## Structural contributions of Zn in enhancing CO<sub>2</sub> hydrogenation to methanol over Zn<sub>x</sub>ZrO<sub>y</sub> catalysts†

Zinat Zanganeh, Max Bols, Parviz Yazdani, Hilde Poelman and Mark Saeys \*

Single-reactor CO<sub>2</sub> conversion to light olefins via methanol is currently obstructed by the incompatible reaction conditions for the CO<sub>2</sub> to methanol and methanol to olefin steps. The conventional Cu/ZnO-Al<sub>2</sub>O<sub>3</sub> CO<sub>2</sub> hydrogenation catalysts produce excessive CO and rapidly deactivate at the high temperatures preferred for methanol to olefins with zeolite or SAPO catalysts. Zn<sub>x</sub>ZrO<sub>y</sub> catalysts are a promising alternative to Cu/ZnO-Al<sub>2</sub>O<sub>3</sub>. We studied Zn<sub>x</sub>ZrO<sub>y</sub> with varying Zn doping levels, using XRD, XPS, H<sub>2</sub>-TPR, CO<sub>2</sub>-TPD, N<sub>2</sub>-physisorption, DRIFT, and Raman spectroscopy, along with CO<sub>2</sub> conversion and methanol selectivity measurements, to examine structure-performance relationships in CO<sub>2</sub> hydrogenation to methanol. The interplay between dopant concentration, calcination temperature, and crystal structure dictates the catalyst's phase composition, which correlates with catalytic performance. The pristine ZrO<sub>2</sub> is a mixture of tetragonal and monoclinic phases. At Zn/Zr = 0.01, the tetragonal phase is dominant, while for Zn/Zr = 0.07–0.28, the cubic phase is obtained. Above Zn/Zr = 0.28, phase separation of ZnO occurs. For CO<sub>2</sub> hydrogenation to methanol, a Zn/Zr = 0.07–0.28 performs best. Zinc addition increases catalyst surface area, pore volume, basicity, and reducibility. XPS analysis reveals zinc enrichment near the surface and the formation of Zr–O–Zn species upon Zn incorporation into ZrO<sub>2</sub>. A clear correlation between Zn content and catalyst activity is generally absent, but this relationship becomes evident in cubic-phase materials. At least in part, the relevance of zinc doping for CO<sub>2</sub> to methanol lies in its ability to distort the structure of zirconia, creating a cubic phase, with implications for selectivity that correlate with the adsorption of CO<sub>2</sub> and H<sub>2</sub>.

## 1. Introduction

Catalytic hydrogenation of CO<sub>2</sub> to methanol (CTM) is an exothermic reaction facing slow reaction kinetics at low temperatures and low, thermodynamically limited selectivity at higher temperatures. The predominant methanol production route converts methane-derived syngas to methanol at 200–300 °C over a benchmark Cu/ZnO-Al<sub>2</sub>O<sub>3</sub> catalyst through a CO<sub>2</sub> intermediate, involving water-gas-shift, with additional CO<sub>2</sub> feeding to match the net reaction stoichiometry.<sup>1</sup> To circumvent the thermodynamic limitation and enable higher temperature conditions, a tandem process is considered with *in situ* methanol to olefins (MTO) conversion over a Brønsted acid catalyst, regularly a zeolite or SAPO material.<sup>2,3</sup> The CTM-MTO tandem offers a direct selective route to C<sub>2</sub>–C<sub>3</sub> olefins<sup>4</sup> as an alternative to Fischer–

Tropsch synthesis with limited selectivity to light olefins.<sup>5</sup> The MTO reaction is optimized above 380 °C. This is a mismatch with the lower temperatures required for existing CTM catalysts, which are selective to CO instead of methanol at these high temperatures.<sup>6</sup> Several alternative CTM catalysts are considered. Zinc-doped zirconium oxide (Zn<sub>x</sub>ZrO<sub>y</sub>) is particularly interesting for its improved CO<sub>2</sub> to methanol conversions and selectivity at higher temperatures, achieving 85% methanol selectivity at 320 °C.<sup>7</sup> Other metal dopants in zirconia have also been explored, yielding promising catalysts with diverging specifications.<sup>6,8–10</sup>

Most studies attribute zinc's promotional effect to its incorporation in the active sites interacting with CO<sub>2</sub> and H<sub>2</sub>,<sup>7,11</sup> H<sub>2</sub>-TPR measurements demonstrate that Zn addition enhances reducibility, increasing H<sub>2</sub> consumption and shifting it to lower temperatures.<sup>12</sup> A lowered take-off temperature for H<sub>2</sub>–D<sub>2</sub> isotope scrambling, from 250 to 147 °C, is reported in Zn-doped *versus* undoped ZrO<sub>2</sub>.<sup>13</sup> DFT calculations support this finding, indicating a low-barrier heterolytic H<sub>2</sub> dissociation on Zn<sub>x</sub>ZrO<sub>y</sub> with the formation of Zn–H.<sup>13</sup> Zn addition may affect both surface oxygen

concentration and its chemical nature. Counteracting the beneficial effect of surface oxygen in  $H_2$  activation for CTM conversion,<sup>14</sup> oxygen vacancies have been reported as active sites for  $CO_2$  activation in this process. Through EPR and XPS measurements, several types of oxygen vacancies and their concentrations have been associated with coordinatively unsaturated Zr atoms (CUS-Zr). These surface species were correlated to  $CO_2$  adsorption and reverse water gas shift (RWGS) activity.<sup>15</sup> However, various forms of  $CO_2$  adsorption on the  $ZrO_2$  surface are described.<sup>16–20</sup> Among these, the insertion of  $CO_2$  into Zr-OH is associated with oxygen vacancies and CUS-Zr on the surface.<sup>17,21,22</sup> Besides  $CO_2$  and  $H_2$  activation, combining activated  $CO_2$  and  $H_2$  on the surface to form intermediates towards methanol is required. DFT has suggested that Zn facilitates the hydrogenation of surface Zr-bound intermediates through the proximity of Zn-H surface species.<sup>13</sup> Differences in surface intermediates and weaker  $CO_2$  adsorption have been observed in DRIFTS on  $Zn_xZrO_y$  compared to  $ZrO_2$ .<sup>13,23</sup> It has been suggested that formate's C-O bond cleavage is easier on asymmetric Zn-O-Zr sites than on symmetric Zr-O-Zr sites, facilitating the formation of C-H bonds and methanol synthesis.<sup>13,24</sup>

Numerous additional explanations for the Zn promotional effect are found in literature, which are not necessarily mutually exclusive. XRD results show that Zn addition contracts the  $ZrO_2$  crystal lattice, forms a solid solution, and alters  $ZrO_2$  crystal phases.<sup>12,23,25</sup> The incorporation of  $ZnO$  nanoparticles into the  $ZrO_2$  matrix is pointed out by EXAFS and correlates with the formation of Zn-O-Zr species.<sup>11</sup> Some researchers point at the  $ZnO$ - $ZrO_2$  interface as the dominant active site in  $CO_2$  hydrogenation.<sup>11,23,26</sup> Other researchers, however, hypothesize that the growth of  $ZnO_x$  clusters during the reaction improves methanol synthesis by enhancing  $H_2$  dissociation.<sup>27</sup>  $ZrO_2$  inherently contains weak  $Zr^{4+}$ - $O^{2-}$  Lewis acid-base (LAB) pairs,<sup>28</sup> whose reactivity in heterolytic  $H_2$  dissociation is influenced by the crystal phase, exposed facets, and the orientation of LAB pair sites.<sup>29,30</sup> The introduction of Zn distorts the  $ZrO_2$  lattice, leading to changes in both bulk and surface properties.

