Tunable bis(pyridinium amidate) ligands efficiently promote palladium-catalyzed ethylene polymerization

Esaïe Reusser and Martin Albrecht *

A useful strategy for the co-polymerization of ethylene and functional olefins relies on palladium catalysts, as palladium typically shows in contrast to many other metals a high tolerance to a variety of functional groups. Here we have prepared a set of palladium complexes containing a *N,N*-bidentate coordinating bis(pyridinium amidate) (bisPYA) ligand. Ligand variation included either *para*- or an *ortho*-pyridinium amidate arrangement, with the pyridinium site either sterically flexible or locked through a dimethyl substitution *ortho* to the amidate. Activation of these complexes with NaBARf in the presence of ethylene indicated that sterically locked ligand structures promoted ethylene conversion and produced polymeric materials. In particular, complex **4d** with an *ortho*-pyridinium amidate bisPYA ligand was active with a production of 10.8 kg polyethylene per mol palladium at room temperature and 1 bar ethylene. Synthesis of the complexes in the presence of K_2CO_3 or Ag_2CO_3 afforded adducts in which the K^+ or Ag^+ ion is bound by the two oxygens of the bisamidate core, thus leading to trimetallic $Pd \cdots K \cdots Pd$ complexes. Such adduct formation indicates a dual role of NaBARf in halide abstraction and metal sequestration, thus rationalizing the need for 2.5 equivalent of NaBARf per palladium complex for effective polymerization.

Introduction

A comparison of classic palladium-based catalysts for olefin (co)polymerization, such as those reported by Brookhart,¹ Drent² and others^{3,4} has revealed that sterically adaptable and strongly electron-donating ligands such as **I** (Fig. 1) are beneficial and in fact essential for the production of polymeric materials.^{5–11} Building on these findings, pyridinium amidate (PYA) ligands that combine the structural versatility of these systems with strong donating properties have been proposed as an alternative to address specific challenges in Pd-catalyzed polymerization.¹² The adaptable PYA scaffold is attractive for modulating both electronically and sterically the metal coordination sphere,¹³ making it a promising platform for facilitating the copolymerization of ethylene with polar monomers. However, attempts to use dissymmetric *N,N'* ligands with a PYA *N*-donor and a chelating imine such as pyridine (**II**, Fig. 1), pyrazole, oxazole, or triazole displayed significant limitation and produced almost exclusively butenes *via* ethylene dimerization rather than polymerization.^{14,15} While this product selectivity was initially attributed to fast β -hydrogen elimination, recent mechanistic investigations indicated a step-growth mechanism rather than a chain-growth, implying re-coordination of butene as the critical step

that controls further conversion of dimers to oligomers and polymers.^{16,17} These mechanistic insights also suggest a key role of the ancillary ligand and the counterion,¹³ and suggest optimization of the steric and electronic properties of the chelating *N*-ligand as a key methodology for catalyst improvement.

Here, we introduce a novel class of palladium complexes supported by strongly donating and sterically versatile bisPYA ligands **III** (Fig. 1). Deliberate substitution of the *ortho*-positions of the PYA scaffold increases steric shielding, which plays an important role in improving the reactivity and selectivity of the catalyst. These ligands are sterically similar to state-of-the-art Brookhart's α -diimine ligands^{18–23} while having significantly altered electronic properties. Specifically, the introduction of two strongly electron-donating PYA groups within one ligand generates an electron-rich metal center, which is expected to be beneficial for higher polymerization productivity.²⁴ Here, we demonstrate that appropriately tailored bisPYA ligands induce high catalytic activity and effectively promote polymerization even under very mild conditions.

Results and discussion

Synthesis of the complexes

The synthesis of the bisPYA ligands started from the appropriately substituted aminopyridine **1a–d** (Scheme 1).

