The oxygen evolution reaction (OER) is a crucial component of the oxygen-containing reactions for developing sustainable energy conversions. However, it still requires developing efficient catalysts that can overcome the sluggish reaction kinetics. Recent studies on oxygen electrocatalysis predominantly persist on the thermodynamic viewpoint of oxygen adsorption, while the catalytic role of spin remains greatly elusive. In this work, we investigated the impact of spin on the OER performance of a two-dimensional iron-based metal-organic framework (2D Fe-MOF) using spin-polarized first-principles calculations. Our results reveal that the pristine Fe-MOF at the high spin state exhibits electronic properties suitable for an OER electrocatalyst. Even after adsorption, Fe-MOF preserves its high spin state; such magnetic stability ensures the consistent application of OER. Moreover, adsorption on 2D Fe-MOF is spin-dependent. It validates that the spin states can regulate adsorption strength for the OER. Remarkably, spin-sensitive 2D Fe-MOF yields a significantly low overpotential of 0.49 V, comparable to precious catalysts. Furthermore, the spin-related charge transfer and orbital interaction originate from the overlapping between the O p_z of the oxygen intermediates and the Fe dz² of the Fe active site. This reveals that the OER on the Fe-MOF is the selective spin-orbital dependent. Overall, spin is inevitable in enhancing the OER process, making our work valuable in the development of MOF catalysts. Our finding enriches the atomistic understanding of OER in the development of noble-metal-free MOF catalysts.

Spin is a fundamental quantum characteristic of electrons, possessing two possible states: spin-up or spin-down. Organic molecules generally have spin-up and spin-down electrons equally distributed, resulting in a paired spin or singlet state. In contrast to this generalization, molecular oxygen (O2) in the ground state has two unpaired electrons or triplet state (S=1), which is ~1 eV energetically more favorable than its singlet state (S=0). Spin configurations of O2 suggest that spin can play a crucial role in oxygen-involved catalytic reactions. 1-6 In particular, the oxygen evolution reaction (OER) necessitates a spin transition, as singlet H₂O and OH must transform into triplet O₂ as a final product (Scheme 1 in the Supporting Information). Such a singlet-to-triplet process causes the spinforbidden transition that contributes to the inherently sluggish reaction kinetics with high overpotential in OER.^{2,3,7} Thus, spindependent oxygen reactions can proceed more efficiently in the presence of appropriate catalysts that overcome the barrier associated with spin transitions. 1,2 Despite its fundamental importance, the spin impact has been largely overlooked in traditional catalyst designs. Addressing this challenge requires new strategies incorporating spin as an additional degree of freedom into catalyst development, as supported by previous

Transition metal (TM) containing catalysts have been suited as a spin-polarized catalyst to improve oxygen reactions because their d-states interact with the unpaired electron and spin configuration from oxygen intermediates.^{3,4} Especially, the high spin of Fe is likely to promote the OER for pairing the spinoriented electrons from triplet O2.16 In addition, Fe is an abundant and cost-effective metal in the earth's crust and exhibits significant characteristics in OER due to its chemical environment.¹⁷⁻²¹ Significant efforts have been made in graphene-based single-atomic-catalysts (SACs) for oxygen reactions.²²⁻²⁶ Namely, FeN₄-embedded SACs have been widely investigated as promising catalysts for OER due to their suitable binding strength for oxygen intermediates.^{24,25} However, SACs in fabrication still face challenges such as low extrinsic metal loading and undesirable atom aggregation, which hinder not only the homogeneous dispersion of metal active sites but also the precise relationship between spin-state regulation and catalytic activity. 27,28

While burgeoning the development of SACs, two-dimensional metal-organic frameworks (2D MOFs) have been investigated due to their planar structure, hierarchical porosity, high stability, good electrical conductivity, and catalytic activity. $^{29-40}$ Importantly, 2D MOF materials have been facilitated by a self-assembled structure built from organic linkers and uniformly distributed intrinsic metal nodes, creating planar periodic networks with $\pi\text{-conjugated}$ ligand environment and isolated single-metal sites.

