Computational design of an improved photoswitchable psychedelic based on light absorption, membrane permeation and protein binding

Vito F. Palmisano,^{ab,e} Claudio Agnorelli,^c Shirin Faraji^{*a} and Juan J. Nogueira^{id} ^{*bd}

Psychedelic compounds can induce rapid-acting and long-lasting antidepressant benefits. Understanding the role of their hallucinatory effects is crucial for shaping the future trajectory of antidepressant drug development. Photoswitchable compounds targeting the 5-HT_{2A}R offer precise spatio-temporal control over the activation of different downstream pathways. In this work, we computationally discovered PQ-azo-*N,N*-DMT (**34**), a photoswitch with improved features compared to the previously synthesized azo-*N,N*-DMT (**1**). The new compound shows tight binding to the 5-HT_{2A}R, retaining all important interactions of lysergic acid diethylamide (LSD), exhibits positive membrane permeability, and has a strong red-shifted absorption that would allow photocontrol in the visible spectrum.

1 Introduction

After decades of global constraint on research, the current “renaissance” of scientific interest in psychedelic compounds is one of the most promising areas in mental health.¹ There is a significant growing body of preclinical^{2–4} and clinical evidence^{5–9} that psychedelic compounds can induce significant rapid-acting and long-lasting therapeutic effects, as opposed to typical psychiatric medications that require repeated exposure and have a longer onset of action.^{10,11} While serotonergic psychedelics, such as lysergic acid diethylamide (LSD) or *N,N*-dimethyltryptamine (*N,N*-DMT) (Fig. 1A) display intricate polypharmacology,¹² they exhibit high affinity for the serotonin or 5-hydroxytryptamine (5-HT) receptors.¹³ The leading hypothesis of their psychoactivity and structural plasticity is through the activation of the 5-HT_{2A} receptor (5-HT_{2A}R),^{14–17} despite recent findings suggesting that the antidepressant activity of 5-HT_{2A}R agonists may be independent of their psychoactive properties^{18–20} or even independent of 5-HT_{2A}R activation.²¹ It is of great interest for designing new

improved antidepressants to understand whether the acute drug-induced experiences and antidepressant effects can be entirely separated, and demonstrate whether these subjective experiences are mere byproducts of psychedelic compounds or integral to their therapeutic efficacy.²²

activation but was still found to bind at similar μmolar concentrations. Although the *trans* isomer can bind to the receptor at concentrations similar to the *cis* isomer, its ability to activate the receptor (efficacy) is significantly lower, indicating that the photosensitive molecule functions as an “efficacy switch”, maintaining selectivity for the 5-HT_{2A}R without losing its specificity. An issue encountered was a slight residual activity in the *trans*-enriched state, attributed to incomplete (back)-switching. To corroborate this hypothesis, it is essential to conduct an in-depth study of the photophysics of (1) and design compounds that exhibit a significant energy gap between the excitations responsible for the photoisomerization pathways. These compounds must also meet all the requirements for being effective agonists of the 5-HT_{2A}R and permeate spontaneously through the cell membrane.

In this computational work, we characterized the binding mode, membrane permeability and photophysics of the recently synthesized (1), using molecular dynamics (MD), umbrella sampling (US), quantum mechanics/molecular mechanics (QM/MM) and free energy calculations. Our goal was to develop a compound that tightly binds to the orthosteric binding pocket (OBP) of the 5-HT_{2A}R in at least one of the two isomers, with positive membrane permeability, a red-shifted wavelength of absorption, and a substantial energy gap between the two reversible photoisomerizations. From a pool of 160 compounds (80-*trans*, 80-*cis*), PQ-azo-*N,N*-DMT (34) (Fig. 1D) was found to have all the aforementioned characteristics and, thus, presents improved physico-chemical properties compared to (1).

2 Computational details

2.1 QM excited-state calculations

The construction of all 160 structures was performed using the IQmol Molecular Viewer.³⁴ The selection of these compounds was guided by the study of Aleotti *et al.*, which evaluated similar systems with enhanced push and pull substituent strengths.³⁵ Subsequently, a conformational search was carried out using a combination of the conformer-rotamer ensemble sampling tool (CREST) and command line energy sorting ensemble (CENSO).^{36,37} After an iterative metadynamics run performed by CREST, the 20 lowest energy conformers were input into CENSO. An initial pre-screening of the input conformers was performed through single-point energy calculations at the quantum mechanical level, using the B97-D3/def-SV(P) level of theory with the GFN2-xTB solvation model and a threshold energy of 4.0 kcal mol⁻¹.^{38,39} Subsequently, more accurate electronic and solvation energies were calculated in a second screening at the r2SCAN-3c/def2-mTZVPP level of theory, with a threshold energy of 3.0 kcal mol⁻¹.³⁷ The geometries of the relevant conformers were initially optimized at the r2SCAN-3c/def2-mTZVPP level to obtain relatively accurate geometries rapidly for the entire molecular set coming from the previous screening. Then, only the lowest energy structure was reoptimized at the B3LYP/cc-pVDZ level of theory with D3 empirical dispersion and the polarizable continuum model, using a dielectric constant of 78.355 to simulate a water

