproduced by  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{II and III})$ , both of which exhibit a free NH group. In addition, the  $(\text{H}_2\text{O})_2$  unit of isomers II and III give rise to  $\nu_{\text{OH}}^{\text{b}}$  and  $\nu_{\text{OH}}^{\text{f}}$  bands of the  $\text{H}_2\text{O}$  donor, which are predicted to be close to the D'/D'' and C'/C'' pairs. Their corresponding  $\nu_{\text{NH}}^{\text{b}}$  bands may be attributed to bands F'/F''. The interpretation of the weak bands Y and X is less certain, as no fundamentals are predicted in this range for any of the considered isomers. Similar to the  $n = 1$  cluster, they may arise from Fermi resonance of  $2\beta_{\text{NH}}/\nu_{\text{NH}}^{\text{b}}$ .<sup>54,67</sup> In summary,  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$  is concluded as the major carrier of the IRPD spectrum of  $\text{Py}_2^+(\text{H}_2\text{O})_2$ , while  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{II and III})$  account for all remaining weaker transitions. When comparing the computed and measured intensities of the assigned  $\nu_{\text{NH}}^{\text{b}}$  bands (Fig. 6a), the relative abundances of isomers I–III can roughly be estimated as 65, 10, and 25%, consistent with their relative free energies of  $G_0 = 0.0, 11.1, \text{ and } 8.2 \text{ kJ mol}^{-1}$ , respectively.

Interestingly, microhydration reduces the energy gap  $\Delta E_0(\text{a-p})$  between  $\text{Py}_2^+(\text{a})$  and  $\text{Py}_2^+(\text{p})$  due to the more favourable formation of H-bonded solvent networks with two  $\text{NH}\cdots\text{O}$  ionic H-bonds. For example,  $\Delta E_0(\text{a-p}) = 7.5$  and  $3.7 \text{ kJ mol}^{-1}$  for  $n = 0$  and  $1$ , respectively. Indeed, for  $n = 2$  the most stable  $\text{Py}_2^+(\text{p})(\text{H}_2\text{O})_2(\text{I})$  isomer with a  $\text{Py}_2^+(\text{p})$  core is computed to be even more stable than  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$  by  $\Delta E_0(\text{a-p}) = -1.0 \text{ kJ mol}^{-1}$  (Fig. S7, ESI<sup>†</sup>). However, from an entropic point of view,  $\Delta G_0(\text{a-p}) = +6.0 \text{ kJ mol}^{-1}$  for  $n = 2$  due to the strain imposed by the H-bonded network.

The two most stable  $\text{Py}_2^+(\text{p})(\text{H}_2\text{O})_2(\text{I and II})$  isomers form tetra- and tricyclic rings involving  $\text{Py}_2^+(\text{p})$  and  $(\text{H}_2\text{O})_2$ , with  $\Delta E_0 = -1.0$  and  $+3.4 \text{ kJ mol}^{-1}$ , respectively. In  $\text{Py}_2^+(\text{p})(\text{H}_2\text{O})_2(\text{I})$ ,  $(\text{H}_2\text{O})_2$  acts as a dual H-bond acceptor with two individual  $\text{NH}\cdots\text{O}$  H-bonds, while in  $\text{Py}_2^+(\text{p})(\text{H}_2\text{O})_2(\text{II})$  both NH groups attack the donor of  $(\text{H}_2\text{O})_2$  via a bifurcated  $\text{O}\cdots(\text{HN})_2$  configuration, similar to monohydrated  $\text{Py}_2^+(\text{p})\text{H}_2\text{O}(\text{I})$ . The larger PA of  $(\text{H}_2\text{O})_2$  results in a larger cooperative effect, thereby reducing  $\Delta E_0(\text{a-p})$ . Although  $\text{Py}_2^+(\text{p})(\text{H}_2\text{O})_2(\text{I})$  is predicted as the most stable  $\text{Py}_2^+(\text{H}_2\text{O})_2$  structure at  $T = 0 \text{ K}$  and the OH stretches ( $\nu_3$ ,  $\nu_{\text{OH}}^{\text{f}}$ ,  $\nu_1$ ,  $\nu_{\text{OH}}^{\text{b}}$ ) seem to be consistent with the observed bands A, B, and E, the predicted  $\nu_{\text{NH}}^{\text{b}}$  bands disagree with the IRPD spectrum (Fig. S8 and Table S6, ESI<sup>†</sup>). The same conclusion applies also to the next stable  $\text{Py}_2^+(\text{p})(\text{H}_2\text{O})_2(\text{II})$  isomer with a  $\text{Py}_2^+(\text{p})$  core. Therefore, the population of  $\text{Py}_2^+(\text{p})(\text{H}_2\text{O})_2$  isomers is concluded to be below the detection limit of 15%, considering the achieved signal-to-noise ratio of band F and the computed IR oscillator strengths of  $\nu_{\text{NH}}^{\text{b}}$  bands of  $\text{Py}_2^+(\text{a/p})(\text{H}_2\text{O})_2(\text{I})$ .

### 3.5. $\text{Py}_2^+(\text{H}_2\text{O})_3$

The optimised geometries of  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_3(\text{I-III})$  based on the most abundant structure of  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$  are shown in Fig. 5d–f. All isomers are constructed through two  $\text{NH}\cdots\text{O}$  H-bonds, in which one NH group is solvated by  $(\text{H}_2\text{O})_2$  and the other one by a single  $\text{H}_2\text{O}$ . They differ only by the orientation of the linear  $(\text{H}_2\text{O})_2$ , which is close to that in isomers II–IV of  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2$ , and their energies increase as  $E_0 = 0.0, 0.4$ , and  $3.2 \text{ kJ mol}^{-1}$ , respectively. Similar to  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{II and III})$ ,  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_3(\text{II})$  with the free dangling  $(\text{H}_2\text{O})_2$  is more stable than  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_3(\text{I})$  at higher temperature ( $G_0 = 0.0$  vs.  $3.5 \text{ kJ mol}^{-1}$ ). In general, the intermolecular distances in  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_3(\text{I-III})$  are longer compared to those of  $\text{Py}_2^+(\text{H}_2\text{O})_2(\text{II-IV})$  due to the weaker H-bonds, resulting in slight blueshifts of  $\nu_{\text{NH/OH}}^{\text{b}}$ . The weaker H-bonds in  $n = 3$  are due to increased delocalisation of the excess positive charges on the Py units compared to  $n = 2$ , resulting again from an increased perturbation of the CR by the third  $\text{H}_2\text{O}$  ligand.