studies of organometallic materials, molecular complexes, and metal-based oxides.⁸⁻¹⁴ In this context, spin-polarized surfaces can regulate the spin states of reactants and intermediates, accelerating slow spin-transition kinetics and enhancing OER efficiency.^{1,4,15}

Such intrinsic metal site in the 2D MOF allows systematic high-, intermediate-, and configurations, which can serve as an ideal platform for regulating the spin state.41,42 Nevertheless, the progress in addressing the spin impact on 2D MOFs remains limited. In particular, the underlying relationships between geometry, spin, electronic, and catalytic properties have not been fully understood.

In this work, we emphasize the significance of the spin impact by regulating the spin state of the Fe site in the 2D Fe-MOF to define its optimal spin-polarized configuration for the OER. Upon adsorption of oxygen intermediates, the Fe-MOF satisfies the favourable free energy criteria required for the OER, thereby facilitating the reaction. This study not only deepens the understanding of spin-dependent OER electrocatalysis on the Fe-MOF but also paves the way for future research by modulating a spin-based design strategy to develop an efficient MOF electrocatalyst and enhance OER performance.

Structure and electronic properties of a pristine monolayer.

We selected the 2D Fe-MOF with Fe-metal nodes and benzene organic linkers since it is a compact representative of 2D MOFs as a case study. Figure 1a shows the periodic structural view of a 2D Fe-MOF monolayer built from Fe₃(C₆O₆)₂-unit cell, where a Fe atom is surrounded by four O ligands, creating planar coordination as a FeO₄ complex that is connected with the neighbouring carbon rings. The optimized lattice parameter is $\alpha=b=13.377$ Å, consistent with the previous result.⁴³ The nearest Fe-Fe distance in the monolayer is 6.69 Å, thus too far to be directly coupled. We compared the electronic configurations for the 2D Fe-MOF at various spin states (Fig. S1); the high spin-polarized electronic configuration is preferable at the present system. Thus, Figure 1b shows the spin-polarized band structure near the Fermi level (E_F) from -1 to 1 eV, where a dashed line indicates the position of the E_F at 0 eV. Foremost, the Fe-MOF shows a metallic character with uneven spin channels. In particular, the energy states near the E_F exhibit a notable absence of a band gap, resulting in its behaviour as a

metallic conductor. This inherent conductivity plays a crucial role in facilitating rapid electron transfer during chemical reactions, particularly aiding in the efficient generation from singlet H₂O/OH⁻ to triplet O₂. Figure 1c presents the projected density of states (PDOS) of the Fe site to further discern the electronic feature of the Fe-MOF. It shows that the Fe-d orbital splits into energetically different states of dx2-y2, dz2, dyz, dxz, and dxy, due to the crystal field (Fig. S2). The sub-energy levels further facilitate the capture of the O molecule during the reaction. In addition, we estimated that Fe-MOF bears the high spin state of Fe with +3 valence (Table S1). Thus, Fe-MOF exhibits the high spin-polarized electronic characteristics that make it well-suited for use as an electrocatalyst.

Adsorption on Fe-MOF monolayer. We considered four crucial reaction steps for OER to define the catalytic feature of the Fe-MOF (Figure 2a). The oxygen intermediates prefer to adsorb on the central Fe site of FeO₄ (dashed blue circle). The resultant configurations are marked as *OH, *O, *OOH, and *O₂, respectively. To initiate the OER process on the Fe-MOF, we calculated the adsorption energy (E_{ads}) of oxygen intermediates at various spin states. $E_{\rm ads}$ for each case shows a negative value (Figure 2b and Table S2), which is also consistent with a tendency of integrated crystal orbital Hamiltonian population (Fig. S3). It implies that the O species can be spontaneously adsorbed on the Fe site. Moreover, the adsorption on Fe-MOF is spin-dependent; $E_{\rm ads}$ excluding spin provides a large value, while $E_{\rm ads}$ including spin endows a relatively low value. It indicates that the spin states can be used to regulate the adsorption strength and further facilitate the oxygen reaction process.