environment.⁴⁰ Although the protocol could have ended at the r2SCAN-3c stage, we decided to use an hybrid functional to improve the geometry and also to ensure consistency with the level of theory subsequently used for the TD-DFT excited-state calculations. In addition, while standard hybrid functionals such as B3LYP may be inadequate for true long-range charge-transfer excitations, our study focused exclusively on tracking the relative red-shift of the local $\pi\pi^*$ band, for which B3LYP-D3 remains a consistent choice. Fig. S1–S5 show the *trans* conformations of all the optimized compounds, while Tables S1–S5 list the energies and oscillator strengths of the first 10 singlet excited states (see SI).

2.2 Initial structures

The holo-structure of the 5-HT_{2A}R bound to the non-selective agonist LSD was obtained from the RCSB-PDB (PDB ID: 6WGT).²⁵ While alternative structures have been recently crystallized,²⁰ the LSD-bound structure was deemed most suitable for the study due to the size of the ligands under investigation and the ergotamine domain which contains the structure of the tryptamine domain of the photoswitchable compounds. For both (1) and (34) the predominant titration state in an aqueous solution at neutral pH is the protonated form, since the pK_a is > 7.8. Thus, it was selected for all simulations. The final geometries were used to compute restricted electrostatic potential (RESP) charges⁴¹ from the electrostatic potential at the Hartree Fock (HF)/6-31G* level, and these charges were embedded into MOL2 files generated with the AmberTools Antechamber suite.⁴² We adopted HF/6-31G* specifically to remain consistent with the FF19SB force-field parametrisation for aminoacids, which relies on RESP charges to reproduce electrostatic interactions in biomolecular simulations.⁴³ Force constants for the dihedral angles (-C-N=N-C- and -C-C-N=N-) of the photoswitches were adopted from previous work.⁴⁴ By aligning the indole group to the crystallized structure of LSD and considering insights from mutagenesis studies,^{45–49} the photoswitches were manually placed focusing on key features: the protonated tertiary amine nitrogen interacting with D155, the indole -N1 atom forming a hydrogen bond with S242, and the aromatic indole group engaging in hydrophobic interactions with W336, F339, and F340. Missing heavy atoms and hydrogens were added with the tleap module of the Amber20 package for the 5-HT_{2A}R.⁴² All membrane-protein-ligand systems were constructed using CHARMM-GUI.⁵⁰ The protein was oriented along the z-axis using the orientations of proteins in membranes database and the positioning proteins in membrane web server.⁵¹ Subsequently, N- and C-end groups were amidated and acetylated. The resulting structure was then embedded within a 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC) lipid bilayer with dimensions of 50 × 50 lipid components in the *xy* plane and solvated in a rectangular box with aqueous solvent and NaCl at a concentration of 0.15 mol L⁻¹. Potential parameters for the protein, lipids, water, and ligands were taken from the FF19SB, Lipid17, TIP3P, and GAFF2, respectively.^{43,52–54}

2.3 Molecular dynamics simulations

MD simulations for the solvated membrane-protein-ligand system were performed with the CUDA version of the AMBER20

package.⁴² First, energy minimization was carried out with the steepest descent method for 5000 steps followed by the conjugate gradient method for additional 5000 steps. Positional restraints were applied to the membrane–protein–ligand system gradually starting from 10, 7.5, 5, 2.5, 1 to 0.5 kcal (mol⁻¹ Å⁻²) while heated from 0 to 303.15 K in six steps of 1250 ps, with the Langevin thermostat for a total of 7500 ps. The desired density was reached by running an equilibration in the NPT ensemble with a Monte Carlo barostat and a semi-isotropic pressure scaling for 4 ns for 500 ps. An unconstrained production run was carried out at 303.15 K for 5 independent copies of 1 μs for LSD, *cis*-(1), *trans*-(1), *Cis*-(1) and *trans*-(1) for a total simulation time of 25 μs. During the full MD protocol, a timestep of 2 fs was employed, and the cutoff radius and switching distance to compute the non-bonded interactions were set to 12.0 Å and 10 Å, respectively. Bond lengths involving hydrogen atoms were kept fixed using the SHAKE algorithm.^{55,56} Electrostatic interactions were calculated using the Ewald particle mesh method with a grid spacing of 1 Å.⁵⁷

2.4 End state free energy calculations

The relative binding free energy of all the systems was calculated with the 1 average molecular mechanics generalized Born surface area (MMGBSA) method.⁵⁸ Bond radii were set to *mbondi2* based on *igb* = 5 of the AMBER implementation,⁵⁹ and salt concentration was set to 0.15 mol L⁻¹. A total of 500 equidistant snapshots were selected to calculate the MMGBSA total binding free energy for each molecule. In addition, a pairwise residue free-energy decomposition analysis was performed to obtain the contribution of each residue–ligand interaction to the total binding free energy. The decomposition was performed by considering residues within a radius of 7 Å distance from the ligand.