Zn can influence the concentration, nature, and proximity of Zr-OH, surface oxygen, and CUS-Zr in various ways while also introducing Zn-H, Zn-O-Zr, Zn-O-Zn, and  $ZnO_x$  motifs. Conclusive evidence for their relative contributions to CTM activity and selectivity is lacking. To offer another viewpoint to this puzzle, this study investigates the association between Zn doping and the  $ZrO_2$  crystal phase and its subsequent impact on CTM. The aspect of the crystal phase has been largely overlooked in the Zn promotional effect, in contrast to other promotor metals (Y, Mg, Ca,...).<sup>31,32</sup> Most studies report  $ZrO_2$  transitioning to the tetragonal phase after Zn addition.<sup>11,13,22,26,33,34</sup> Notably, a recent study emphasized the influence of the  $ZrO_2$  crystal phase on methanol synthesis, showing that the tetragonal phase achieved higher methanol selectivity and space-time yield compared to the monoclinic phase. This was attributed to well-dispersed  $ZnO$  clusters on tetragonal  $ZrO_2$ , particularly under catalytic

conditions.<sup>26</sup> However, doping  $ZrO_2$  with Zn has been reported by several authors to induce a crystal structure alteration, stabilizing the cubic phase either in the bulk *via* coprecipitation or near the surface through impregnation.<sup>7,23</sup> Despite these observations, the direct relationship between the cubic phase of doped  $ZrO_2$  and CTM catalysis has so far not been investigated.<sup>35–37</sup>

We prepared  $Zn_xZrO_y$  through coprecipitation, with Zn/Zr molar ratios ranging from 0.01 to 0.56.  $Zn_{0.19}ZrO_y$  samples are calcined at various temperatures. We measure surface area, pore volume, temperature-programmed reducibility,  $CO_2$  uptake, XRD, Raman, DRIFT and XPS spectra, and CTM catalysis to correlate structure and performance. The data indicate that the 'one fits all' active-site or surface structure explanations suggested in the literature are likely incomplete descriptions of the Zn promotion of  $ZrO_x$  for CTM.

## 2. Experimental

### 2.1. Catalyst synthesis

$Zn_xZrO_y$  samples were synthesized through coprecipitation, using nitrate precursors of zinc and zirconium, and sodium carbonate as the precipitating agent. Zinc nitrate hexahydrate ( $Zn(NO_3)_2 \cdot 6H_2O$ , Sigma-Aldrich, purity  $\geq 99\%$ ) was dissolved in a variable ratio into a 0.11 M solution of zirconium oxynitrate ( $ZrO(NO_3)_2 \cdot 5H_2O$ , Sigma-Aldrich, purity  $\geq 98\%$ ) under stirring at 65 °C. Subsequently, a 0.30 M sodium carbonate solution ( $Na_2CO_3$ , Sigma-Aldrich, purity  $\geq 99\%$ ) was added dropwise as the precipitating agent until the pH reached 9. The resulting suspension was aged for one hour at 65 °C. The precipitate was washed with deionized water until a pH of 7 was obtained. After filtration, the obtained material was dried overnight at 80 °C and then calcined for 3 hours at 500 °C under static air (heating ramp of 3 °C min<sup>-1</sup>). The dried  $Zn_{0.19}ZrO_y$  was also calcined at 550, 700, and 800 °C using the same heating ramp. The catalysts are denoted as  $Zn_xZrO_y$ -*T*, where *x* indicates the Zn/Zr molar ratio and *T* is the calcination temperature. The  $ZnO$  reference sample was synthesized using the same procedure by precipitating zinc nitrate hexahydrate with sodium carbonate, followed by aging, filtration, washing, and drying, but it was calcined at 350 °C.

### 2.2. Catalyst characterization

X-ray diffraction (XRD) measurements of the calcined catalysts were conducted on a Siemens Diffractometer Kristalloflex D5000, applying  $Cu K\alpha$  radiation ( $\lambda = 0.154$  nm). The powder diffraction pattern was recorded in a  $2\theta$  range of 20–70° with a step size of 0.025°. The data were analysed employing DIFFRAC. EVA V5.2 software. Raman spectra of the powdered samples were recorded on a Raman spectrograph using a KAISER optical system coupled with a 532 nm laser source. The textural properties of the as-prepared catalysts were analysed by nitrogen adsorption/desorption isotherms at  $-196$  °C in a Micrometrics Tristar-II 3020 instrument. Before the measurements, 400 mg of the calcined samples (150–250  $\mu m$ ) were degassed at 350 °C for 6 hours using a Micromeritics Smart Prep device. The data were

analysed using MicroActive software version 5.00. The specific surface area was determined using the Brunauer–Emmett–Teller (BET) method, utilizing nitrogen adsorption data at relative pressures between 0.05 and 0.30 to estimate surface area based on multilayer adsorption theory. The pore volume and pore size were calculated using the Barrett–Joyner–Halenda (BJH) method, derived from the Kelvin equation, relating the changes in the adsorbed or desorbed volume at different pressures to the pore radius, assuming cylindrical pore geometry. SEM-EDX measurements were performed using a JEOL JSM-5400 equipped with an INCAx X-ray detector. The measurements were carried out at energies between 5 to 20 kV.

The temperature-programmed experiments were conducted in a Micromeritics AutoChem 2920 equipped with a thermal conductivity detector and mass spectrometer. The temperature of the catalyst bed was measured with a K-type thermocouple touching the sample. Typically, 100 mg of the calcined samples (150–250  $\mu\text{m}$ ) were loaded into a quartz U-tube and pretreated under 60 Nml  $\text{Ar min}^{-1}$  at 500 °C for 1 h at atmospheric pressure. The temperature-programmed reduction ( $\text{H}_2$ -TPR) profile was recorded by heating the sample from 50 to 750 °C at a rate of 10 °C  $\text{min}^{-1}$ , while exposing it to a 5%  $\text{H}_2$ /Ar stream (60 Nml  $\text{min}^{-1}$ ) and maintaining the temperature at 750 °C for 10 minutes. At the same time, a mass spectrometer measured the formed water during the process. The  $\text{CO}_2$  adsorption capacity of the as-prepared samples was studied by  $\text{CO}_2$  temperature-programmed desorption ( $\text{CO}_2$ -TPD).  $\text{CO}_2$  adsorption was carried out under 60 Nml  $\text{min}^{-1}$   $\text{CO}_2$  at 50 °C for 2 hours. After evacuating the physically adsorbed  $\text{CO}_2$  for 2 hours at 50 °C, the temperature-programmed desorption (TPD) profile was recorded by heating the sample from 50 to 500 °C at 10 °C  $\text{min}^{-1}$  under 60 Nml  $\text{min}^{-1}$  helium. The desorbed  $\text{CO}_2$  was quantified by integrating the area under the deconvoluted desorption profile.

The surface chemical properties of samples were studied using X-ray photoelectron spectroscopy (XPS) with an SSI S-probe equipped with a monochromatic Al  $\text{K}\alpha$  source ( $h\nu = 1486.6$  eV). Data acquisition was carried out under ultra-high vacuum conditions ( $9 \times 10^{-7}$  Pa). Survey scans were measured at a constant pass energy of 140.8 eV. High-resolution scans were recorded at 90.15 eV for Zr 3d, Zn 2p, O 1s, and C 1s core level for  $\text{ZrO}_2$ ,  $\text{Zn}_{0.07}\text{ZrO}_y$ -500,  $\text{Zn}_{0.19}\text{ZrO}_y$ -500,  $\text{Zn}_{0.19}\text{ZrO}_y$ -700, and  $\text{Zn}_{0.19}\text{ZrO}_y$ -800. All binding energies were calibrated using the C 1s peak of adventitious carbon at a binding energy of 284.8 eV.

Diffuse Reflectance Infrared Fourier Transform Spectroscopy (DRIFTS) measurements were conducted at 10 bar using a Harrick flow reactor equipped with ZnSe windows mounted in a Praying Mantis accessory within a Bruker Tensor 27 FTIR. To clarify the effect of Zn doping on  $\text{ZrO}_2$ , we selected  $\text{ZrO}_2$ ,  $\text{Zn}_{0.19}\text{ZrO}_y$ , and  $\text{Zn}_{0.56}\text{ZrO}_y$  for our DRIFT study. 30 mg of samples were diluted with 100 mg KBr and placed in the sample holder cup of a high-temperature cell. After pretreatment at 400 °C for 1 hour under an Ar atmosphere, background IR spectra were collected under Ar. The gas mixture was then introduced into

the cell *via* mass flow controllers, and each spectrum was recorded at a resolution of 4  $\text{cm}^{-1}$ , with an average of 32 scans per spectrum. In the  $\text{CO}_2$  adsorption experiment,  $\text{CO}_2$  was adsorbed by flowing 2 ml  $\text{min}^{-1}$   $\text{CO}_2$  in 16 ml  $\text{min}^{-1}$  Ar for 40 minutes, followed by the removal of weakly adsorbed species under Ar. For the methanol adsorption experiment, 2.3 ml  $\text{min}^{-1}$  of methanol with 130 ml  $\text{min}^{-1}$  Ar was introduced for 30 minutes at 200 °C. After methanol adsorption, physically adsorbed species were removed in an 130 ml  $\text{min}^{-1}$  Ar flow, and the spectra of the remaining adsorbed methanol were collected.