 $E_{\rm ads}$ value also differs at each oxygen intermediate and follows the trend of *O > *OH > *OOH > *O_2, causing the features of the various oxygen species. Importantly, our result satisfies the condition for an effective catalyst (*OH > *OOH) to facilitate continuous product release. Herein, while the first oxygen intermediate (*OH) adsorbs at the Fe active site, the oxygen product after the *OOH is released, attainable a next OER cycle. Subsequently, the $E_{\rm ads}$ value of *O₂ is significantly lower than others. Such weak adsorption of *O₂ is the key to enhancing OER. Hence, the present Fe-MOF at the high spin demonstrates promising catalytic activation and holds potential as an effective OER catalyst.

Structural distortion. The oxygen intermediate disturbs the original structure of the Fe-MOF when the oxygen reaction occurs, creating a pyramidal geometry (insets in Table 1). To be precise, we compare the structural distortion that occurs in the environment of FeO₄, in both the absence and presence of oxygen intermediate (details in Table S3-S4). Herein, the oxygen intermediate evidently binds to the Fe site, forming the *O-Fe bond with its bond length L_{*O-Fe} . A longer bond yields weaker adsorption, as validated by the less negative value of overall ICOHP, and vice versa (Fig. S4a).

ARTICLE Journal Name

Since O_2 is a decisive step, but also the bottleneck for the OER process, the O_2 desorption should be feasible to overcome and proceed with the reaction. Our result shows that the bond index of *O_2 -Fe in the high spin state is significantly lower than the non-spin case, suggesting that the O_2 desorption can be more favourable in this state (Fig. S4b). Thus, the high-spin-polarized configuration is considered for further calculation. We illustrate another notable change created in the FeO₄ after the adsorption, where the Fe site moves upward relative to the basal plane along the z-direction. Such a local displacement of the Fe site ($D_{\rm Fe\ site}$) disturbs the formal orbitals of the Fe. Thus, the structural distortions during the entire OER process can lead to substantial changes to the electronic and magnetic properties of MOF, which in turn affect the catalytic performance of the MOF.

Electronic and magnetic properties of Fe-MOF after the adsorption. We calculated the projected density of states (PDOS) for the oxygen intermediates and the Fe site to gain deeper insights into the changes in the electronic structure following adsorption. Figure 3a demonstrates that *O pz of the absorbed intermediates hybridizes Fe dz². Meanwhile, *O p_x and *O p_v merely overlap Fe dxz or dyz, respectively (see Fig. S5-S6). However, there is no obvious overlapping with Fe dx²-y² and Fe dxy. Hence, it is indeed a selective orbital-dependent interaction.44 Notably, the PDOS after adsorption of oxygen intermediates shows a generic trend; the orbital diagram of Fe-MOF can be summarized in a single scheme (Figure 3b). Herein, dz², dyz and dxz orbitals hybridize with the oxygen intermediates, however, the dx2-y2 and dxy orbitals interact less with the intermediate. This situation infers that the electrons predominantly transfer between certain orbitals of the Fe atom and the oxygen intermediate. As seen in the PDOS, the hybridization of Fe dz² and *O p_z of the absorbed oxygen intermediates steadily persists near E_F. This result implies that the dz²-orbital predominantly participates in the reaction process, conditioning a charge transfer from the monolayer to the adsorbed oxygen intermediates along the z-direction. In short, spin-resolved DOS analysis reveals that Fe-MOF with the discrete Fe-d states exhibit strong spatial orbital overlap and orbital-dependent interaction with the adsorbed intermediates. Figure 4 displays the charge density difference $(\Delta \rho)$ and the spin redistribution of O intermediates adsorbed on the Fe site, As seen in Fig. 4a, $\Delta \rho$ is mostly found on the O-intermediates and neutral on the rest of the architecture, where the yellow iso-surface indicates the charge accumulation. This situation indicates that the monolayer with the high spin donates the charge to the attached O-atom and also affects the end O-/Hatom. The Bader charge analysis also supports that the Ointermediates gain 0.52, 0.79, 0.45, and 0.34 e-charges from the monolayer with the high spin, indicating the electron transfer between the monolayer and the intermediates. It also shows the trend of *O > *OH > *OOH > *O₂ which is consistent with that of ICOHP. Given this observed trend, it becomes apparent that a higher (lower) electron transfer to the adsorbed oxygen intermediates implies a strong (moderate) degree of adsorption (ICOHP value in Fig. S3)