Department of Chemistry, Biochemistry and Pharmaceutical Sciences, University of Bern, Freiestrasse 3, 3012 Bern, Switzerland. E-mail: martin.albrecht@unibe.ch

Fig. 1 Structural comparison between the state-of-the-art palladium olefin (co)polymerization precatalyst supported by α -diimine ligands (I), pyridyl-PYA ligands (II) inducing di- and oligomerization, and bisPYA ligands investigated in this work.

Condensation with either diethyl oxalate or oxalyl chloride yielded the corresponding bis(amides), and subsequent pyridine *N*-methylation followed by anion exchange with NH_4PF_6 afforded the bisPYA ligand precursors **2a–d** as PF_6 salts. Complete methylation was evidenced by a characteristic downfield shift of the pyridinium proton resonances. For example, the pyridinium H^6 resonance shifted from $\delta_{\text{H}} = 8.32$ in the bis(amide) to 8.64 in **2d**.

Crystals suitable for X-ray diffraction analysis were grown for **2b** and **2d** by slow diffusion of Et_2O into a MeCN solution of the bisPYA salts. These compounds were of interest as they feature identical steric environments around the amide site, yet differ in the position of the pyridine nitrogen. Analysis of the molecular structure of the *para*-PYA system **2b** revealed an $\sim 60^\circ$ torsion angle between the amide and the pyridinium heterocycle (Fig. 2). In contrast, the heterocycles in the *ortho*-PYA salt **2d** are quasi orthogonal to the amide unit with an $84.3(5)^\circ$ torsion angle. This trend is in line with the smaller torsion angles in the *para*-PYA salt **2a** compared to the *ortho*-PYA analogue **2c** (6.94° vs. 40.46°),²⁵ though in this latter comparison, the different *ortho*-substitution pattern may play a significant role.^{15,26} In contrast, a comparison of the smaller torsion angle in **2b** vs. large angles in **2d** suggests that the *ortho* vs. *para*-PYA substitution influences the

arrangement of the heterocycle with respect to the amide unit independent of steric components.

The bis(PYA) salt **2c** readily formed the deprotonated free bis(PYA) ligand **3c** in the presence of DBU. Double deprotonation and formation of **3c** was evidenced by a substantial upfield shift of all the pyridinium proton signals ($\Delta\delta_{\text{H}}$ up to 1.2 ppm). Similarly, the NCH_3 resonance shifted from $\delta = 4.20$ to 3.72 ppm. In contrast to **2c**, the other bis(PYA) salts failed to give clean reactions. Attempts to deprotonate these salts with bases such as K_2CO_3 , DBU, or LiHMDS all failed (Scheme 2). While characteristic resonances of the deprotonated bis(PYA) were observed *in situ*, e.g. treatment of **2d** with 2.5 eq. DBU resulted in a diagnostic²⁷ upfield shift of the NCH_3 resonance from $\delta_{\text{H}} = 4.26$ to 3.70, isolation of this species by sequential THF washing did not lead to any clean material.^{28,29} With a stronger base like LiHMDS, an unknown species was isolated, tentatively assigned to the Li adduct (Fig. S17 and S18).³⁰

Single crystal structure determination of **3c** revealed some degree of double-bond localization within the pyridine ring, e.g. $C_{\text{pyr}3}-C_{\text{pyr}4}$ decreased from 1.380(2) Å in **2c**²⁵ to 1.3653(19) Å in **3c**, and the exocyclic $C_{\text{PYA}}-\text{N}_{\text{PYA}}$ bond shortened from 1.3924(19) Å in **2c** to 1.338(14) Å. Moreover, the amide unit and the pyridinium heterocycle are essentially co-planar with a torsion angle $C_{\text{CO}}-\text{N}_{\text{PYA}}-C_{\text{PYA}}-\text{N}_{\text{pyr}} = 4.01(9)^\circ$ vs. $40.46(15)^\circ$ in the salt precursor. However, the two amide units lost co-planarity and are essentially orthogonal in **3c** with $\text{N}_{\text{PYA}}-\text{C}_{\text{CO}}-\text{C}_{\text{CO}'}-\text{N}_{\text{PYA}'} = 89.40(11)^\circ$ (cf. $0.0(3)^\circ$ in **2c**). This arrangement also led to a close 2.23(1) Å contact between H3 of the pyridinium ring and the adjacent carbonyl oxygen.