**2.2.1.  $\text{CO}_2$  hydrogenation.** The performance of the catalysts in  $\text{CO}_2$  hydrogenation was assessed at 45 bar and 300–400 °C in a high-pressure plug flow reactor with an internal diameter of 9 mm equipped with a 3 mm thermowell. Typically, 300 mg of the sieved catalyst (150–250  $\mu\text{m}$ ), diluted with 300 mg of quartz (150–250  $\mu\text{m}$ ), was loaded between two layers of quartz wool within the isothermal zone of the reactor. The catalysts underwent a one-hour pretreatment under 100 Nml  $\text{min}^{-1}$  Ar at 400 °C. They were then cooled to 300 °C, after which the reactant gas mixture was introduced through calibrated Bronckhorst mass flow controllers, maintaining a ratio of  $\text{H}_2:\text{CO}_2:\text{Ar} = 3:1:1$  at constant pressure and flowrate (45 bar and  $\text{GHSV} = 21\,000$  Nml  $\text{g}_{\text{cat}}^{-1} \text{h}^{-1}$ ). The reaction temperature was incrementally increased from 300 to 400 °C in intervals of 25 °C and held for 2 hours at each temperature to establish steady-state conditions. The stability of the  $\text{Zn}_{0.19}\text{ZrO}_y$ -500 catalyst was evaluated by varying the reaction temperature and subsequently returning to the initial temperature, allowing for assessment of its performance consistency and resilience under elevated temperatures. The outlet gas line was maintained at 150 °C to prevent condensation of the reaction products. The reaction effluent was analysed online using a TRACE-1310 GC analyser equipped with Rt-Ubond (FID), Hayesep N and ShinCarbon-ST (1st TCD), and RT-QBond and RT-MolSieve 5A (2nd TCD) columns. The fulfilment of the Wheeler–Weisz and Carberry criteria confirmed the absence of transport limitations. The catalysts' performance was evaluated by calculating  $\text{CO}_2$  conversion ( $X(\text{CO}_2)$ ), methanol selectivity ( $S(\text{CH}_3\text{OH})$ ), and methanol space-time yield (STY( $\text{CH}_3\text{OH}$ )) as follows:

$$X(\text{CO}_2) = \frac{F(\text{CO}_2)_{\text{in}} - F(\text{CO}_2)_{\text{out}}}{F(\text{CO}_2)_{\text{in}}} \times 100\% \quad (1)$$

$$S(\text{CH}_3\text{OH}) = \frac{F(\text{CH}_3\text{OH})}{F(\text{CO}_2)_{\text{in}} - F(\text{CO}_2)_{\text{out}}} \times 100\% \quad (2)$$

$$\text{STY}(\text{CH}_3\text{OH}) = \frac{F(\text{CH}_3\text{OH}) \times \text{MW}(\text{CH}_3\text{OH})}{V \times m_{\text{catalyst}}} \quad (3)$$

where  $F$  represents the volumetric flow rate calculated based on the Ar internal standard,  $\text{MW}(\text{CH}_3\text{OH})$  is the molecular weight of methanol,  $m_{\text{catalyst}}$  is the catalyst weight in grams, and  $V$  is the molar volume of an ideal gas at normal conditions.

### 3. Results and analysis

#### 3.1. Structure and general properties of the $Zn_xZrO_y$ catalysts

The preparation of the  $Zn_xZrO_y$  precipitate follows a commonly used coprecipitation recipe comparable to other studies on CTM.<sup>7,13</sup> Seven different Zn/Zr molar ratios were used to prepare the  $ZrO_2$ ,  $Zn_{0.01}ZrO_y$ ,  $Zn_{0.07}ZrO_y$ ,  $Zn_{0.19}ZrO_y$ ,  $Zn_{0.28}ZrO_y$ ,  $Zn_{0.44}ZrO_y$  and  $Zn_{0.56}ZrO_y$  precursors. After calcination at 500 °C, their physical properties and those of the ZnO sample as an extra reference were measured (Table 1). As reported in the literature,  $Zn_{0.19}ZrO_y$  performs best in CTM conversion and selectivity at 350 °C.<sup>7</sup> This sample is, therefore, besides the standard 500 °C calcination temperature, also calcined at 550, 700, and 800 °C. Different levels of Zn addition and calcination temperatures are expected to change the main crystal phase of the bulk and distribute Zn differently between bulk and surface.<sup>38</sup> The bulk phase correlates to surface properties that underpin heterogeneous catalysis through exposed crystal planes and surface energy, including porosity, surface area, and texture.

Elemental analysis using scanning electron microscopy equipped with energy-dispersive X-ray spectroscopy (SEM-EDX) confirmed the successful Zn addition into  $ZrO_2$  (Tables 1 and S1†). In XRD (Fig. 1), no ZnO crystals were detected in the samples with Zn/Zr ratios of 0.01–0.19, indicating that Zn is either finely distributed within these samples, present as small-sized crystallites (<3 nm), or is amorphous. On samples with Zn/Zr = 0.44–0.56, a hexagonal ZnO phase is visible beside the main  $ZrO_2$  phase. Calcination of  $Zn_{0.19}ZrO_y$  at 800 °C also causes ZnO phase separation and  $ZrO_2$  phase transition to monoclinic and tetragonal.

The higher surface Zn/Zr ratio detected in XPS (Table 1), compared to the nominal elemental composition, suggests an enrichment of Zn near the surface,<sup>12,23</sup> implying the formation of an imperfect mixed metal oxide with a higher

concentration of Zn in the skin layer than in the bulk; increasing the calcination temperature to 700 °C results in a higher concentration of Zn near the surface. Upon calcination at 800 °C, however, the Zn surface excess decreases (Fig. S2†), correlating with the appearance of ZnO crystals in XRD due to sintering.

Three main  $ZrO_2$  phases are found in the XRD spectra: tetragonal, monoclinic, and cubic (Fig. 1a). In agreement with earlier reports, pristine  $ZrO_2$  contains monoclinic and tetragonal phases.<sup>7</sup> A small addition of Zn (Zn/Zr = 0.01) results in a partial phase transformation from monoclinic to tetragonal, while larger amounts of Zn lead to the appearance of a cubic phase. From Zn/Zr = 0.07 upwards, the lattice also contracts with increasing Zn content, indicated by the shift of the diffraction peak near 30° to higher angles (Fig. 1b). This shift is consistent with the displacement of Zr (0.82 Å) by the smaller Zn cation (0.74 Å)<sup>15</sup> within the crystal lattice. A Zn/Zr molar ratio  $\geq 0.07$  leads to the formation of the cubic phase, as evidenced by the presence of symmetrical single peaks instead of double peaks at  $2\theta = 35.5^\circ$ ,  $50.9^\circ$  and  $60.5^\circ$ . ZnO remains undetectable up to Zn/Zr = 0.19. Excess Zn in the  $Zn_{0.28}ZrO_y$ -500 sample, surpassing the solid solution limit (Zn/Zr = 0.24),<sup>23</sup> alters the crystalline structure (Fig. 1b). The alteration induced by high zinc concentration broadens the peaks, shrinks the unit cell due to inhomogeneously strained crystallites, and shifts the diffraction peaks to higher angles.<sup>7,39,40</sup> The broadening peaks may indicate the presence of multiple phases within the material.<sup>7</sup> In  $Zn_{0.44}ZrO_y$ -500 and  $Zn_{0.56}ZrO_y$ -500, the excess ZnO gives rise to measurable diffractions, in addition to the cubic  $ZrO_2$  diffractions.