The IRPD spectrum of  $\text{Py}_2^+(\text{H}_2\text{O})_3$  is compared in Fig. 6 to the linear IR spectra computed for  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_3(\text{I-III})$ . The positions and widths of the transitions observed are listed in Tables S1 and Fig. S7 (ESI<sup>†</sup>) along with vibrational and isomer assignments. The isomers based on the  $\text{Py}_2^+(\text{p})$  core are shown in Fig. S9 (ESI<sup>†</sup>) and their IR spectra are compared in Fig. S10 (ESI<sup>†</sup>). Compared to the  $n = 1$ –2 clusters, the IRPD spectrum of  $n = 3$  is significantly more congested with broader bands (9–85  $\text{cm}^{-1}$ ), thus complicating the assignment. It exhibits nine transitions at 3732 (A), 3642 (B), 3702 (C'), 3683 (C), 3293 (F), 3139 (F'), 3459 (D), 3388 (D'), and 3139 (G)  $\text{cm}^{-1}$ . The trend in the IRPD spectra of mono- and dihydrated  $\text{Py}_2^+(\text{a})$  in Fig. 1 provides hints about potential  $\text{Py}_2^+(\text{H}_2\text{O})_3$  structures. First, the absence of a sharp peak E ( $\nu_{\text{NH}}^{\text{f}}$ ) indicates that both NH groups of  $\text{Py}_2^+$  are hydrated. Second, bands C/C' and D/D', which are typical for  $\nu_{\text{OH}}^{\text{f}}$  and  $\nu_{\text{OH}}^{\text{b}}$  modes of single-donor  $\text{H}_2\text{O}$  ligands are enhanced compared to those in the IRPD spectrum of  $\text{Py}_2^+(\text{H}_2\text{O})_2$ . This observation suggests an increased abundance of structures with an  $\text{NH}\cdots\text{O}$  H-bond of the NH groups to a

(H<sub>2</sub>O)<sub>2</sub> chain. Band F ( $\nu_{\text{NH}}^{\text{b}}$ ) at 3293 cm<sup>-1</sup> appears similarly to  $\nu_{\text{NH}}^{\text{b}}$  of  $n = 1-2$ , indicating the presence of a NH group which is H-bonded to a single H<sub>2</sub>O ligand. The intense and broad feature attributed to F1/G at 3139 cm<sup>-1</sup> covers  $\nu_{\text{CH}}$  and has a comparable intensity to band F assigned to the more strongly H-bonded  $\nu_{\text{NH}}^{\text{b}}$  of an NH group binding to (H<sub>2</sub>O)<sub>2</sub>. Band F of the  $n = 3$  cluster is blueshifted compared to those of  $n = 1-2$ , indicating that the H-bond strength weakens with increasing number of H<sub>2</sub>O ligands around Py<sub>2</sub><sup>+</sup>. This observation is typical for noncooperative effects of progressive interior ion solvation and indicates that the partial positive charge on the Py units of Py<sub>2</sub><sup>+</sup> decreases with increasing  $n$ , thereby weakening the charge-dipole interaction of the NH...O H-bonds. Overall, the IRPD spectrum of Py<sub>2</sub><sup>+</sup>(H<sub>2</sub>O)<sub>3</sub> is consistent with the computed Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>3</sub>(I-III) isomers, although only I and II are required to explain all observed transitions, in particular in the  $\nu_{\text{OH}}^{\text{b}}$  range.

Because I and II are nearly isoenergetic, both isomers should be considered. Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>3</sub>(I) has three intense bands ( $\nu_{\text{NH}}^{\text{b}}$ ,  $\nu_{\text{OH}}^{\text{b}}$ ) predicted below 3500 cm<sup>-1</sup> and five weak bands ( $\nu_1$ ,  $\nu_{\text{OH}}^{\text{f}}$ ,  $\nu_3$ ) above 3600 cm<sup>-1</sup>. The lowest  $\nu_{\text{NH}}^{\text{b}}$  band arising from the H-bond to (H<sub>2</sub>O)<sub>2</sub> is strongly coupled with the aromatic  $\nu_{\text{CH}}$  modes (local mode mixing). This coupled  $\nu_{\text{NH}}^{\text{b}}$  and the second  $\nu_{\text{NH}}^{\text{b}}$  at 3268 cm<sup>-1</sup>, which comes from the H-bond to H<sub>2</sub>O, are consistent with the observed bands at 3139 and 3293 cm<sup>-1</sup> (F1 and F), respectively. The  $\nu_{\text{OH}}^{\text{b}}$  mode of the OH...O H-bond of (H<sub>2</sub>O)<sub>2</sub> reproduces the observed band at 3459 cm<sup>-1</sup> (D). The free OH stretches  $\nu_3$ ,  $\nu_{\text{OH}}^{\text{f}}$ , and  $\nu_1$  correspond to the observed bands A and B. However, the bands C and C' at 3683 and 3702 cm<sup>-1</sup>, which are more intense and sharper than A and B and correspond to  $\nu_{\text{OH}}^{\text{f}}$  of a single-donor H<sub>2</sub>O, are not predicted well by isomer I. On the other hand, isomer II offers the same assignment as Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>3</sub>(I), except that  $\nu_{\text{OH}}^{\text{b}}$  corresponds to the observed band D'. However, again bands C and C' cannot be fully explained by II in terms of both their intensities and positions.