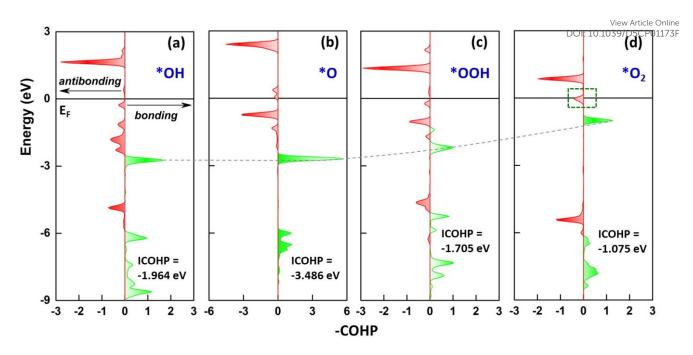

Fig. 5 The projected Crystal Orbital Hamilton Population (pCOHP) analysis of (a) *OH, (b) *O, (c) *OOH, and (d)*O₂ absorbed on the Fe site, representing the pair of Fe dz² and O pz, where the bonding orbital state is a positive value (right arrow) and the antibonding orbital state is a negative value (left arrow).

Furthermore, it is worth considering the induced magnetic moment of oxygen intermediates (Fig. 4b). The *OH, *O, and *OOH intermediates yield small positive values of 0.22, 0.44, and 0.32 μ_B , respectively, which originate from their weak diamagnetic response to the Fe active site of high spin-polarized 2D Fe-MOF. In contrast, the *O₂ shows a negative induced magnetic moment that is 2 times larger than those of the *OH and *OOH intermediates. This observation suggests that the paramagnetic properties of *O₂ quickly respond to the Fe active site of high spin-polarized 2D Fe-MOF. Meanwhile, the spin magnetic moment of the Fe ion slightly changes from 3.77 μ_B to 4.1 $\mu_{\rm B}$, indicating the Fe ion preserves its high-spin state after the adsorption (Fig. 4c). Such magnetic moment stability allows Fe to proceed with consistent bonding-antibonding interactions with the oxygen intermediates, which is a crucial factor for catalytic performance.

We have conducted the projected crystal orbital Hamiltonian population (pCOHP) analysis to evaluate the catalytic property. As presented above in PDOS, we found that the oxygen intermediates strongly interact with the Fe site through the hybridization of their O p_z and Fe dz² orbitals. Therefore, the antibonding-bonding property of O-Fe pair at certain orbitals is worth considering. In this regard, Figure 5 represents the corresponding profile for the coupling of Fe dz² and O pz. The bonding orbital states are below the E_F , further attributing to the bond strength between the oxygen intermediate and the Fe site. For the *OH and *O, the Fe-O pair shows significant bonding states over the antibonding states with a more negative ICOHP, indicating a stronger chemisorption. Starting with the *OOH, the bond states yield

less negative ICOHP, indicating the bond strength weakening between the Fe and the intermediate, which is the essential catalytic property necessary for OER completion. Meanwhile, the antibonding states above $E_{\rm F}$ reflect an interaction feature between Fe-O pair. For the *OH, the antibonding states (<2.5 eV) indicate that the first reaction step is firmly attached to the surface, conditioning well for the next reaction step. The antibonding states for *O remain within the relevant energy range, enabling the reaction to proceed consistently. Starting with the *OOH, the antibonding states shift to the vicinity of $E_{\rm F}$, further facilitating the reaction. For the final decisive step of OER, the downshift of antibonding states becomes significant. Notably, a small but non-negligible anti-bonding state crossing $E_{\rm F}$ is crucial for the O_2 release, beneficial for the completing of the reaction cycle.