Calcining the  $Zn_{0.19}ZrO_y$  sample at higher temperatures (Fig. 1c) maintains the cubic phase at least up to 700 °C. At 800 °C, ZnO phase separation and cubic phase transformation to tetragonal and monoclinic phases occur.

**Table 1** Properties of the as-synthesised samples

<sup>a</sup> Identified in XRD (m: monoclinic, t: tetragonal, and c: cubic phase). <sup>b</sup> Determined using the BET method. <sup>c</sup> Determined from BJH adsorption isotherm. <sup>d</sup> Measured by integrating the peaks in  $H_2$ -TPR between 50–700 °C. <sup>e</sup> Measured by integrating the peaks in  $CO_2$ -TPD between 50–500 °C. <sup>f</sup> Calculated from EDX results at 20 kV electron beam energy.

**Fig. 1** (a) XRD patterns of  $\text{Zn}_x\text{ZrO}_y$ -500 catalysts, (b) enlarged XRD patterns of  $\text{Zn}_x\text{ZrO}_y$ -500 catalysts in the  $2\theta$  range of  $29.5$ – $31.0^\circ$ , and (c) XRD patterns of  $\text{Zn}_{0.19}\text{ZrO}_y$ -7 calcined at  $500$ ,  $550$ ,  $700$ , and  $800$  °C (m- $\text{ZrO}_2$ : PDF card 81.1314, t- $\text{ZrO}_2$ : PDF card 50-1089, c- $\text{ZrO}_2$ : PDF card 65-0461, and h- $\text{ZnO}$ : PDF card 05-0664).

The samples' Raman spectra (Fig. 2 and ESI† section 2 – Raman spectroscopy) confirm the same crystal phases as those measured by XRD.

Table 1 and Fig. S1† present the nitrogen adsorption/desorption results, all indicating mesoporous materials. Up to  $\text{Zn/Zr} = 0.28$ , surface area and pore volume increase with Zn loading. Beyond this, surface area decreases. The  $\text{Zn}_{0.44}\text{ZrO}_y$ -500 and  $\text{Zn}_{0.56}\text{ZrO}_y$ -500 isotherms resemble a bimodal mesoporous material, combining  $\text{ZrO}_2$  and  $\text{ZnO}$  isotherms (Fig. S1a†). The region corresponding to  $P/P^0 > 0.87$  implies the presence of larger mesopores attributed to the formation of  $\text{ZnO}$  particles, consistent with the XRD results. The other

hysteresis region, within the range  $0.45 < P/P^0 < 0.87$ , represents the smaller mesopores of the mixed oxide. Elevating the calcination temperature to  $700$  °C and  $800$  °C alters the pore geometry, resulting in partially blocked pores (Fig. S1b†) and reduced surface area. The pore size distribution in Fig. S1c and d† illustrates changes in pore size resulting from zinc addition and the influence of calcination temperature on pore size distribution. The graphs show that pore enlargement occurs with calcination temperature exceeding  $550$  °C.

The  $\text{Zr}$  3d and  $\text{Zn}$  2p XPS spectra are shown in Fig. 3. The  $\text{ZrO}_2$  profile can be fitted with three Gaussian-shaped doublets,

Fig. 2 Raman spectra of  $\text{Zn}_{0.19}\text{ZrO}_y$ - $T$  calcined at 500, 700, and 800 °C.

each exhibiting a spin-orbital splitting of 2.4 eV, typical for zirconia. The bands centred at 180.9 and 182.3 eV are assigned to the monoclinic and tetragonal phases of  $\text{ZrO}_2$ , respectively.<sup>41</sup> The shift of the bands upon adding Zn indicates an alteration in the electronic and structural properties of Zr species in  $\text{Zn}_x\text{ZrO}_y$ .<sup>42</sup> The high energy band centred at 182.6 eV corresponds to bulk Zr in cubic  $\text{ZrO}_2$ , indicating the phase transformation from tetragonal to cubic.<sup>43,44</sup> The low energy band at 181.3 eV is assigned to Zr in Zn-O-Zr motifs.<sup>9,23,38,42,45,46</sup> Zinc incorporation generates new surface Zr species in lower

oxidation states, with a 179.9 eV centred XPS band, especially in the  $\text{Zn}_{0.19}\text{ZrO}_y$ -500 sample. Elevating the calcination temperature to 700 °C leads to a decrease in the concentration of Zr species in lower oxidation states, Fig. 3a and Table S2.†

Further increasing the calcination temperature to 800 °C shifts the Zr 3d<sub>5/2</sub> bands to 180.9 and 182.3 eV, resembling the Zr 3d doublets observed in the pure  $\text{ZrO}_2$  spectrum. This shift is attributed to the phase transformation of zirconia and the formation of monoclinic and tetragonal crystals at 800 °C, consistent with the XPS spectra observed for pure  $\text{ZrO}_2$ .

The Zn 2p spectra of the samples are shown in Fig. 3b. The binding energies of Zn 2p<sub>3/2</sub> and Zn 2p<sub>1/2</sub> in pure hexagonal ZnO centre at 1021.0 and 1044.1 eV, respectively.<sup>42</sup> Metallic Zn has a similar binding energy to ZnO, but isolated metallic Zn is not expected in these samples. The presence of Zn species at higher binding energy (1022.6 eV) in  $\text{Zn}_x\text{ZrO}_y$  originates from the different coordination structures, suggesting that the Zn species are in contact with the oxygen of  $\text{ZrO}_2$ , forming Zn-O-Zr bonds.<sup>46</sup> This coordination environment, with higher electronegativity than the oxygen ligand in bulk ZnO, contributes to the observed shift in binding energy<sup>38</sup> and suggests a charge transfer between  $\text{O}^{2-}$ ,  $\text{Zr}^{4+}$ , and  $\text{Zn}^{2+}$ .<sup>45</sup> These observations point to the possible incorporation of Zn into the  $\text{ZrO}_2$  lattice, forming a mixed oxide. The Zn-O-Zr species disappear after calcination above

Fig. 3 XPS spectra of (a) Zr 3d in  $\text{ZrO}_2$ ,  $\text{Zn}_{0.07}\text{ZrO}_y$ -500,  $\text{Zn}_{0.19}\text{ZrO}_y$ -500,  $\text{Zn}_{0.19}\text{ZrO}_y$ -700, and  $\text{Zn}_{0.19}\text{ZrO}_y$ -800 and (b) Zn 2p in  $\text{Zn}_{0.07}\text{ZrO}_y$ -500,  $\text{Zn}_{0.19}\text{ZrO}_y$ -500,  $\text{Zn}_{0.19}\text{ZrO}_y$ -700, and  $\text{Zn}_{0.19}\text{ZrO}_y$ -800.

Fig. 4 Temperature-programmed  $\text{H}_2$  reduction of (a)  $\text{Zn}_x\text{ZrO}_y$ -500 catalysts and (b)  $\text{Zn}_{0.19}\text{ZrO}_y$ - $T$  calcined at 500, 550, 700, and 800 °C.

700 °C due to the reduced contact between Zn and  $\text{ZrO}_2$  related to the decreased surface area<sup>38</sup> and the formation of  $\text{ZnO}$  particles.  $\text{Zn} 2p_{3/2}$  and  $\text{Zn} 2p_{1/2}$  peaks become broader in  $\text{Zn}_{0.19}\text{ZrO}_y$ -500, originating from the partially charged Zn species. Increasing the calcination temperature to 700 °C reduces the 1017.4 eV band associated with  $\text{Zn}^{(2-\delta)+}$  species, and this peak disappears entirely when the sample is calcined at 800 °C. The high-intensity peak centred at 1020.1 eV in  $\text{Zn}_{0.19}\text{ZrO}_y$ -800 is likely linked to the phase-separated  $\text{ZnO}$  species at the interface of  $\text{ZrO}_2$ .