In an effort to assign bands C and C', isomers based on Py<sub>2</sub><sup>+</sup>(p) are considered because the most stable structure found for  $n = 3$ , Py<sub>2</sub><sup>+</sup>(p)(H<sub>2</sub>O)<sub>3</sub>(I), is indeed more stable than Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>3</sub>(I),  $D_0 = 43.3$  vs. 36.6 kJ mol<sup>-1</sup> (Fig. S9, ESI†). In this structure, the third H<sub>2</sub>O expands the H-bonded solvent network of the four-membered Py<sub>2</sub><sup>+</sup>(p)(H<sub>2</sub>O)<sub>2</sub>(I) ring at its surface, resulting in two ionic NH...O and two neutral OH...O H-bonds. Compared to Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub>(I), all H-bonds become stronger because of cooperativity. Due to the same cooperative effect, Py<sub>2</sub><sup>+</sup>(p)(H<sub>2</sub>O)<sub>3</sub>(I) is more stable than Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>3</sub>(I) by  $\Delta E_0 = 7.7$  kJ mol<sup>-1</sup>. However, due to the strain of its cyclic H-bond network,  $\Delta G_0$  is still in favour of Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>3</sub>(I) by 1.4 kJ mol<sup>-1</sup>. Its predicted IR spectrum differs slightly in the  $\nu_{\text{OH}}$  range, exhibiting two  $\nu_{\text{OH}}^{\text{f}}$  and two  $\nu_{\text{OH}}^{\text{b}}$  at 3720/3706 and 3458/3363 cm<sup>-1</sup>, and  $\nu_{3/1} = 3727/3641$  cm<sup>-1</sup>, respectively. Comparing this predicted IR spectrum with the measured IRPD spectrum, peaks A and B may also be assigned to  $\nu_3$  and  $\nu_1$ , C/C' to  $\nu_{\text{OH}}^{\text{f}}$ , and D/D' to  $\nu_{\text{OH}}^{\text{b}}$ , while F/F' match with  $\nu_{\text{NH}}^{\text{b}}$  (Fig. S10 and Table S8, ESI†). A further local minimum, Py<sub>2</sub><sup>+</sup>(p)(H<sub>2</sub>O)<sub>3</sub>(II), in which the third H<sub>2</sub>O is attached at another binding site in the (H<sub>2</sub>O)<sub>3</sub> network is also predicted to be more stable than

Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>3</sub>(I) by  $\Delta E_0 = 5.0$  kJ mol<sup>-1</sup> (Fig. S9, ESI†). Its predicted IR spectrum is, however, not compatible with the IRPD spectrum in the  $\nu_{\text{NH}}^{\text{b}}$  range. Hence, the two most stable antiparallel Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>3</sub>(I and II) isomers and the most stable parallel Py<sub>2</sub><sup>+</sup>(p)(H<sub>2</sub>O)<sub>3</sub>(I) isomer can fully account for the measured IRPD spectrum. Due to the broad widths of the bands observed in the IRPD spectrum, a more definitive determination of their individual contributions is not feasible at the current spectral resolution. Unfortunately, the achieved Py<sub>2</sub><sup>+</sup>(H<sub>2</sub>O)<sub>3</sub>Ar ion yield has been insufficient to record a cold spectrum with better resolution for the  $n = 3$  cluster.

### 3.6. Impact of stepwise hydration on the CR

Inspection of Fig. 1 reveals that the free NH stretch band  $\nu_{\text{NH}}^{\text{f}}$  (band E) of the free Py units shows small but systematic shifts as a function of solvation. Our previous study demonstrates a linear correlation between  $\nu_{\text{NH}}^{\text{f}}$  of the free Py unit in Py<sub>*n*</sub><sup>+</sup> with  $n = 0-2$  and its partial charge  $q_{\text{Py}}$ ,  $\nu_{\text{NH}}^{\text{f}}(q_{\text{Py}})/\text{cm}^{-1} = -83.8 q_{\text{Py}}/e + 3527.8$  as indicated by the dashed line in Fig. 7.<sup>23</sup> Using this correlation,  $\nu_{\text{NH}}^{\text{f}}$  measured for Py<sub>2</sub><sup>+</sup>N<sub>2</sub> has been successfully used to determine small changes in the charge distribution of Py<sub>2</sub><sup>+</sup>(a) upon N<sub>2</sub> complexation due to symmetry breaking and charge delocalisation.<sup>23</sup> H<sub>2</sub>O solvation induces a stronger perturbation of Py<sub>2</sub><sup>+</sup>(a) because of its large dipole moment,<sup>54,102</sup> leading to a stronger H-bond and larger charge delocalisation. As a result,  $\nu_{\text{NH}}^{\text{f}}$  measured for Py<sub>2</sub><sup>+</sup>H<sub>2</sub>O is slightly more blue-shifted than  $\nu_{\text{NH}}^{\text{f}}$  of Py<sub>2</sub><sup>+</sup>N<sub>2</sub> (3492 vs. 3490 cm<sup>-1</sup>), corresponding to a lower partial charge on free Py ( $q_{\text{Py}} = 0.427$  vs. 0.451e). This experimentally determined charge,  $q_{\text{Py}} = 0.427e$ , agrees reasonably well with the NBO charge computed for Py<sub>2</sub><sup>+</sup>(a)H<sub>2</sub>O(I),  $q_{\text{Py}} = 0.441e$ . For Py<sub>2</sub><sup>+</sup>(H<sub>2</sub>O)<sub>2</sub>,  $\nu_{\text{NH}}^{\text{f}}$  observed at 3493 cm<sup>-1</sup> is assigned to the minor Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub>(III) isomer. The partial charge of its free Py unit estimated as  $q_{\text{Py}} = 0.415e$  from the correlation is well reproduced by its NBO charge of 0.413e. Its NH...O H-bond is stronger than in Py<sub>2</sub><sup>+</sup>(a)H<sub>2</sub>O(I) because the PA of (H<sub>2</sub>O)<sub>2</sub> is higher than the PA of H<sub>2</sub>O (808 vs. 691 kJ mol<sup>-1</sup>).<sup>70,71,80</sup> Because the IE of the Py(H<sub>2</sub>O)<sub>2</sub> unit in Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub>(III) is lower than the IE of PyH<sub>2</sub>O in Py<sub>2</sub><sup>+</sup>(a)H<sub>2</sub>O(I), the partial charge on free Py is lowered in Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub>(III) compared to Py<sub>2</sub><sup>+</sup>(a)H<sub>2</sub>O(I). Interestingly, a comparison between the higher-energy isomers III and IV of Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>2</sub>, which differ by the way the (H<sub>2</sub>O)<sub>2</sub> dimer binds to Py<sub>2</sub><sup>+</sup>(a) (linear or cyclic) reveals that subtle differences in the solvation network also have an impact on the charge of the free Py unit ( $q_{\text{Py}} = 0.413$  vs. 0.425e, Fig. S5, ESI†). The smaller charge transfer to (H<sub>2</sub>O)<sub>2</sub> in IV compared to III ( $q_{\text{H}_2\text{O}} = 0.046$  vs. 0.059e) may be an indication of the weaker H-bonds in the solvent network. Therefore, the charge distribution and CR in Py<sub>2</sub><sup>+</sup>(a) can be affected by the H-bond strength even for similar hydration motifs. As can be seen from Fig. 7, the two available experimental  $\nu_{\text{NH}}^{\text{f}}$  data points for isomer I of  $n = 1$  and isomer III of  $n = 2$  are compatible with the initially derived linear  $q_{\text{Py}}-\nu_{\text{NH}}^{\text{f}}$  dependence.