2.5 Membrane permeation

The photoswitches *cis*-(1), *trans*-(1), *cis*-(34), and *trans*-(34) were then embedded within a POPC lipid bilayer with dimensions of 50 × 50 lipid components in the *xy* plane and solvated in a rectangular box with aqueous solvent and NaCl at a concentration of 0.15 mol L⁻¹. Potential parameters for the lipids, water, and ligands were taken from the Lipid17, TIP3P, and GAFF2, respectively.^{52–54} An energy minimization was carried out with the steepest descent method for 5000 steps followed by the conjugate gradient method for additional 5000 steps. The membrane and the ligand were subjected to positional restraints of 10 kcal (mol⁻¹ Å⁻²) while being heated in the NVT ensemble from 0 to 303.15 K with the Langevin thermostat with a relaxation time of 1 ps for a total simulation time of 750 ps and 2 fs timestep. Then, an NPT simulation was evolved with a Monte Carlo barostat and semi-isotropic pressure scaling and a Langevin thermostat with a relaxation time of 1 ps for 500 ps with a timestep of 2 fs. Subsequently, a single harmonic restraint of 2.5 kcal (mol⁻¹ Å⁻²) was applied to maintain the distance between the center of mass (CoM) of the POPC bilayer and the initial position of the ligand at *z* = 0 Å during a production run of 100 ns. A pulling run was conducted to gradually diffuse the ligand from the membrane center (*z* = 0 Å)

to the bulk water phase (*z* = 36 Å). The pulling rate employed was 1 Å ns⁻¹. This pulling process was performed to obtain initial geometries for subsequent US simulations, which are described later. Pulling the ligand from the center of the membrane towards the water phase is beneficial for achieving faster convergence of the PMF compared to pulling from the water phase into the membrane.⁶⁰ During the full MD protocol, a timestep of 2 fs was employed, the cutoff radius and switching distance to compute the non-bonded interactions were set to 12 Å and 10 Å, respectively. Bond lengths involving hydrogen atoms were kept fixed using the SHAKE algorithm.^{55,56} Electrostatic interactions were computed using the particle-mesh Ewald method with a grid spacing of 1 Å.⁵⁷ US was employed to explore the diffusion pathway from the center of the bilayer to the bulk solvent.⁶¹ In this approach, a single harmonic restraint with a force constant of 2.5 kcal (mol⁻¹ Å⁻²) was applied to restraint the value of the reaction coordinate (RC), which was defined as the *z*-axis component of the distance between the CoM of the POPC bilayer and the CoM of the compounds. The RC was divided into 45 windows spaced at intervals of 0.8 Å along the *z*-direction from the center of the membrane (*z* = 0 Å) to the water phase (*z* = 36 Å). In each window, a MD trajectory was evolved for 50 ns, and the analyses were performed on the full 50 ns of each simulation. Energy convergence analyses were based on previous findings of permeation of tryptamines in a POPC lipid bilayer.⁶² The weighted histogram analysis method^{63,64} was used to calculate the potential of mean force (PMF) along the RC for each compound based on the data obtained from each US simulation, which allowed to determine the logarithm of the effective permeability (log *P*_{eff}) as illustrated in previous works.^{65,66}

2.6 QMMM excited states calculations

The absorption spectra of *cis*-(1), *trans*-(1), *cis*-(34) were computed in the 5-HT_{2A}R using QM/MM calculations performed on 100 snapshots taken equidistantly from the 500 frames used for MMGBSA. The MoBioTools package⁶⁷ was used to extract the geometries, split the system into the QM and MM regions, and prepare the input for the QM/MM calculations using the electrostatic embedding scheme. The QM region consisted of the photoswitches and is modeled using TD-DFT including the first 10 singlet excited states at B3LYP-D3/cc-pvdz level of theory, while the MM region consisted of explicit point charges that included the rest of the system.^{68,69}

3 Results and discussion

3.1 QM excited-state calculations

A fundamental characteristic required for a photoswitch to be effectively used in a biological environment for receptor activation and deactivation is the ability to undergo photoisomerization at two distinctly separated wavelengths.⁷⁰ Furthermore, during the optimization of the chemical structure, it is essential to aim for a pronounced red shift in the absorption spectrum, enhancing its potential for *in vivo* applications.⁷¹ Starting with (1), in this work, a