The reducibility of the catalysts with  $\text{H}_2$  is directly relevant to the activation of  $\text{H}_2$  required for the  $\text{CO}_2$  hydrogenation catalysis.<sup>7</sup> Fig. 4 shows  $\text{H}_2$  temperature-programmed reduction profiles. The reduction of  $\text{ZrO}_2$  is challenging and requires high temperatures.<sup>13</sup> Increasing the Zn/Zr ratio up to 0.19 progressively shifts the reduction to lower temperatures and increases the reducibility (quantified in Table 1), revealing the presence of more reducible oxygen species on the surface, which aligns with the observation of low binding energies in  $\text{Zr}$  and  $\text{Zn}$  XPS. In the  $\text{Zn}_{0.44}\text{ZrO}_y$ -500 and  $\text{Zn}_{0.56}\text{ZrO}_y$ -500 samples, the exposed  $\text{ZnO}$  particles result in noticeable  $\text{H}_2$  consumption compared to the  $\text{Zn}_{0.01}\text{ZrO}_y$ -500 sample. The  $\text{Zn}_{0.28}\text{ZrO}_y$ -500

reduction profile shifts to lower temperatures, likely due to the formation of nano-sized  $\text{ZnO}$  particles with facilitated reduction compared to bulk  $\text{ZnO}$ . Increasing the calcination temperature gradually shifts the reduction to lower temperatures. In the  $\text{Zn}_{0.19}\text{ZrO}_y$ -700 sample, the low-temperature reduction can be attributed to the enrichment of the surface with Zn, as seen in XPS. In the  $\text{Zn}_{0.19}\text{ZrO}_y$ -800 sample,  $\text{ZnO}$  phase separation lowers the initial reduction temperatures.

$\text{CO}_2$  activation is generally linked to the acid–base properties of the zirconia catalyst surface, with basic surface OH sites forming bicarbonate and acid–base Lewis pairs forming monodentate and bidentate carbonate species.<sup>47,48</sup> The changes in  $\text{ZrO}_2$  basicity upon Zn incorporation and the impact of calcination temperature were assessed using temperature-programmed  $\text{CO}_2$  desorption ( $\text{CO}_2$ -TPD, Fig. 5). Deconvolution of the profiles (Fig. S4†) reveals three desorption features in each sample. According to their peak desorption temperatures, these correspond to weak (100 °C), medium (150–190 °C), and strong (>200 °C) basic sites. The medium and strong basic sites have been linked to chemisorbed  $\text{CO}_2$  on  $\text{Zn}-\text{O}-\text{Zr}$  sites or surface oxygen vacancies.<sup>8</sup>  $\text{CO}_2$  adsorption gradually increases with Zn loading from 14.0  $\mu\text{mol g}^{-1}$  for  $\text{ZrO}_2$  to 37.5  $\mu\text{mol g}^{-1}$

Fig. 5 Temperature-programmed  $\text{CO}_2$  desorption of (a)  $\text{Zn}_x\text{ZrO}_y$ -500 catalysts and (b)  $\text{Zn}_{0.19}\text{ZrO}_y$ - $T$  calcined at 500, 550, 700, and 800 °C.

for  $\text{Zn}_{0.28}\text{ZrO}_y$ -500, and then declines sharply (Table 1). Introducing zinc in a Zn/Zr ratio of 0.01 leads to a 17% increase in total  $\text{CO}_2$  adsorption without notable alterations in the  $\text{CO}_2$  desorption trend (Fig. 5a). This correlates with the transition of monoclinic zirconia to the tetragonal phase, characterized by higher basicity compared to the monoclinic phase,<sup>49</sup> and results in a marginal enhancement in catalyst activity. In the  $\text{ZrO}_2$  catalyst comprising monoclinic and tetragonal phases, strong surface  $\text{CO}_2$  adsorption sites are present. The addition of Zn, however, reduces the strength of these strong basic sites, likely due to the phase transformation from monoclinic, which contains stronger adsorption sites,<sup>50</sup> to tetragonal and cubic phases. Weaker basic sites are reported to facilitate  $\text{CO}_2$  activation and its conversion to formate.<sup>51</sup> Increasing the Zn/Zr ratio up to 0.28 enhances the number of basic sites. The  $\text{CO}_2$  desorption profiles of  $\text{Zn}_{0.07}\text{ZrO}_y$ -500 and  $\text{Zn}_{0.19}\text{ZrO}_y$ -500 exhibit remarkable similarity. The strong basic sites account for half of the total basicity, and the introduction of Zn shifts the temperature of the strong basic sites to lower temperatures (Table S3†). A higher calcination temperature shifts the strong basic sites to slightly higher temperatures (Fig. 5b). At 700 °C, the temperature at which the catalyst is on the verge of phase transformation, the basicity increases to 37.9  $\mu\text{mol g}^{-1}$ . With a further increase in the calcination temperature to 800 °C, the basicity decreases sharply, primarily attributable to limited surface area (see Table 1) and the accumulation of  $\text{ZnO}$  crystals on the surface, which have low  $\text{CO}_2$  adsorption capacity.

### 3.2. DRIFTS

Understanding the adsorption of  $\text{CO}_2$  and methanol on  $\text{ZrO}_2$  and  $\text{Zn}_x\text{ZrO}_y$  mixed oxides is helpful to unravel the effect of Zn on surface interactions and catalytic behaviour. To this

end, we studied the formation of surface species from  $\text{CO}_2$  and methanol adsorption, followed by evacuation under argon.

**3.2.1.  $\text{CO}_2$  interaction with  $\text{Zn}_x\text{ZrO}_y$ .** On pure  $\text{ZrO}_2$ ,  $\text{CO}_2$  adsorption at 325 °C initially results in the formation of weakly interacting (wi- $\text{HCO}_3^-$ ) as well as monodentate bicarbonates (m- $\text{HCO}_3^-$ ), and carbonates (m- $\text{CO}_3^{2-}$ ). Over time, bidentate bicarbonates (b- $\text{HCO}_3^-$ ) and carbonates (b- $\text{CO}_3^{2-}$ ) also appear, with their intensities progressively increasing, Fig. 6a and S5.† The formation of bicarbonates ( $\text{HCO}_3^-$ ) indicates the presence of surface  $\text{OH}^-$  groups,<sup>52</sup> while carbonates ( $\text{CO}_3^{2-}$ ) derive from interaction with surface oxygens. After evacuation under Ar, the weakly interacting and monodentate bicarbonates disappear and the intensity of the monodentate carbonate decreases, indicating the removal of less stable surface species (Fig. 6b).

On  $\text{Zn}_{0.19}\text{ZrO}_y$ -500,  $\text{CO}_2$  initially adsorbs as monodentate carbonates (m- $\text{CO}_3^{2-}$ ) species and weakly interacting bicarbonates (wi- $\text{HCO}_3^-$ ). With time, again bidentate carbonates (b- $\text{CO}_3^{2-}$ ) emerge, but now accompanied by the appearance of polydentate carbonates (p- $\text{CO}_3^{2-}$ ), Fig. 6a and S5.† Following evacuation under Ar (Fig. 6b), the weakly interacting bicarbonates (wi- $\text{HCO}_3^-$ ) disappear, the monodentate carbonates (m- $\text{CO}_3^{2-}$ ) decrease, the polydentate carbonates (p- $\text{CO}_3^{2-}$ ) remain stable, and the DRIFTS features of the bidentate carbonates shift to lower wavenumbers, indicating changes in their binding strength. The formation of bidentate carbonates at different wavelengths, 1578  $\text{cm}^{-1}$  and 1564  $\text{cm}^{-1}$ , is reported to correspond to two slightly different structural arrangements without further specification.<sup>52</sup>

The addition of Zn alters the surface sites, as observed in DRIFTS, and this coincides with changes in  $\text{CO}_2$  adsorption behaviour, as observed in  $\text{CO}_2$ -TPD (Fig. 5). A commonly

**Fig. 6** DRIFTS spectra of (a)  $\text{CO}_2$  adsorption at 325 °C and 10 bar on  $\text{ZrO}_2$ ,  $\text{Zn}_{0.19}\text{ZrO}_y$ -500, and  $\text{Zn}_{0.56}\text{ZrO}_y$ -500 after 40 minutes under 2  $\text{ml min}^{-1}$   $\text{CO}_2$  and 16  $\text{ml min}^{-1}$  Ar and (b) after 40 minutes evacuation at 325 °C and 10 bar under 16  $\text{ml min}^{-1}$  Ar (m: monodentate, b: bidentate, wi: weakly interacting, and p: polydentate species).

stated explanation is an alteration of surface OH groups,<sup>13,17,52,53</sup> however the underlying drivers remain unclear. A possible explanation is an altered surface OH distribution on different  $ZrO_x$  phases. The monoclinic phase is described to be rich in surface OH groups,<sup>17,52,54</sup> while the cubic phase exposes facets with less surface OH.<sup>55</sup> XRD analysis (Fig. 1) indicates a shift towards the cubic phase upon Zn incorporation, but the correspondence to the amount of surface bicarbonates in DRIFTS and  $CO_2$ -TPD is not straightforward. Additionally, XPS data (Fig. 3) confirm the formation of Zn–O–Zr sites on the surface upon Zn addition. These Zn–O–Zr sites provide new adsorption sites,<sup>13</sup> possibly supporting the polydentate adsorption of carbonate, characterized by peaks at  $1400$ – $1480\text{ cm}^{-1}$ .<sup>17,54</sup>

Limited  $CO_2$  adsorption on  $Zn_{0.56}ZrO_y$ -500 is in line with the formation of ZnO covering the surface, as confirmed by XRD and  $N_2$  physisorption. This is consistent with the limited  $CO_2$  adsorption capability of ZnO, as evidenced by the  $CO_2$ -TPD results (Fig. 5).