To systematically analyse the impact of stepwise hydration on the CR, we consider the related Py<sub>2</sub><sup>+</sup>(a)(H<sub>2</sub>O)<sub>*n*</sub> isomers for  $n = 1-3$ , in which a linear (H<sub>2</sub>O)<sub>*n*</sub> chain is attached to one Py unit *via* a linear NH...O ionic H-bond. These are isomers I

Fig. 7 (a) Observed  $\nu_{\text{NH}}^f$  values for Py,  $\text{Py}_2^+$ , and  $\text{Py}_2^+$  (open circles) and  $\text{Py}_2^+\text{N}_2$  and  $\text{Py}_2^+(\text{H}_2\text{O})_{1,2}$  (filled circles) as a function of the calculated NBO charge on the free Py unit ( $q_{\text{Py}}$ ). The dashed line is a linear fit obtained by using  $\nu_{\text{NH}}^f$  of Py,  $\text{Py}_2^+$ , and  $\text{Py}_2^+$ . (b) Expanded view in the vicinity of  $\text{Py}_2^+$  and its solvated clusters.

( $n = 1$ ), III ( $n = 2$ ), and linear ( $n = 3$ ) shown in Fig. 3 and 5, respectively. As the PA of  $(\text{H}_2\text{O})_n$  clusters increases with  $n$  ( $691 < 808 < 862 \text{ kJ mol}^{-1}$  for  $n = 1-3$ )<sup>70,71,120,121</sup> the  $\text{NH} \cdots \text{O}$  H-bond becomes stronger and shorter ( $1.809 > 1.720 > 1.685 \text{ \AA}$ ). The gradually increasing negative  $\rho^*$  values with increasing  $n$  ( $-0.034, -0.043, -0.047 \text{ a.u.}$ ) from the NCI analysis (Fig. S11, ESI†) and  $E^{(2)}$  donor-acceptor interaction energies ( $30.0 < 54.6 \approx 50.5 \text{ kJ mol}^{-1}$ ) support the increased H-bond strengths, which are well reproduced by the strongly redshifted  $\nu_{\text{NH}}^f$  available from the experiment ( $3228 > 3014 \text{ cm}^{-1}$  for  $n = 1-2$ ) and the calculation ( $3223 > 3068 > 2937 \text{ cm}^{-1}$  for  $n = 1-3$ , Table S9, ESI†). The increased H-bond strengths of the  $\text{NH} \cdots \text{O}$  and  $\text{OH} \cdots \text{O}$  H-bonds as a function of  $n$  are also visible in the increased cooperativity calculated from the difference between the total interaction energy and the sum of the individual interactions (13% for  $n = 2$  and 20% for  $n = 3$ , Table S10, ESI†). This result is in line with the increasing charge transfer to the solvent (0.033, 0.059, 0.056e). As a result of the stronger H-bond, the N-H bond of the free Py units contracts slightly ( $1.0057 > 1.0054 > 1.0053 \text{ \AA}$ ), leading to increasing computed  $\nu_{\text{NH}}^f$  ( $3506 < 3510 < 3512 \text{ cm}^{-1}$  for  $n = 1-3$ ), which are in good agreement with available experimental values ( $3492 < 3493$  for  $n = 1-2$ ). As  $\nu_{\text{NH}}^f$  increases with  $n$ , the computed NBO charges on the free Py unit decrease accordingly ( $0.441 > 0.413 > 0.402e$ ). These values agree well with those derived from the  $q_{\text{Py}}-\nu_{\text{NH}}^f$  relation using the experimental  $\nu_{\text{NH}}^f$

values ( $0.427 > 0.415 > 0.403e$ ). Interestingly, the total charge transfer to  $(\text{H}_2\text{O})_3$  of 0.056e is close to that of  $(\text{H}_2\text{O})_2$ , 0.059e, due to the similar IEs of  $\text{Py}(\text{H}_2\text{O})_2$  and  $\text{Py}(\text{H}_2\text{O})_3$  computed as 7.46 and 7.47 eV, which relates to the similar IEs of  $(\text{H}_2\text{O})_2$  and  $(\text{H}_2\text{O})_3$  reported as 10.73 and 10.06 eV.<sup>122</sup> Therefore, the critical hydration number for the partial charge transfer from  $\text{Py}_2^+(\text{a})$  to the  $\text{H}_2\text{O}$  solvent cluster may be determined as  $n = 2$ .

Next, we discuss the impact of the CR interaction on the H-bond motifs. Due to its  $C_{2h}$  symmetry, the two N-H bonds in  $\text{Py}_2^+(\text{a})$  have the same acidity and strength ( $r_{\text{NH}} = 1.0061 \text{ \AA}$ ). In  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$ ,  $\text{H}_2\text{O}$  forms an  $\text{NH} \cdots \text{O}$  H-bond ( $R_{\text{NH} \cdots \text{O}} = 1.809 \text{ \AA}$ ,  $D_0 = 46.3 \text{ kJ mol}^{-1}$ ) to one of the two NH groups and elongates it to  $r_{\text{NH}} = 1.0219 \text{ \AA}$ . Symmetry reduction upon monohydration causes an unequal charge distribution on the two Py units,  $q_{\text{Py}} = 0.526$  and  $0.441e$ . Due to the decreased positive partial charge on the free Py unit, its N-H bond contracts to  $r_{\text{NH}} = 1.0057 \text{ \AA}$ . In  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$ , the second  $\text{H}_2\text{O}$  ligand prefers to solvate the remaining free NH group and restores  $C_{2h}$  symmetry and consequently the maximal CR in  $\text{Py}_2^+(\text{a})$  ( $q_{\text{Py}} = 0.461e$ ), rather than forming a  $(\text{H}_2\text{O})_2$  solvent network. This preference for interior ion solvation over the formation of the H-bonded network is observed because the additional strong charge-dipole interaction, although slightly noncooperative, is still more favourable than the significantly cooperative dipole-dipole interaction in the  $(\text{H}_2\text{O})_2$  chain. As a result of restored  $C_{2h}$  symmetry, the two H-bonds in  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$  have equal strength with  $R_{\text{NH} \cdots \text{O}} = 1.826 \text{ \AA}$ ,  $r_{\text{NH}} = 1.0202 \text{ \AA}$ , and  $D_0 = 44.2 \text{ kJ mol}^{-1}$ , although slightly weaker than the single one in monohydrated  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$ . These relative H-bond strengths are also obtained from the NCI analysis ( $\rho^* = -0.034 > -0.033 \text{ a.u.}$  for  $n = 1$  and 2, Fig. S11, ESI†). The weaker H-bond in dihydrated  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$  is rationalised by the reduced charge on the H-bond donor Py units (0.461 vs. 0.526e, Fig. 3 and 5), resulting in weaker local charge-dipole interactions between Py and  $\text{H}_2\text{O}$ .