Catalytic performance. Figure 6 displays the Gibbs free energy change (ΔG) of reaction steps at two different potentials, including a reference potential of 0 V and an equilibrium potential of 1.23 V (details in Table S5). Foremost, we compared the spin-polarized and unpolarized energy changes of OER at U=0 V. All the reaction steps for the spin-polarized configuration show the lower ΔG values rather than that of non-spin-polarized one. Such energy difference indicates that the spin-polarized 2D Fe-MOF is energetically favourable and evidently beneficial to OER. At U=1.23 V, the ΔG decreases to the negative (exothermic) value, satisfying the criterion of $\Delta G \leq 0$ eV. It indicates that the product becomes thermodynamically stable. Furthermore, the overpotential for the spin-polarized configuration reduced to 0.49 V (0.97 V excluding spin), which

ARTICLE Journal Name

is comparable to those of well-known OER catalysts. 45,46 It confirms that the spin impact is inevitably significant to the catalytic performance of Fe-MOF.

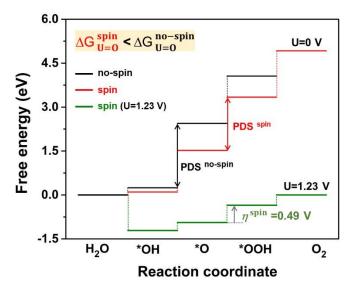

Fig. 6 Gibbs free energy changes (in eV) for O intermediates on the Fe-MOF during the OER. The free energies are calculated at two different potentials. The potential-determining step (PDS) is *OOH, while the overpotential η is found to be 0.49 V at the equilibrium potential, including a spin.

Conclusions

In this work, we focus on how spin affect the OER at the atomic scale using spin-polarized first-principles DFT calculations. The structural, electronic, and magnetic properties of a 2D Fe-MOF have been investigated at various spin states during the OER process. The electronic structure of the Fe-MOF in the high spin state behaves as a metallic conductor, making it a suitable OER electrocatalyst. Once the adsorption occurs, the spindependent E_{ads} endows a favourable value that can facilitate the oxygen reaction process. The spin-resolved PDOS results reveal that the Fe site splits into the evenly distributed discrete levels, promoting the electron transfer and enhancing of the OER. When the spin is considered in the free energy calculations, the free energy changes and the overpotential of 2D Fe-MOF in the high spin state are significantly reduced. It indicates that the spin-polarized 2D Fe-MOF is energetically favourable to OER. Overall, our finding not only provides insights into advancing OER mechanisms on the noble-metal-free MOF catalyst but is also used to rationally design a new OER catalyst with exceptional performance by tuning its spin state.

Computational details

The first-principles calculations based on density functional theory (DFT) were performed using the Vienna 5AB 1 Hitto Simulation Package (VASP, v.5.4.4).47 All calculations were carried out within the framework of projector augmented wave (PAW) pseudopotentials and plane-wave basis set with a cut-off energy of 520 eV. The exchange-correlation function was treated with a spin-polarized PBE + U method (U = 4), including Grimme's D3 corrections. All calculations in this work were included SOC for the iron-based MOF to estimate the spinrelated properties. The Γ -centred grid of $8 \times 8 \times 1$ k-points for sampling of Brillouin zone (BZ) were applied in the calculations. In the structure, a vacuum region higher than 15 Å is added to the perpendicular direction to the basal plane, in order to simulate an isolated layer without spurious interactions between layers in the adjacent periodic cells. All structures throughout DFT calculations were fully optimized until the convergence thresholds of the total energy and the atomic forces were below 0.1 µeV and 1 meV/Å respectively. The geometry, spin density, and charge density differences were visualized by the VESTA software. 48 The crystal orbital Hamilton population (COHP) and crystal orbital bond index (COBI) were implemented by the LOBSTER code to analyse the electronic bonding characteristics.49

The adsorption energy (E_{ads}) of oxygen species on 2D Fe-MOF is estimated using the following equation:

$$E_{ads} = E_{system} - E_{pristine} - E_{O species}$$

where E_{system} , $E_{pristine}$, and $E_{O\ species}$ are the total energies of the O-adsorbed system, the pristine monolayer, and the free oxygen species, respectively. The negative value of E_{ads} indicates exothermic adsorption.