**3.2.2. Methanol interaction with  $Zn_xZrO_y$ .** Methanol adsorbs on metal oxides surfaces either associatively as intact methanol or dissociatively, forming a methoxy group and a proton. Associative adsorption of methanol *via* its oxygen atom occurs on sufficiently strong Lewis acid sites (LAS) that are not surrounded by highly basic sites. When the LAS is adjacent to basic sites and is not strong enough to favour associative adsorption, a Lewis acid–base pair (LAB) enables dissociative adsorption.<sup>56–58</sup> On  $ZrO_2$ , (Fig. 7) methanol exclusively adsorbs dissociatively, forming methoxy species through interactions with Lewis acid  $Zr^{4+}$  sites adjacent to lattice oxygen basic sites (LAB). In contrast, on  $Zn_{0.19}ZrO_y$ -500, additionally LAS-bound methanol is formed (bands at

$1100$ ,  $2870$ , and  $2960\text{ cm}^{-1}$ ), suggesting the presence of new adsorption sites. This is likely achieved by an altered distribution of basic sites on the surface, facilitating the adsorption of intact methanol.

Dissociative methanol adsorption is observed on all tested samples, but on  $Zn_{0.56}ZrO_y$ -500, these peaks shift to higher wavenumbers, indicating further changes in the surface's electronic environment due to increased Zn content and ZnO formation. The peak intensity at  $1160\text{ cm}^{-1}$  on  $ZrO_2$  also decreases and shifts to  $1150\text{ cm}^{-1}$  upon Zn addition, reflecting alterations in the adsorption sites.

### 3.3. Performance test

The performance for  $CO_2$  hydrogenation was evaluated at  $45$  bar and  $300$ – $400\text{ }^\circ C$  for all synthesized catalysts. Methanol and CO were the main products. Trace amounts of methane and dimethyl ether were also detected in the reactor effluent. Methane formation occurs only at elevated temperatures, above  $350\text{ }^\circ C$ , reaching a maximum formation of  $0.25\%$  of the methanol over  $Zn_{0.56}ZrO_y$ -500 at  $400\text{ }^\circ C$ . DME is produced through the sequential dehydration of methanol on acid sites, reaching a maximum formation of  $3.11\%$  of the methanol over  $Zn_{0.07}ZrO_y$ -500 at  $375\text{ }^\circ C$ . The CTM performance of  $Zn_{0.19}ZrO_y$ -500 at  $350\text{ }^\circ C$  was tested by increasing the reaction temperature and then returning to  $350\text{ }^\circ C$ . The catalyst maintained stable methanol selectivity and STY throughout temperature fluctuations, demonstrating its robustness and ability to perform well under changing thermal conditions (Fig. S6†).

Fig. 8a illustrates the temperature dependence of  $CO_2$  conversion and methanol selectivity. Zinc introduction into

Fig. 7 DRIFT spectra of methanol adsorption at  $200\text{ }^\circ C$  and  $10$  bar on  $ZrO_2$ ,  $Zn_{0.19}ZrO_y$ -500, and  $Zn_{0.56}ZrO_y$ -500 (the spectra were recorded after evacuation of physically adsorbed species under a flow of  $130\text{ ml min}^{-1}$  Ar).

**Fig. 8** Effect of temperature on (a) CO<sub>2</sub> conversion and methanol selectivity and (b) methanol STY of Zn<sub>x</sub>ZrO<sub>y</sub>-500 catalysts, at 45 bar, H<sub>2</sub>:CO<sub>2</sub>:Ar = 3:1:1, and GHSV = 21000 Nml g<sub>cat</sub><sup>-1</sup> h<sup>-1</sup>. (c) Methanol selectivity versus CO<sub>2</sub> conversion on Zn<sub>0.19</sub>ZrO<sub>y</sub>-500 at 325 °C, 45 bar, H<sub>2</sub>:CO<sub>2</sub>:Ar = 3:1:1, and GHSV = 31500, 21000, and 15750 Nml g<sub>cat</sub><sup>-1</sup> h<sup>-1</sup>. (d) Effect of Zn loading on methanol STY at 350 °C, 45 bar, H<sub>2</sub>:CO<sub>2</sub>:Ar = 3:1:1, and GHSV = 21000 Nml g<sub>cat</sub><sup>-1</sup> h<sup>-1</sup>. (e) Effect of temperature on CO<sub>2</sub> conversion and methanol selectivity and (f) methanol STY of Zn<sub>0.19</sub>ZrO<sub>y</sub>-T catalysts, at 45 bar, H<sub>2</sub>:CO<sub>2</sub>:Ar = 3:1:1, and GHSV = 21000 Nml g<sub>cat</sub><sup>-1</sup> h<sup>-1</sup> (full lines: CO<sub>2</sub> conversion-dotted lines: methanol selectivity).

zirconia increases both CO<sub>2</sub> conversion and methanol selectivity across the temperature range. A Zn/Zr ratio of 0.01 has a negligible impact on the catalyst's CTM activity compared to pure ZrO<sub>2</sub>. This doping level was also insufficient to stabilize the cubic phase. Samples containing Zn/Zr = 0.07–0.19 exhibit the highest CO<sub>2</sub> conversion among

the tested samples. For reaction temperatures up to 350 °C, the selectivity to methanol maximally increases to more than threefold that of the Zn/Zr = 0.01 catalyst for the Zn/Zr = 0.19 catalyst, with the major increase with Zn doping occurring between Zn/Zr = 0.01 and 0.07. However, selectivity sharply declines above 350 °C, especially for the Zn/Zr ≥ 0.07

**Scheme 1**  $\text{CO}_2$  hydrogenation to methanol and CO and sequential reaction of methanol.

catalysts. The decline in selectivity with increasing conversion, induced by decreasing the flow rate (Fig. 8c), for  $\text{Zn}_{0.19}\text{ZrO}_y$ -500, suggests sequential reactions of methanol, Scheme 1.

For all catalysts with a  $\text{Zn}/\text{Zr} > 0.01$ , the methanol space-time yield (STY) peaks at  $350\text{ }^\circ\text{C}$ . The maximum methanol STY,  $0.24\text{ g g}_{\text{cat}}^{-1}\text{ h}^{-1}$ , is achieved with  $\text{Zn}/\text{Zr} = 0.07$ , for which a dominant cubic phase was found. This high STY is maintained up to  $\text{Zn}/\text{Zr} = 0.19$ , after which it gradually decreases with further increases in  $\text{Zn}/\text{Zr}$  ratios (Fig. 8b), accompanied by the formation of hexagonal  $\text{ZnO}$ . Although overall and surface  $\text{Zn}/\text{Zr}$  ratios vary, the catalytic activity is similar for  $\text{Zn}_{0.07}\text{ZrO}_y$ -500 and  $\text{Zn}_{0.19}\text{ZrO}_y$ -500 (Fig. 8d). The decrease in catalyst activity at higher  $\text{Zn}$  loadings up to  $\text{Zn}/\text{Zr} = 0.56$  (in agreement with the literature),<sup>7</sup> suggests that the quantity of zinc does not necessarily lead to a rise in the number of active sites. Instead, it tends to augment the abundance of other sites, such as  $\text{ZnO}$ , with lower activity levels.