systematic *para* substitution was conducted to create push-pull AZ compounds, promising candidates for achieving red-shifted absorption.⁷⁰ In the *trans* isomer, the simultaneous destabilization of the highest occupied π orbital (electron-donating substituents) and stabilization of the lowest unoccupied π^* orbital (electron-withdrawing substituents) leads to a red shift of the bright S_2 ($\pi \rightarrow \pi^*$) absorption, reducing the energy gap with S_1 ($n \rightarrow \pi^*$), known to be the most productive pathway for photoisomerization.³⁵ The *cis* state instead demonstrates a higher quantum yield (QY) of photoisomerization following the excitation to the S_1 state compared to the *trans* isomer, associated with a barrierless and steeper minimum energy path along the torsional motion,⁷² a characteristic observed not only in AZ but also maintained in push-pull systems. Based on this, we hypothesize that our compounds bound to the 5-HT_{2A}R would exhibit a similar behavior, with the *cis* isomer demonstrating a higher QY of photoisomerization due to a steeper and barrierless minimum energy path along the torsional coordinate. Additionally, *ortho*-methoxy substituents were introduced in all possible combinations (Fig. S1–S5), resulting in a red shift primarily in the S_1 ($n \rightarrow \pi^*$) state.⁷³ This modification also slows down the thermal relaxation process, which is known to occur extremely fast in push-pull azobenzenes.⁷⁴

Considering only *para* substitutions, the BZ-azo-*N,N*-DMT class of compounds (Table S2) (see SI) was particularly notable among various groups. These compounds exhibited a significant red-shifted absorption of approximately 1.01 eV for the S_2 ($\pi \rightarrow \pi^*$) state in the *trans* isomer. As a consequence, this state becomes lower in energy than the S_1 ($n \rightarrow \pi^*$) state (not the S_1 anymore), leading to substantial orbital mixing between the two states, while a red shift of 0.32 eV was observed for the S_1 ($\pi/n \rightarrow \pi^*$) state of the *cis* isomer, defined as π/n because of a substantial orbital mixing. Additionally, the PQ-azo-*N,N*-DMT class (Table S3) (see SI) exhibited a significant red shift of 0.61 eV in the S_2 ($\pi \rightarrow \pi^*$) transition, while the other classes showed behavior similar to (1).

Intrigued by the behavior of BZ-azo-*N,N*-DMT and PQ-azo-*N,N*-DMT, we investigated whether these two classes demonstrated a clear separation between absorption and potential photoisomerization in both the *trans*- and *cis*- isomers. Although all BZ compounds exhibited the strongest red-shifted absorption, the bright states of the *trans* and *cis* isomers almost coincide at the same energy, potentially leading to a mixed photostationary distribution and residual activity of the 5-HT_{2A}R. However, for PQ-azo-*N,N*-DMT (Table S3), the *ortho*-substituted compound (34) presented a promising scenario. Its *trans* isomer exhibited a significant red shift, from 3.24 eV to 2.81 eV compared to (1), resulting in a pronounced alteration in the character of the S_2 ($\pi \rightarrow \pi^*$) state (Fig. 3). This shift caused a blending with the closely located S_1 ($n \rightarrow \pi^*$) state at 2.70 eV. In contrast, the *cis* isomer displayed its first excited state, S_1 ($\pi/n \rightarrow \pi^*$), at 2.26 eV, introducing a distinct red shift compared to *cis*-(1), which exhibits this state at 2.57 eV (Fig. 3). Given those changes, a larger energy gap of 0.38 eV between the *trans*-(34) bright state and the *cis*-(34) S_2 ($\pi/n \rightarrow \pi^*$) state, which might prevent the mixing of the two isomers when the molecule is excited. In comparison, for the (1) species, the energy

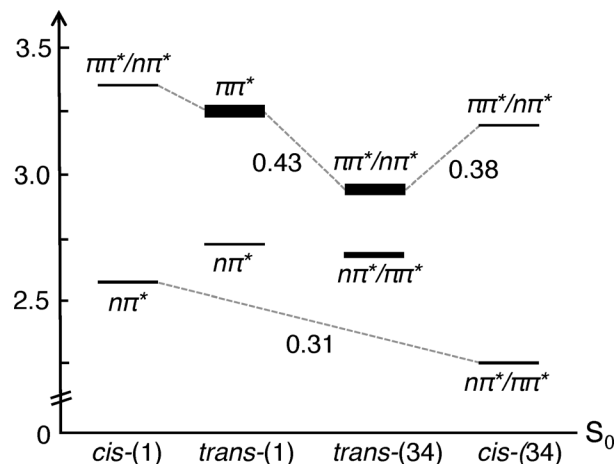

Fig. 3 Energies and oscillator strengths (represented by the width of the lines in a qualitative way) of the relevant electronic excited states of the species azo-*N,N*-DMT (1) and PQ-azo-*N,N*-DMT (34) in their *cis* and *trans* configurations.

difference between the bright states of the two isomers is only 0.14 eV. The scenario of (34) creates an opportunity for photoisomerization from *trans* to *cis* at approximately 2.70 eV and from *cis* to *trans* at around 2.25 eV, minimizing mixing between the two isomers. Since the (34) species presents appropriate absorption features, its adequacy as HT_{2A}R inhibitor will be evaluated in more detail and compared with (1) in the following sections.