As a next step, we analyse the impact of hydration on the CR of  $\text{Py}_2^+(\text{a})$ ,  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$ , and  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$  by comparing the vertical excitation energies for the CR transition ( $\Delta E$ ) using the TD-DFT approach. First, the reliability of the considered dispersion-corrected DFT functionals for predicting the CR transition, namely B3LYP, CAM-B3LYP, B3PW91, and M06-2X with the aug-cc-pVTZ basis set is evaluated by comparing the TD-DFT transition energies of the cations of benzene dimer ( $\text{Bz}_2^+$ ), benzene-naphthalene ( $\text{BzNp}^+$ ), and benzene-toluene ( $\text{BzTol}^+$ ) in their optimised ground state geometries to their experimentally reported values (Table S11, ESI†).<sup>32,44,45,51,53</sup> The CAM-B3LYP-D3 and M06-2X functionals yield results closest to the experimental values. Therefore, the  $\Delta E$  values, obtained for the optimised ground state geometries of  $\text{Py}_2^+(\text{a})$ ,  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$ , and  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$  at the B3LYP-D3 level, are supported by those obtained with the CAM-B3LYP-D3 and M06-2X functionals (Fig. S12 and Table S12, ESI†). To this end,  $\Delta E$  values increase slightly with  $n$  ( $1.7917 < 1.7982 < 1.8015 \text{ eV}$ , Fig. S12, ESI†). The CR transition energy of the dimer cation is roughly given by the difference in the ionisation energies of the two units and its binding energy,  $\Delta E \approx \Delta \text{IE} + 2D_0$ .<sup>51</sup> Within this

approximation,  $D_0$  corresponds to the orbital coupling term ( $2D_0 = 2V$ ). For the  $\text{Py}_2^+(\text{a})$  homodimer (*i.e.*,  $\Delta\text{IE} = 0$ ), the coupling is maximised and given by  $D_0$  (107.4 kJ mol<sup>-1</sup> or 1.11 eV), in line with roughly half of the computed excitation energy ( $\Delta E = 1.79$  eV). For monohydrated  $\text{Py}_2^+(\text{a})$ , the nonvanishing  $\Delta\text{IE}$  value of 0.49 eV for  $\text{PyH}_2\text{O}$  and  $\text{Py}$  (7.60 and 8.09 eV) reduces the orbital overlap and lowers  $D_0$  of  $\text{Py}_2^+\text{H}_2\text{O} \rightarrow \text{Py}^+\text{H}_2\text{O} + \text{Py}$  compared to that of  $\text{Py}_2^+(\text{a})$  from 107.4 to 88.2 kJ mol<sup>-1</sup> ( $1.11 < 0.91$  eV). However, the contribution of  $\Delta\text{IE}$  to  $\Delta E$  roughly compensates for the reduced  $D_0$  value caused by poorer coupling arising from symmetry reduction, leading to an  $\Delta E$  value comparable to that of  $\text{Py}_2^+(\text{a})$ . Because  $\Delta\text{IE} = 0$  for the symmetrically dihydrated  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$  cluster, the CR interaction becomes stronger again due to optimised overlap of the two HOMOs. The  $\Delta E$  of  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$  and  $D_0$  for dissociating the core according to  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2 \rightarrow \text{Py}^+\text{H}_2\text{O} + \text{PyH}_2\text{O}$  are predicted to be slightly higher than that of  $\text{Py}_2^+(\text{a})$  (1.8015 *vs.* 1.7917 eV and 114.4 *vs.* 107.4 kJ mol<sup>-1</sup>, 1.19 *vs.* 1.11 eV, respectively), suggesting that charge delocalisation into the  $\text{H}_2\text{O}$  molecules (0.922 *vs.* 1.0e) might strengthen the CR interaction in the core.

Interestingly, the energy gap  $\Delta E_0(\text{a-p})$  of  $\text{Py}_2^+(\text{H}_2\text{O})_n$  with  $n = 0-3$  decreases with increasing degree of hydration as 7.5 > 3.7 > -1.0 > -7.7 kJ mol<sup>-1</sup> for the most stable isomers (Fig. 8). Hence, stepwise hydration is predicted to reverse the energetic order of the  $\text{Py}_2^+(\text{a})$  and  $\text{Py}_2^+(\text{p})$  cores between  $n = 2$  and 3, suggesting a hydration-induced switch in the structural CR motif. A similar result has been reported for the formation of the most stable  $\text{Py}_3^+$  trimer cation, in which  $\text{Py}$  solvates a  $\text{Py}_2^+(\text{p})$  core whereas  $\text{Py}_2^+(\text{a})$  is most stable for  $\text{Py}_2^+$ .<sup>68</sup> For  $\text{Py}_2^+(\text{H}_2\text{O})_n$  with  $n = 2$ , the  $\text{Py}_2^+(\text{p})$  core isomer becomes more stable because of cooperative  $\text{NH}\cdots\text{O}$  and  $\text{OH}\cdots\text{O}$  H-bonds and increased H-bond strengths as compared to  $n = 1$  while at the same time the  $\text{Py}_2^+(\text{a})$  core isomer suffers from

slight noncooperativity arising from internal ion solvation and slightly reduced H-bond strengths (Fig. S13, ESI†). Both effects are further enhanced for  $n = 3$  (Table S10, ESI†), thereby changing the  $\Delta E_0(\text{a-p})$  gap even more in favour of the  $\text{Py}_2^+(\text{p})$  core. While the measured IRPD spectra are consistent with this computational prediction, better-resolved IRPD spectra are required to provide definitive experimental proof for this drastic impact of solvation on the structure motif of the aromatic CR.