The spin-resolved charge density difference ($\Delta \rho$) is obtained as:

$$\Delta \rho = \rho_{\text{system}} - \rho_{\text{pristine}} - \rho_{\text{O species}}$$

where ρ_{system} , $\rho_{pristine}$ and $\rho_{0 \, species}$ represent the charge density distribution of the O-adsorbed system and pristine monolayer as well as an O species, respectively. In addition, Bader charge analysis is performed to show the electrongaining/withdrawing of oxygenated intermediates.50

The OER in the acidic medium (pH=0) is described as:51

$$2H_2O \rightarrow O_2 + 4H^+ + 4e^-$$

Four elementary reaction steps can be expressed as

$$H_2O + * \rightarrow^*OH + (H^+ + e^-)$$

 $^*OH \rightarrow ^*O + (H^+ + e^-)$
 $H_2O + ^*O \rightarrow ^*OOH + (H^+ + e^-)$
 $^*OOH \rightarrow * + O_2 + (H^+ + e^-)$

More precisely, H2O reaches the catalyst (denoted as *), forming an OH intermediate attached to the surface. This first elementary configuration is hereafter marked as *OH. After separating the (H++ e-) pair, the O intermediate remains on the This article is licensed under a Creative Commons Attribution-NonCommercial 3.0 Unported Licence

Article. Published on 09 May 2025. Downloaded on 5/11/2025 11:04:51 AM

ARTICLE Journal Name

surface, generating the configuration marked as *O. Thereafter, another H₂O interacts with the *O, forming the next configuration of *OOH. By releasing the final (H++ e-) pair, the O₂ is formed from the *OOH.

The Gibbs free energy is expressed as follow:52

$$\Delta G = \Delta E + \Delta ZPE - T \cdot \Delta S + \Delta G_U$$

where ΔE , ΔZPE , and ΔS are the reaction energy found by the DFT calculation, difference in zero-point vibrational energy and entropy during the reaction process, respectively. T is the temperature of 298.15 K. In addition, $\Delta G_U = -eU$, in which U is the potential electrode. One can calculate the free energy changes for each step (ΔG_{OH^*} , ΔG_{O^*} , ΔG_{OOH^*} , ΔG_{O2}) accordingly. The main criterion to facilitate the overall reaction is that the free energy of each elementary reaction must be less than or equal to zero ($\Delta G \leq 0$ eV). To define the optimal potential required to facilitate the OER fairly well, we used the strategy to stepwise increase the potential (U≥0 V).

The difference between two free energies is calculated:53

$$\begin{split} & \Delta G_1 = \ \Delta G_{OH^*} \\ & \Delta G_2 = \ \Delta G_{O^*} - \Delta G_{OH^*} \\ & \Delta G_3 = \ \Delta G_{OOH^*} - \Delta G_{O^*} \\ & \Delta G_4 = \ 4.92 - \Delta G_{OOH^*} \end{split}$$

An overpotential in the free energy profile of the OER is defined:

$$\eta^{OER} = \frac{\max[PDS]}{e} - 1.23 \text{ V}$$

where max[PDS] is the maximum free energy change in the four-step OER reaction (max $[\Delta G_1, \Delta G_2, \Delta G_3, \Delta G_4]$), referred to as the potential-determining step, PDS. Besides, e is the electronic charge and 1.23 V is the oxidation potential needed for an ideal OER catalyst. A low overpotential is preferable to the OER.