These results align with literature, where  $\text{CO}_2$  hydrogenation at  $320\text{--}350\text{ }^\circ\text{C}$ ,  $20\text{--}50\text{ bar}$ ,  $\text{GHSV} = 24\,000\text{ ml g}_{\text{cat}}^{-1}\text{ h}^{-1}$ , and  $\text{H}_2 : \text{CO}_2 = 3\text{--}4$  gives a methanol selectivity ranging from 74 to 86%, with methanol formation rates of  $0.2\text{--}0.3\text{ g g}_{\text{cat}}^{-1}\text{ h}^{-1}$ .<sup>13,22,33,34,59,60</sup> An exception was observed for 13%  $\text{ZnO-ZrO}_2$ , which achieved a higher methanol formation rate of  $0.5\text{ g g}_{\text{cat}}^{-1}\text{ h}^{-1}$  under the same conditions.<sup>7</sup> Operating at lower GHSV values of  $4000\text{--}10\,800\text{ ml g}_{\text{cat}}^{-1}\text{ h}^{-1}$  did not enhance performance, with the methanol formation rate dropping to  $0.15\text{--}0.18\text{ g g}_{\text{cat}}^{-1}\text{ h}^{-1}$ .<sup>8,61</sup> An overview of CTM catalysis in literature is included in the ESI† (Table S4, ESI† section 7).

We selected  $\text{Zn}_{0.19}\text{ZrO}_y$ -500 as the best-performing catalyst and conducted catalytic tests on samples calcined at 550, 700, and  $800\text{ }^\circ\text{C}$  (Fig. 8e). Within the examined temperature range, conversion is highest for  $\text{Zn}_{0.19}\text{ZrO}_y$ -550 but declines for higher calcination temperatures. Methanol selectivity becomes less temperature-dependent when using catalysts calcined at 700 and  $800\text{ }^\circ\text{C}$ . Fig. 8f illustrates the methanol space-time yield plotted against temperature. Higher calcination temperatures shift the point of maximum STY to a higher temperature.

## 4. Discussion

### 4.1. Preparation parameters for different zirconia phases

Through varying degrees of zinc doping and different calcination temperatures, we obtained  $\text{Zn}_x\text{ZrO}_y$  materials of monoclinic, tetragonal, and cubic polymorphs, as demonstrated in earlier literature.<sup>62</sup> Monoclinic zirconia is stable at low temperatures, transitioning to the tetragonal phase at around

$1170\text{ }^\circ\text{C}$ , and then into the cubic phase at  $2370\text{--}2680\text{ }^\circ\text{C}$ .<sup>63</sup> The stability of the tetragonal or cubic phase depends on grain size and chemical composition. Particles larger than 30 nm are most stable as monoclinic  $\text{ZrO}_2$ , those smaller than 14 nm as tetragonal  $\text{ZrO}_2$ , and particles smaller than 6 nm as the metastable cubic  $\text{ZrO}_2$  phase.<sup>43,64-66</sup> The tetragonal or cubic zirconia can additionally be stabilized by doping an aliovalent cation such as  $\text{Zn}^{2+}$  into zirconia,<sup>16,67-69</sup> by adding stabilizing oxides,<sup>70</sup> or by adjusting the calcination temperature.<sup>63</sup> Doped cations replace some zirconium ions in the crystal lattice, altering its electronic structure and introducing lattice strains that hinder oxygen atoms' movement and inhibit phase transitions from cubic to other crystalline phases.<sup>43,71-73</sup> With increasing  $\text{Zn}$  doping, the dominant  $\text{ZrO}_2$  crystal phase alters from monoclinic to tetragonal and then to cubic. At calcination temperatures above  $800\text{ }^\circ\text{C}$ , the kinetic barriers preserving the metastable cubic phase are surpassed,<sup>74,75</sup> leading to the transition of the material into tetragonal and monoclinic phases.

In this study, beyond  $\text{Zn}/\text{Zr} = 0.28$ ,  $\text{ZnO}$  phase separation happens, observed as hexagonal  $\text{ZnO}$ . Synthesizing catalysts with a  $\text{Zn}/\text{Zr}$  ratio up to 0.28 increased surface area, pore volume, and basicity. However, the  $\text{Zn}/\text{Zr}$  ratio exceeding 0.44 resulted in bimodal mesoporous materials, indicating the formation of  $\text{ZnO}$  particles and lower surface area, leading to inferior catalytic performance.

### 4.2. Surface property correlations and CTM catalysis

Adding zinc at a  $\text{Zn}/\text{Zr}$  ratio of 0.01 has a negligible impact on the catalyst's activity in methanol synthesis and is insufficient to stabilize the cubic phase. With  $\text{Zn}/\text{Zr} = 0.07$  and 0.19, enhanced methanol STY, 34 times higher than the unpromoted  $\text{ZrO}_2$  catalyst, is observed at  $350\text{ }^\circ\text{C}$  and this coincides with the phase transition to cubic phase. With  $\text{Zn}/\text{Zr}$  ratios of 0.44–0.56, again lower activity is obtained (Fig. S8†) which coincides with zinc phase separation forming hexagonal  $\text{ZnO}$ . This aligns with existing literature,<sup>23</sup> indicating other types of  $\text{Zn}$  sites, such as  $\text{ZnO}$ , with lower activity levels are formed at such high  $\text{Zn}/\text{Zr}$  ratios.

This study aims to assess the structure–function relationship by which the  $\text{Zn}_x\text{ZrO}_y$  crystal phase influences CTM catalysis. The investigated samples yield a large variety of surface physical and chemical properties. From the correlation plot in Fig. 9a, it is clear that many variables correlate strongly among the assessed samples. When focusing exclusively on the pure cubic-phase samples, however, the correlations are very different, highlighting distinct behaviour within this subset. Moreover, the correlation plot indicates a strong positive correlation between cubic phase and selectivity, space-time yield, and  $\text{CO}_2$  conversion in CTM at  $350\text{ }^\circ\text{C}$ . The other phases on the other hand show a negative correlation. The addition of  $\text{Zn}$  to  $\text{ZrO}_2$  enables and enhances  $\text{CO}_2$  conversion and methanol selectivity, as shown in Fig. 9b. Most interestingly, while a general trade-off between conversion and selectivity is observed among the tested samples, those with a pure cubic phase achieve the highest

**Fig. 9** (a) Surface property correlations and CTM catalysis within all samples and (b) methanol selectivity versus CO<sub>2</sub> conversion at 350 °C, 45 bar, H<sub>2</sub>:CO<sub>2</sub>:Ar = 3:1:1, and GHSV = 21 000 Nml g<sub>cat</sub><sup>-1</sup> h<sup>-1</sup> (blue colour: pure cubic-phase, grey colour: cubic-phase + h-ZnO, and orange colour: the rest of the samples).

selectivity for methanol at a given conversion at 350 °C. Although ZrO<sub>2</sub> and Zn<sub>0.19</sub>ZrO<sub>y</sub>-800 convert CO<sub>2</sub> to a similar extent and exhibit comparable crystal phases, the presence of Zn in Zn<sub>0.19</sub>ZrO<sub>y</sub>-800 promotes selective methanol production in the reaction.

The cubic materials are also those with the highest pore volume and surface area, smallest pore size, and highest surface Zn. We therefore additionally look at surface properties in relation to pore volume, surface area, or surface zinc concentration as these metrics more suitably pinpoint desirable properties of the surface structure on a molecular level. Individual two-dimensional plots are shown in Fig. 10 and 11, and ESI† section 9 – parameters correlation where it can also be seen that samples with a pure cubic phase occupy distinct regions in the plots (shown in blue).