### 3.7. Impact of partial charge of $\text{Py}$ on strength of H-bonds

The current study offers the unique opportunity to evaluate the strengths of the  $\text{NH}\cdots\text{O}$  H-bonds between  $\text{H}_2\text{O}$  and  $\text{Py}$  as a function of the  $\text{Py}$  charge in  $\text{PyH}_2\text{O}$ ,  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$ , and  $\text{Py}^+\text{H}_2\text{O}$  because in all three charge states ( $q_{\text{Py}} = 0.0, 0.5, 1.0e$ ) a similar linear H-bond motif is observed.<sup>54,55,80</sup> Indeed, with increasing charge, the experimental  $\nu_{\text{NH}}$  values shift progressively to the red ( $3448 > 3228 > 2945$  cm<sup>-1</sup>)<sup>54,55</sup> due to the increasing strength of the  $\text{NH}\cdots\text{O}$  H-bond. This trend is well supported by the computations, according to which the H-bonds become shorter and stronger with increasing charge ( $R_{\text{NH}\cdots\text{O}} = 1.991 > 1.809 > 1.704$  Å,  $D_0 = 17.6 < 46.3 < 65.1$  kJ mol<sup>-1</sup>,  $\rho^* = -0.023 > -0.034 > -0.045$  a.u., Fig. S14, ESI†), mostly due to the additional charge-dipole forces. The H-bond in  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}$  is quite a bit stronger than the average of  $\text{PyH}_2\text{O}$  and  $\text{Py}^+\text{H}_2\text{O}$  (by 5.0 kJ mol<sup>-1</sup>) mainly due to the reorganisation of the charge resonance in  $\text{Py}_2^+(\text{a})$  upon monohydration, causing the charge of the proton donor  $\text{Py}$  (0.526e) to be slightly higher than 0.5e.

Next, we consider the preferred dihydration motifs of  $\text{Py}$ ,  $\text{Py}^+$ , and  $\text{Py}_2^+$  to discuss the evolution of the H-bonded solvent network as a function of charge and the number of available  $\text{NH}$  proton donor groups. Neutral  $\text{Py}(\text{H}_2\text{O})_2$  has a cyclic ( $\sigma$ - $\pi$  bridge) structure, in which a linear  $\text{OH}\cdots\text{O}$  H-bonded ( $\text{H}_2\text{O})_2$  dimer binds to  $\text{Py}$  by  $\text{NH}\cdots\text{O}$  and  $\text{OH}\cdots\pi$  H-bonds.<sup>55</sup>

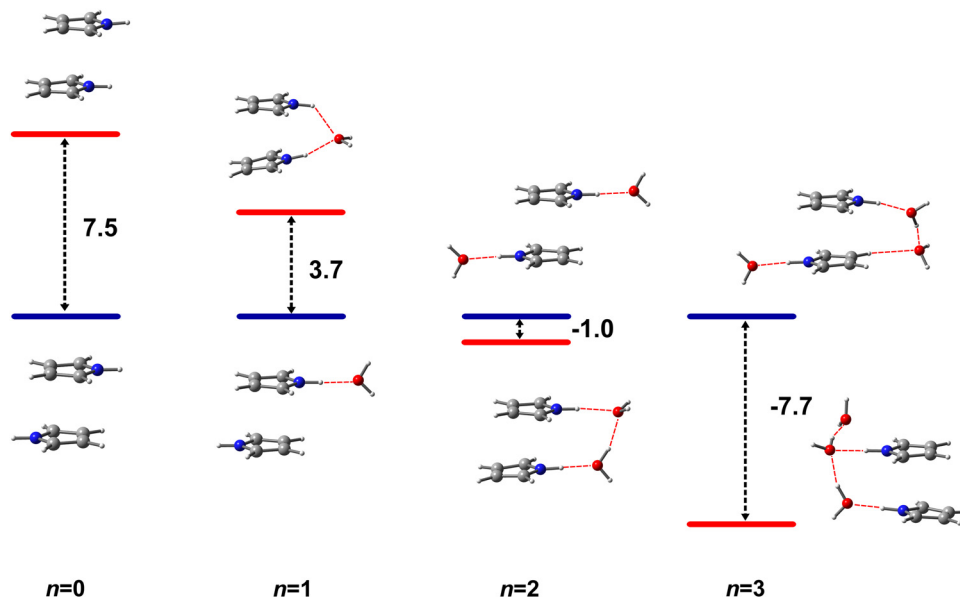

Fig. 8 Relative energy differences ( $\Delta E_0$  in kJ mol<sup>-1</sup>) of the most stable structures of  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_n$  and  $\text{Py}_2^+(\text{p})(\text{H}_2\text{O})_n$  ( $n = 0-3$ ) depending on the hydration number ( $n$ ) calculated at the B3LYP-D3/aug-cc-pVTZ level.