3.2 Binding to the 5-HT_{2A}R

To validate whether the selected compounds could bind and maintain the canonical binding pose of tryptamines and ergotamines within the OBP of the 5-HT_{2A}R, the *N,N*-DMT domain of (1) and (34) in both isomers was superimposed onto the rigid tryptamine domain of LSD using VMD.⁷⁵ Both LSD and the photoswitches remained tightly bound to the OBP for the whole simulation time of 5 μ s, as indicated by the root mean square deviations (Fig. S6) (see SI). The MMGBSA method was employed to estimate the relative binding free energies (ΔG_{tot}) and further decompose it into van der Waals (ΔG_{vdw}) and electrostatic (ΔG_{el}) interactions between the ligand and receptor, as well as changes in the solvation energy (ΔG_{sol}) of the receptor and ligand complex by the implicit solvent upon binding. Additionally, each energy term was further decomposed into pairwise residue–ligand binding free energies to identify the main amino acids contributing to the binding process. Both *cis*-(34) and *trans*-(34) exhibit more favorable ΔG_{vdw} than (1) and LSD due to their bulkier domains that establish numerous hydrophobic residues in the pore (Table 1). This stabilization results in more favorable ΔG_{tot} values compared to LSD and both *trans*- and *cis*-(1). In addition, for both (1) and (34), the *trans* isomer exhibits less favorable ΔG_{el} compared to the *cis*, indicating an overall different character of interaction inside the OBP.

The OBP is positioned approximately 10 Å inside the 5-HT_{2A}R protein from the extracellular medium. Helices S3, S5, S6, S7, and extracellular loop 2 (ECL2) fold toward the center of the pore, constituting the most implicated protein fragments

Table 1 Binding free energy decomposition (ΔG_{tot}) into van der Waals (ΔG_{vdw}), electrostatic (ΔG_{el}), and solvation (ΔG_{sol}) components for all compounds under investigation. Logarithm of the effective permeability ($\log P_{\text{eff}}$) of all the compounds permeating into a POPC lipid bilayer

Compound	ΔG_{vdw}	ΔG_{el}	ΔG_{sol}	ΔG_{tot}	$\log P_{\text{eff}}$
LSD	-47.8	-73.7	66.8	-54.8	
<i>Cis</i> -(1)	-49.7	-78.2	71.5	-56.4	1.36
<i>Trans</i> -(1)	-50.6	-69.9	66.1	-54.4	1.49
<i>Cis</i> -(34)	-60.4	-73.0	74.5	-65.9	1.34
<i>Trans</i> -(34)	-65.6	-68.4	67.2	-66.9	1.51

in drug binding. The S3 helix accommodates the ethylamine domain of all the compounds, where D155 plays a crucial role in anchoring it to the pocket through a salt bridge between the $^+\text{NH}(\text{CH}_3)$ group of the ligands and the negatively charged COO^- side chain of D155 (Fig. 4B).⁷⁶ This interaction is confirmed by the strong electrostatic interactions observed in the energy decomposition analysis (Fig. 5). Continuing along the S3 helix, V156 creates alkyl- π interactions with the aromatic indole (Fig. 4B). Despite not being part of mutagenesis studies, computational studies have previously identified V156 as a robust contributor to the binding of 25X-NBOMEs and LSD.⁷⁷ S159 forms interactions with both LSD and the photoswitches, where the -OH side chain creates a hydrogen bond with the tertiary alkyl amines of the compounds. This interaction is observed within the first 10 residues only in *cis*-(34) (Fig. 5). In contrast, primary amines such as 5-HT are known to interact more strongly with this residue, forming multiple hydrogen

bonds.^{25,47} In the S5 helix, S242, a unique residue of the 5-HT_{2A}R among the 5-HTRs family, engages in hydrogen bonding with the indole -N1 of all compounds through its -OH side chain, except for *trans*-(34), which is slightly displaced (Fig. 5).⁷⁸ The photoswitches experience additional stabilization through interactions with L228 and L229 in ECL2, which appears to be weaker in LSD and not shown within the first 10 energy decomposed residues (Fig. 5). L229, identified as a “lid” of the ECL2, was shown to induce receptor closure and enhance the stabilization of LSD.^{25,79} Additionally, F234 and V235 at the extracellular edge of the S5 helix contribute to this stabilization.

The hydrophobic S6 region participating in the OBP enhances ligand interaction through cation- π and π - π interactions with the indole group of all the ligands. Four key aromatic residues, namely W336, F339, F340, and N343 contribute significantly to the binding of all compounds. W336, referred to as the “toggle switch,” has recently been shown to guide G_q efficacy through an alteration of the χ_2 dihedral angle in the class of 25CN-NBx compounds.²⁶ In our dynamics of tryptamines, the χ_2 dihedral angle remained at its initial value of the 5-HT_{2A}R-LSD holo-structure. F340 engages in a T-shaped π π interaction with the indole aromatic group, where the van der Waals term dominates. Mutagenesis studies have indicated that the F340L mutation significantly reduces the affinity of various 5-HT_{2A}R agonists, including 5-HT and 5MeO-*N,N*-DMT. However, the F340Y mutation, maintaining an aromatic residue at the position, behaves similarly to the native receptor, emphasizing the requirement for an aromatic residue rather