For all samples, there is a clear positive correlation between specific surface area and conversion and for samples containing

cubic phase, there is a clear negative correlation between selectivity and pore volume (Fig. S7†) in which the cubic-phase-free samples do not fit. From Fig. 9b and S8b,† while conversion correlates strongly positively with pore volume (and thus negatively with selectivity, as is logically expected) for all samples, the pure cubic samples still demonstrate high selectivity at high pore volumes. This may, in part, be attributed to their unique combining of high CO<sub>2</sub> adsorption per pore volume and selectivity as well as their low H<sub>2</sub> uptake per pore volume (Fig. 10). From the available data, we cannot draw full conclusions on what sets the cubic phase samples apart from the others in this regard, but the observed beneficial effect of lower H<sub>2</sub> uptake is surprising. It counterintuitively seems to favour selectivity to the more reduced methanol over CO, potentially by limiting further methanol decomposition to CO, while hydrogen activation and spillover are commonly seen as the rate-determining step (RDS) in methanol synthesis.<sup>74,75</sup> The

**Fig. 10** Effect of pore-volume normalized (a) CO<sub>2</sub> uptake and (b) H<sub>2</sub> uptake on methanol selectivity at 350 °C, 45 bar, H<sub>2</sub>:CO<sub>2</sub>:Ar = 3:1:1, and GHSV = 21 000 Nml g<sub>cat</sub><sup>-1</sup> h<sup>-1</sup> (blue colour: pure cubic-phase, grey colour: cubic-phase + h-ZnO, and orange colour: the rest of the samples).

**Fig. 11** For a sub-selection of the measured samples, all with a dominant cubic phase; effect of (XPS) surface Zn/Zr ratio on (a) pore volume normalized  $H_2$  uptake (solid points) and methanol selectivity (empty points), and (b)  $CO_2$  conversion (solid points) and methanol STY (empty points), (blue colour: pure cubic-phase + h-ZnO) and (c) effect of (XPS) surface Zn-O-Zr species on  $CO_2$  conversion (solid points) and methanol selectivity (empty points), at 350 °C, 45 bar,  $H_2:CO_2:Ar = 3:1:1$ , and GHSV = 21 000 Nml  $g_{\text{cat}}^{-1} h^{-1}$ .

existence of the cubic phase may confound solid-phase diffusion during synthesis, which could enhance favourable zinc speciation at the surface. While surface zinc is essential, CTM catalysis appears to be more advantageous with cubic phase catalysts for reasons not fully addressed by current data. Coupled with literature, linking  $CO_2$  adsorption to oxygen vacancy sites<sup>17,21,22</sup> suggests that surface zinc indeed facilitates  $CO_2$  adsorption. However, the cubic phase seems to provide a specific combination of oxygen vacancies and surface zinc, promoting CO formation only to a limited extent compared to other catalysts.<sup>15</sup>

The role of the crystal phase in methanol synthesis was highlighted in a recent study examining monoclinic *versus* tetragonal phases. The tetragonal phase achieved significantly higher methanol selectivity (81% *versus* 39%) and STY (0.04 *versus* 0.02  $g g_{\text{cat}}^{-1} h^{-1}$ ) compared to the monoclinic phase at 320 °C, using a  $Zn_xZrO_y$  catalyst.<sup>26</sup> In the present study, methanol STY reached 0.20  $g g_{\text{cat}}^{-1} h^{-1}$  on the cubic phase sample, with comparable selectivity, underscoring the importance of stabilizing the optimal crystal phase. Clearly, certain crystal phases, in particular the cubic one, enhance the performance of  $Zn_xZrO_y$  catalyst in CTM. In addition to the Zn-induced phase change observed in XRD (Fig. 1), DRIFTS indicates that Zn influences surface basicity, which also affects

CTM catalysis by means of  $CO_2$  and methanol chemisorption (Fig. 5–7). Hence, Zn contributes to CTM catalysis by inducing structural changes in two ways. Disentangling the latter requires further study of the quantitative structure–function relations.

It is informative to further analyse surface Zn's electronic properties for the samples containing cubic phase  $Zn_xZrO_y$ , and their association with CTM catalysis (Fig. 11). For the cubic samples calcined at 500 °C, particularly in the ZnO phase-separated samples ( $Zn_{0.44}ZrO_y$  and  $Zn_{0.56}ZrO_y$ ), a positive correlation is observed between the increased surface Zn/Zr concentration and the pore-volume normalized  $H_2$  uptake (Fig. 11a). This suggests a role for surface Zn (or ZnO) in steering selectivity through the surface density of adsorbed  $H_2$ . In Fig. 11a, methanol selectivity peaks at a surface Zn/Zr ratio of 0.2–0.4. However, further increasing the surface Zn/Zr ratio and the formation of ZnO particles negatively affects methanol selectivity. Fig. 11b confirms that  $CO_2$  conversion and methanol STY are optimal within a narrow range of surface Zn/Zr ratios. More specifically, the presence of Zn–O–Zn bonds correlates positively with methanol selectivity and negatively with  $CO_2$  conversion, (Fig. 11c), suggesting that  $H_2$  activation over Zn–O–Zr sites is not rate controlling, since a higher Zn–O–Zr surface fraction yields a lower conversion. This implies that the electronic properties of the surface

atoms are crucial in determining the catalyst's behaviour, especially when the crystal phase is cubic. This electronic interaction is presumably more important than the physical characteristics of the pores, as it directly affects the reactivity and selectivity of the catalysts. This is supported by efforts to increase surface area using the evaporation-induced self-assembly method (EISA) to achieve  $96\text{ m}^2\text{ g}^{-1}$  compared to  $48\text{ m}^2\text{ g}^{-1}$  with the coprecipitation method, which resulted in only a minor increase in  $\text{CO}_2$  conversion, from 4% to 5.5% at  $320\text{ }^\circ\text{C}$ .<sup>33</sup>

## 5. Conclusions

This study explored the influence of Zn on the structure of  $\text{Zn}_x\text{ZrO}_y$  and its catalytic performance in  $\text{CO}_2$  hydrogenation to methanol. Zinc incorporation into the zirconia lattice induces a phase transformation from monoclinic and tetragonal to mainly tetragonal phase in  $\text{Zn}_{0.01}\text{ZrO}_y$ -500. The cubic phase becomes dominant from a Zn/Zr ratio of 0.07. Catalysts with a Zn/Zr ratio of 0.07 and 0.19 demonstrate enhanced methanol formation. The cubic phase remains stable up to the calcination temperature of  $700\text{ }^\circ\text{C}$ , above which a transition to tetragonal and monoclinic phases occurs. The decreased catalytic activity of such samples can be attributed to the formation of agglomerated  $\text{ZnO}$  particles and the phase transformation.

An optimal zinc content for CTM catalysis facilitates the formation of a mixed oxide, resulting in the formation of the cubic phase and enhances  $\text{CO}_2$  adsorption sites. Elevating the calcination temperature further indicates the significance of the cubic zirconia crystal phase. Within the pure cubic-phase samples, the surface Zn/Zr ratio and the concentration of Zr–O–Zn species correlate positively with  $\text{CO}_2$  adsorption capacity and methanol selectivity. Insufficient zinc content fails to stabilize the cubic phase, while excessive zinc content leads to  $\text{ZnO}$  phase separation. Both are detrimental to catalyst performance. Although the surface Zn/Zr ratio shows a positive correlation with pore volume-normalized  $\text{H}_2$  uptake, increased  $\text{H}_2$  uptake does not necessarily translate to improved CTM performance. Rather, a narrow range of surface Zn/Zr is advantageous, enhancing both methanol selectivity and  $\text{CO}_2$  conversion.

Further analysis of the catalysts at  $350\text{ }^\circ\text{C}$  reveals the underlying drivers for  $\text{CO}_2$  conversion to methanol, indicating that moderate Zn doping combined with a pure cubic phase induces the most effective CTM catalysts regarding methanol space–time yield (STY). Because a variety of catalytically relevant surface properties vary simultaneously, pinpointing the exact reason for this observation on an active site level remains challenging, both from our collected data and existing literature. A possible explanation lies in the changed concentration and distribution of surface basicity on the zirconia surface. Nevertheless, we identify informative correlations for CTM catalysis and can conclude that a ‘one-fits-all’ explanation of the role of zinc in promoting  $\text{ZrO}_x$  catalysts for CTM is inadequate. It is an example of the commonly

encountered complexity in catalytic structure–function relationships.

## Data availability

The processed data supporting this article ( $\text{N}_2$  physisorption, XPS, SEM-EDX,  $\text{CO}_2$ -TPD, DRIFTS and catalyst stability test) have been included as part of the ESI.† Raw data are available on request from the corresponding author.