In contrast,  $\text{Py}^+(\text{H}_2\text{O})_2$  has a linear chain structure with adjacent  $\text{NH}\cdots\text{O}$  and  $\text{OH}\cdots\text{O}$  H-bonds because of the strongly anisotropic charge-dipole interaction and the repulsive interaction between  $\text{Py}^+$  and the  $\pi$ -bonded OH hydrogen.<sup>80</sup> On the other hand,  $\text{Py}_2^+(\text{a})$  with its two NH groups offers two strongly acidic H-bond attractors for individual  $\text{H}_2\text{O}$  ligands so that in the  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$  global minimum both positive partial charges are solvated, thereby restoring the CR. Nonetheless, the  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{II}$  and  $\text{III})$  local minima with an  $\text{NH}\cdots\text{O}$  H-bond of one NH group to a linear  $(\text{H}_2\text{O})_2$  are energetically competitive with  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$ . Isomer III is more stable than II at higher temperatures due to entropy and exhibits a similar binding motif as  $\text{Py}^+(\text{H}_2\text{O})_2$ . Because of the CR interaction and the strongly reduced positive charge, the  $\text{NH}\cdots\text{O}$  and  $\text{OH}\cdots\text{O}$  H-bonds in  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{III})$  are weaker than those in  $\text{Py}^+(\text{H}_2\text{O})_2$  ( $R_{\text{NH}\cdots\text{O}} = 1.720$  vs.  $1.609$  Å,  $R_{\text{OH}\cdots\text{O}} = 1.773$  vs.  $1.732$  Å,  $D_0 = 38.8$  vs.  $46.1$  kJ mol<sup>-1</sup> for loss of  $\text{H}_2\text{O}$ ,  $\rho_{\text{NH}\cdots\text{O}}^* = -0.043$  vs.  $-0.050$  a.u.,  $\rho_{\text{OH}\cdots\text{O}}^* = -0.037$  vs.  $-0.041$  a.u., Fig. S14, ESI†) which is well supported by the measured  $\nu_{\text{OH}}^{\text{b}}$  values ( $3306$  vs.  $3388$  cm<sup>-1</sup> for  $q_{\text{Py}} = 1.0$  and  $0.5e$ ).<sup>80</sup> The H-bond cooperativity is drastically reduced from 30% to 13% (Table S10, ESI†), which is nearly the same as that of the neutral cluster (12%),<sup>80</sup> although the H-bonds are much stronger in  $\text{Py}_2^+(\text{H}_2\text{O})_2(\text{III})$  (Fig. S14, ESI†). Therefore, although the excess charge of  $0.5e$  substantially increases the H-bond strength due to the additional charge-dipole interaction, it does not increase the degree of cooperativity in the H-bonded network.

In the following, we compare the mono- and dihydration motifs of neutral and cationic  $\text{Py}_2^{(+)}$  by considering  $\text{Py}_2(\text{H}_2\text{O})_n$  and  $\text{Py}_2^+(\text{H}_2\text{O})_n$  with  $n = 1-2$ . Neutral  $\text{Py}_2$  has a T-shaped structure with an  $\text{NH}\cdots\pi$  H-bond.<sup>61,63,66</sup> In  $\text{Py}_2\text{H}_2\text{O}(\text{I})$ ,  $\text{H}_2\text{O}$  forms a cyclic structure with T-shaped  $\text{Py}_2$  via  $\text{NH}\cdots\text{OH}\cdots\pi$  bonds (Fig. S15, ESI†).<sup>55,123</sup> Upon ionisation, the cyclic  $\text{Py}_2\text{H}_2\text{O}$  structure opens toward linear  $\text{Py}_2^+(\text{a})\text{H}_2\text{O}(\text{I})$  due to the repulsive interaction between  $\text{Py}_2^+$  and the  $\pi$ -bonded  $\text{H}_2\text{O}$  ligand arising from the excess positive charge.<sup>80</sup> Interestingly, due to the stable cyclic structure with two neutral H-bonds,  $D_0$  of  $\text{Py}_2\text{H}_2\text{O}$  is almost comparable to that of  $\text{Py}_2^+\text{H}_2\text{O}$  featuring a single ionic H-bond ( $38.3$  vs.  $46.3$  kJ mol<sup>-1</sup>). All minima calculated for neutral  $\text{Py}_2(\text{H}_2\text{O})_2$  have cyclic structures and differ depending on whether one or two  $\text{H}_2\text{O}$  molecules are present in the cycle (Fig. S15, ESI†). The global minimum,  $\text{Py}_2(\text{H}_2\text{O})_2(\text{I})$ , has a similar structure as  $\text{Py}_2\text{H}_2\text{O}(\text{I})$  with a  $(\text{H}_2\text{O})_2$  dimer replacing  $\text{H}_2\text{O}$ . In  $\text{Py}_2(\text{H}_2\text{O})_2(\text{II})$ , higher in energy by only  $3.3$  kJ mol<sup>-1</sup>, both  $\text{H}_2\text{O}$  molecules form individual  $\text{NH}\cdots\text{O}$  and  $\text{OH}\cdots\pi$  H-bonds to the two Py units. Upon  $\pi$  electron emission,  $\text{Py}_2(\text{H}_2\text{O})_2(\text{I})$  likely converts to  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{II}$  and  $\text{III})$ , while  $\text{Py}_2(\text{H}_2\text{O})_2(\text{II})$  probably generates  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$  due to the repulsive interactions between the positive excess charge and the  $\pi$ -bonded OH hydrogens, thus breaking the  $\text{OH}\cdots\pi$  H-bonds. In the cationic clusters,  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$  becomes more stable because it forms a stronger CR than  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{II}$  and  $\text{III})$ . Hence, ionisation changes the order of the isomeric structures of dihydrated  $\text{Py}_2$ .

$\text{Py}_2^+(\text{a})$  offers two spatially separated acidic functional NH groups. Their hydration motifs, interior ion solvation or

formation of a single H-bonded solvent network, become competitive starting from two  $\text{H}_2\text{O}$  molecules, as demonstrated for  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$  and  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{II}$  and  $\text{III})$ . Similar competing hydration motifs are observed for the previously studied microsolvation of the 5-hydroxyindole cation ( $5\text{HI}^+$ ), a bicyclic aromatic ion offering an NH group in the pyrrole ring and an OH group at the phenyl ring.<sup>83</sup>  $5\text{HI}^+(\text{H}_2\text{O})_2(\text{OH}/\text{NH})$ , in which both acidic functional groups are solvated by a single  $\text{H}_2\text{O}$  ligand, corresponding to interior ion solvation, is found as the dominant isomer, whereas  $5\text{HI}^+(\text{H}_2\text{O})_2(\text{OH}/\text{H}_2\text{O}$  or  $\text{NH}/\text{H}_2\text{O})$  isomers with the  $(\text{H}_2\text{O})_2$  dimer chain attached to either the NH or OH group provide only a minor contribution to the population. The high abundance of  $5\text{HI}^+(\text{H}_2\text{O})_2(\text{OH}/\text{NH})$  with slightly noncooperative H-bonds originates from two strongly acidic functional groups.<sup>83</sup> Similarly, the presence of two acidic NH groups is mainly responsible for the high abundance of  $\text{Py}_2^+(\text{a})(\text{H}_2\text{O})_2(\text{I})$  with interior ion solvation, in addition to its favourable CR interaction.