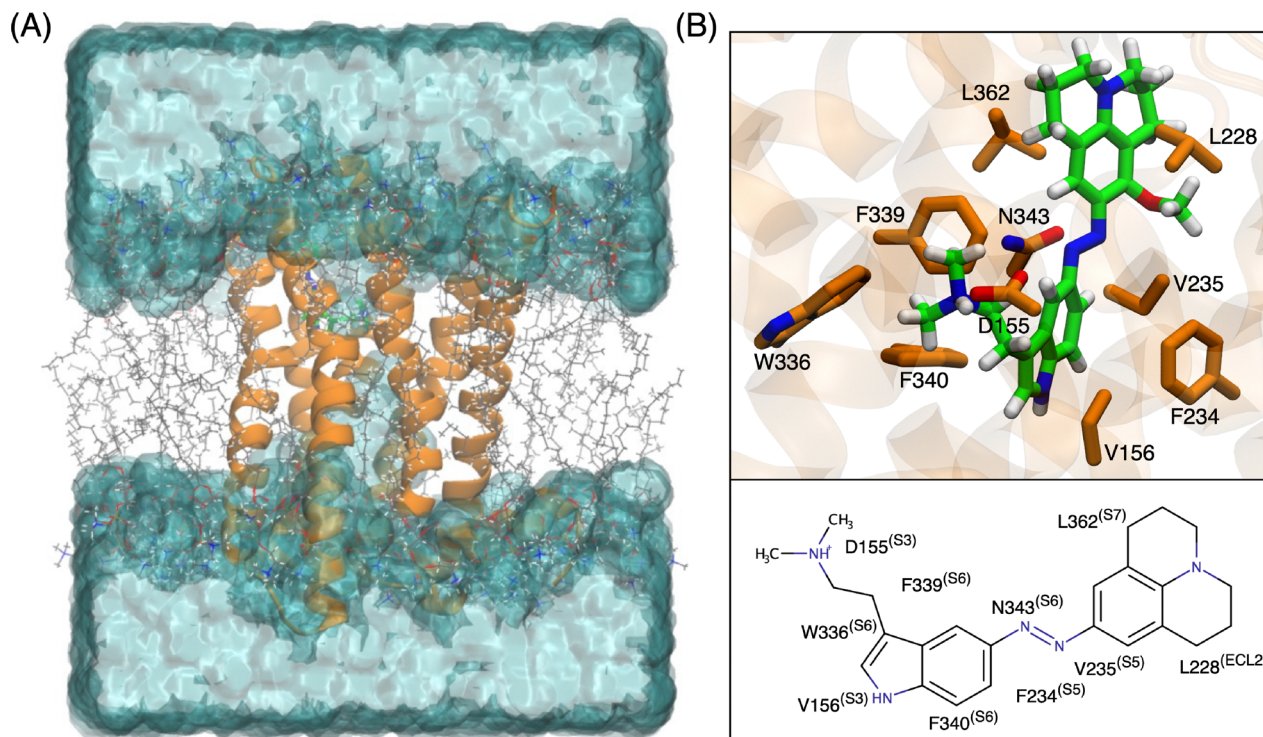

Fig. 4 (A) Representation of PQ-azo-*N,N*-DMT (**34**) (green) inserted into the orthosteric binding pocket (OBP) of the 5-HT_{2A}R embedded in a 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC) lipid bilayer (gray) and water (cyan). (B) The 10 residues and the corresponding helices (S3, S5, S6, S7) along with extracellular loop 2 (ECL2) that contribute to the binding of PQ-azo-*N,N*-DMT (**34**) in the OBP of the 5-HT_{2A}R.

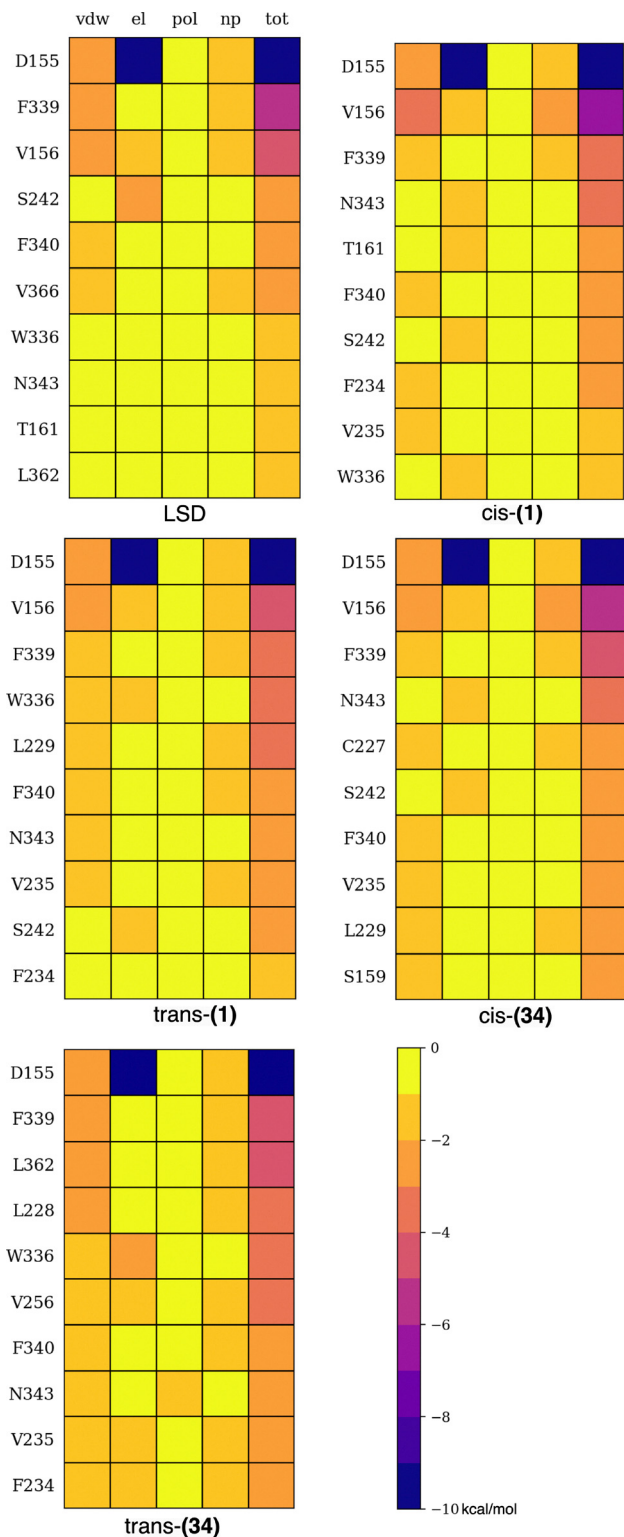

Fig. 5 Pairwise residue decomposition of the van der Waals (ΔG_{vdW}), electrostatic (ΔG_{el}), polar (ΔG_{pol}), non-polar (ΔG_{np}) solvation and total binding free energy (ΔG_{tot}) including the major 10 residue–ligand interactions for all the compounds.

than specifically phenylalanine.^{46,80} Finally, *trans*-(34) exhibits strong interactions with L362 in the S7 helix, a residue that only weakly interacts with LSD. Thus, overall, the four photoswitches

maintain the key interactions within the most relevant helices and exhibit comparable affinity to LSD in the 5-HT_{2A}R. It is important to note that (34), identified in the previous section as the compound with the most appropriate absorption features, displays the tightest binding to the receptor.

3.3 Membrane permeation

Once we have observed in the MD simulations and free energy calculations that the photoswitches were able to retain the key interactions in the OBP, we simulated their permeation within a POPC lipid membrane, which is a necessary step to reach the intracellular 5-HT_{2A}R. Table 1 presents the effective permeability, $\log P_{\text{eff}}$ values obtained from the PMF. A positive $\log P_{\text{eff}}$ indicates that the compound is permeable, while a negative value indicates impermeability. All four compounds exhibit positive permeability, with the *trans* isomers having slightly higher values. All the compounds permeate from the bulk water ($z = 36\text{--}26 \text{ \AA}$) phase to the membrane's head groups ($z = 25\text{--}12 \text{ \AA}$) in a barrierless manner (Fig. 6), until reaching a minimum at 8–11 Å away from the membrane's center, sitting just below the head groups, in a region of medium polarity. Indeed, the *cis* isomers, in particular *cis*-(1), exhibit the closest minimum to the head groups, indicating an overall higher polarity, which can be qualitatively associated with the higher ΔG_{el} inside the OBP. The *trans* isomers display a much deeper minimum and a smaller energy barrier at the membrane's center ($z = 0 \text{ \AA}$), associated with a greater $\log P_{\text{eff}}$ (around 1.50) in comparison to the *cis* isomers (around 1.35). Previously reported values of *N,N*-DMT in a POPC lipid bilayer display a very similar value ($\log P_{\text{eff}} = 1.59$). Thus, the addition of an azobenzene domain and its *ortho*–*para* substituents do not significantly affect the overall permeability of the compound. This suggests that both (1) and (34) can easily permeate, activate intracellular pools of 5-HT_{2A}Rs, and in principle induce neuroplastic effects.¹⁶

3.4 Absorption spectrum including sampling and biological environment

Inspired by the static TD-DFT calculations that showed a red-shifted absorption for (34), in comparison to (1), we computed the absorption spectra of all four isomers embedded in the OBP of the 5-HT_{2A}R (Fig. 7). The static calculations were computed