## 4. Concluding remarks

Herein, we investigate the effects of stepwise microhydration on the CR-stabilised  $\text{Py}_2^+$  homodimer cation by IRPD spectroscopy of mass-selected bare and Ar-tagged  $\text{Py}_2^+(\text{H}_2\text{O})_n$  clusters and complementary quantum chemical calculations at the B3LYP-D3/aug-cc-pVTZ level including NCI, NBO, and TD-DFT analysis. Systematic shifts observed for the  $\nu_{\text{NH}}$  and  $\nu_{\text{OH}}$  stretch bands provide detailed information about the structure and bonding of the observed cluster isomers and the preferred cluster growth, including charge distributions, cooperativity, and the strengths of the CR and H-bonds as a function of the degree and site of hydration. Significantly, the results provide for the first time information about the solvation effects on the fundamental aromatic CR interaction in isolated clusters. The salient results may be summarised as follows.

(1) The preferred cluster growth of  $\text{Py}_2^+(\text{a})$  begins with hydrating the two available acidic NH protons ( $n = 1-2$ ) followed by the formation of a H-bonded solvent network ( $n \geq 3$ ). In general, interior ion hydration is slightly noncooperative, leading to slightly weaker  $\text{NH}\cdots\text{O}$  H-bonds for  $n = 2$  compared to  $n = 1$ . On the other hand, formation of the H-bonded solvent network via  $\text{OH}\cdots\text{O}$  H-bonds is strongly cooperative due to nonadditive induction forces. To this end, for  $n = 2$  the local minima with a  $(\text{H}_2\text{O})_2$  attached to a single NH group become energetically competitive with the most stable symmetrically hydrated global minimum, with an observed population ratio of around 1 : 2 in our plasma expansion. When considering the  $n = 1-3$  isomers in which one of the Py units of  $\text{Py}_2^+(\text{a})$  is solvated by a linear  $(\text{H}_2\text{O})_n$  chain, the  $\text{NH}\cdots\text{O}$  ionic H-bond to the solvent cluster becomes progressively stronger due to increasing proton affinity of  $(\text{H}_2\text{O})_n$ , resulting in larger charge transfer to solvent and stronger  $\nu_{\text{NH}}^{\text{b}}$  redshifts, an effect that seems to converge around  $n = 2-3$ .

(2) The new experimental and computational data for the various  $\text{Py}_2^+(\text{H}_2\text{O})_n$  clusters allow us to further confirm the

roughly linear  $q_{\text{Py}}-\nu_{\text{NH}}^{\text{f}}$  correlation between the free NH stretch frequency of the Py unit and its partial positive charge developed earlier from data of  $\text{Py}^{(+)}$  and  $\text{Py}_2^{+}$ .<sup>23</sup> The experimental  $q_{\text{Py}}$  values obtained for  $\text{Py}_2^{+}(\text{H}_2\text{O})_n$  with  $n = 1-3$  from this  $q_{\text{Py}}-\nu_{\text{NH}}^{\text{f}}$  correlation are in good agreement with the computed NBO charges, once again validating our approach of characterising the CR interaction in aromatic dimers utilising the IRPD technique in the ground electronic state ( $\psi_+$ ).

(3) Our characterisation of the  $\text{Py}_2^{+}(\text{H}_2\text{O})_n$  clusters offers the unique opportunity to determine the effects of sequential hydration on the CR interaction as a function of isomeric structure and cluster size  $n$ . According to a rough approximation, two competing factors have to be considered, namely the difference in the ionisation energies ( $\Delta\text{IE}$ ) and the coupling constant ( $V$ ) approximated by the binding energy  $D_0$ . Monohydration of  $\text{Py}_2^{+}(\text{a})$  reduces the symmetry of the cluster and thus the CR interaction for  $n = 1$ . Symmetric dihydration for  $n = 2$  restores the symmetry and increases the CR again. However, when taking  $\Delta\text{IE}$  into account, the splitting between  $\psi_+$  and  $\psi_-$  ( $\Delta E$ ) giving rise to the CR transition is only weakly affected upon mono- and dihydration, as confirmed by TD-DFT calculations.

(4) Moreover, our experimental IRPD spectra, along with the computational results, provide the first evidence that stepwise hydration induces a change in the preferred CR core ion from the symmetric  $\text{Py}_2^{+}(\text{a})$  structure ( $n \leq 2$ ) to the parallel  $\text{Py}_2^{+}(\text{p})$  core ( $n \geq 3$ ) due to the strong cooperativity favouring the formation of single-sided H-bonded hydration networks. However, IR spectra at higher resolution are required for a definitive proof of this scenario. To this end, IR spectra for clusters with  $n > 3$  may shed further light on this preliminary conclusion, while at the same time further expanding the correlation between the CR interaction and the H-bond motifs.

(5) Comparison of microhydration of Py,  $\text{Py}^{+}$ , and  $\text{Py}_2^{+}$  offers the valuable opportunity to quantitatively characterise the H-bond strength of the aromatic solute to the (dipolar) solvent network as a function of its positive partial charge. Due to the increasing charge-dipole interaction, the  $\text{NH}\cdots\text{O}$  H-bond becomes progressively stronger the larger the charge on the Py unit.

As an outlook, we are currently expanding these studies on the CR interaction in several directions using the same combined experimental and computational approach, including (i)  $\text{Py}_2^{+}$  dimers solvated by molecules with different proton affinities (e.g.,  $\text{CH}_3\text{OH}$ ), (ii) larger  $\text{Py}_n^{+}$  clusters, and (iii) clusters of  $[\text{PyA}]^{+}$  heterodimers with aromatic molecules A with different IEs.

## Data availability

The data supporting this article has been included as part of the ESI.† ESI† includes LID and CID mass spectra, additional isomeric structures and energies, measured and computed harmonic and anharmonic IR spectra of  $\text{Py}_2^{+}(\text{H}_2\text{O})_n$  and  $\text{Py}_2^{+}(\text{H}_2\text{O})_n\text{Ar}$ , NCI analysis of  $\text{Py}^q(\text{H}_2\text{O})_n$ , and frontier MOs and computed CR transition energies of  $\text{Py}_2^{+}(\text{H}_2\text{O})_n$ .