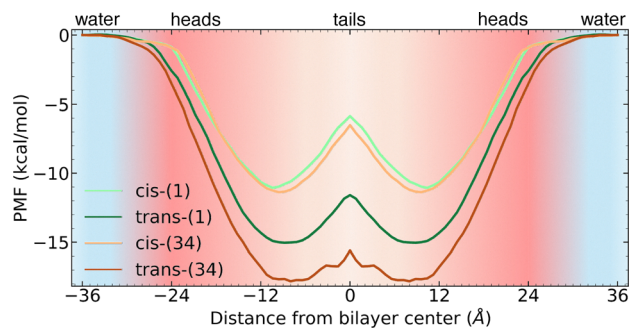

Fig. 6 Symmetric PMF for the photoswitches permeating into a POPC lipid bilayer. The water phase (cyan) extends from $\pm 36 \text{ \AA}$ to $\pm 25 \text{ \AA}$, the head groups (red) from $\pm 24 \text{ \AA}$ to $\pm 13 \text{ \AA}$, and the lipid tails from $\pm 12 \text{ \AA}$ to 0 \AA .

Fig. 7 Absorption spectrum of the *trans*- and *cis*- azo-*N,N*-DMT (**1**) (top) and *trans*- and *cis*- PQ-azo-*N,N*-DMT (**34**) (bottom).

at the optimized geometry with implicit solvation, while the QM/MM calculations were computed from an ensemble of the MD snapshots taken from the production run, allowing the inclusion of the protein environment and vibrational sampling, which may strongly modify the electronic structure of chromophores.^{81–85} For (**34**), a significant red shift is observed for both *trans* and *cis* isomers with respect to (**1**), consistent with predictions from the QM static calculations. In *trans*-(**34**), the first absorption band shows a maximum at 2.95 eV, slightly blue-shifted in comparison to the QM calculations, while in *trans*-(**1**) the first absorption band maximum is found at 3.25 eV, in complete agreement with the QM calculations. In the *cis* isomer, (**34**) and (**1**) display the first absorption band maxima at 2.25 and 2.57 eV, in great agreement with QM calculations. The energy gap between *trans* and *cis* (**34**) absorption ($\Delta E = 0.70$ eV) is similar to that between the *trans* and *cis* (**1**) ($\Delta E = 0.68$ eV). Therefore, in both compounds, the independent excitation of *cis* and *trans* isomers is possible avoiding the mixture of both photoisomers. However, the two isomers of the newly designed compound (**34**) can be excited with light of less energy than (**1**), a desired feature of a photoswitch aimed to be employed in *in vivo* systems, as explained above.

4 Conclusion

Photo-pharmacological compounds targeting GPCRs enable precise spatio-temporal control over the activation of different downstream pathways. The reversibility of the photoisomerization process is a crucial property of AZ-based agonists, enabling precise, light-controlled modulation of biological systems. Within the context of 5-HT_{2A}R, an ideal scenario would involve a molecule that activates a specific pathway, such as G_q or β -arrestin, in one isomer while deactivating it in the other. Alternatively, a compound capable of activating the G_q pathway in one isomer and the β -arrestin pathway in the other isomer would be highly advantageous. However, before reaching such an exquisite control, it is important to design photoswitches that absorb at low energies (large wavelengths) and can photoisomerize from *trans* to *cis* and from *cis* to *trans* using distinct wavelengths and, thus, avoiding the presence of both isomers simultaneously.

In this work, we identified a compound, (**34**), using QM/continuum and QM/MM calculations, which exhibits a significant red-shifted absorption of around 0.40 eV in both isomers relative to (**1**) and a favorable energy gap between the *trans* and *cis* excitation, potentially minimizing residual activity. MD and free energy calculations highlight the tight binding of both (**1**) and (**34**) to the OBP, sharing essential residue interactions with the recently crystallized 5-HT_{2A}R-LSD complex. The calculated PMF and $\log P_{\text{eff}}$ values closely resemble those of previously simulated *N,N*-DMT, with slightly greater permeation in favor of the *trans* isomers for both molecules, implying that both (**1**) and (**34**) have the potential to permeate the neuronal membrane and activate intracellular pools of 5-HT_{2A}R.

This new photopharmacological compound can serve as a starting point for the selective activation of different signaling pathways for the 5-HT_{2A}R. It is important to note that although we have calculated vertical excitations both in implicit solvent and within the protein complex, our current study does not include a detailed mechanistic analysis of the photoisomerization process. Investigating this mechanism should be a primary focus of future work, as it is essential for accurately determining the quantum yield of photoisomerization. Also, at present, light-activated drugs can be used only in tissues we can illuminate without surgery. A good example is KIO-301, now in phase II trials for retinitis pigmentosa: the retina is naturally accessible to light, so no implants are required.⁸⁶ No approved device can deliver sufficient photon flux to deep structures without inserting optical fibres. A high-power functional near infrared spectroscopy array operating at 700–850 nm might switch red-shifted molecules in the outermost millimetres of cortex, but it cannot reach sub-cortical targets.⁸⁷