Scheme 1 Two-step synthesis of bis-PYA ligands **2a–2d**. Conditions: For **2a** and **2c**: 1) diethyl oxalate, neat, 2) MeOTf in CH_2Cl_2 ; for **2b**: 1) oxalyl chloride, NEt_3 in CH_2Cl_2 , 2) MeI in CH_2Cl_2 ; for **2d** 1) oxalyl chloride, NEt_3 in CH_2Cl_2 , 2) MeOTf in CH_2Cl_2 .

Fig. 2 Crystallographically determined molecular structures of a) **2b** and b) **2d** (all hydrogen atoms and anions omitted for clarity). Selected metrics for **2b**: $\text{N}2-\text{C}4$ 1.414(3) Å; $\text{C}7-\text{N}2-\text{C}4-\text{C}3$ $58.8(3)^\circ$; for **2d**: $\text{N}2-\text{C}2$ 1.408(2) Å, $\text{C}7-\text{N}2-\text{C}2-\text{N}1$ $84.3(5)^\circ$.

Scheme 2 Synthesis of Pd complexes **4a–4d** with PYA ligand sites represented in their zwitterionic (pyridinium amidate) resonance form, though there is also contribution from a neutral pyridylidene imine resonance form to be considered. Bottom left: crystallographically determined molecular structure of **3c** (50% probability ellipsoids, hydrogen atoms omitted for clarity). Selected metrics for **3c**: N2–C2 1.338(14) Å; C7–N2–C2–N1 4.01(9)°.

Direct palladation of the bis(PYA) salts **2a–d** without isolation of the deprotonated ligand was accomplished with [PdMeCl(cod)] in the presence of 1,8-bis(dimethylamino)naphthalene (proton sponge) as a base and afforded complexes **4a–d** in 70–89% yield. Alternatively, neutral bis(PYA) **3c** was metalated with [PdMeCl(cod)] in the absence of a base. All four complexes were isolated as air-stable yellow solids. Complex formation was indicated by the high-field singlet of the Pd–CH₃ resonance in the –0.39 to –0.64 range. These frequencies suggest considerable shielding of the methyl group in complexes **4b–d** when compared with related olefin polymerization precatalysts supported by α -diimine ($\delta_{\text{H}} = +0.51$) or C,N-bidentate pyridyl-NHC ligands ($\delta_{\text{H}} = +0.01$).^{17,31–34} Only catalyst precursors with anionic C,O-bidentate phenolate-NHC ligands feature a higher field Pd–CH₃ signal ($\delta_{\text{H}} = -0.81$),³⁵ pointing to a strongly electron-donating bonding mode of the bisPYA ligand (Table S1) and thus a large contribution of zwitterionic resonance structures in **4b–d**. Notably, the Pd–CH₃ resonance of complex **4a** appears at a lower field ($\delta_{\text{H}} = +0.13$). The bis(PYA) ligand in this complex lacks *ortho*-substituents with respect to the amide group, which facilitates a coplanar arrangement of the amide and the pyridinium heterocycle and thus a quinoidal character of the ligand with neutral π -acidic rather than anionic π -basic N-donor sites.³⁶

Characterization of complexes **4b** and **4d** by ¹H NMR spectroscopy revealed a mixture of two species at RT in DMSO, attributed to a mixture of the parent (methyl)

(chloride) complex and its solvento analogue [PdMe(DMSO)(bisPYA)]Cl in a 1:2 and 4:1 ratio, respectively. In support of this assignment, addition of NBu₄Cl increased the ratio of the chlorido complex **4b**, while addition of AgPF₆ afforded the solvento complex, together with some complex degradation products (Fig. S30 and S36). The higher solvento ratio with **4b** compared to **4d** suggests a higher *trans*-influence and stronger σ donor properties of the *para*-PYA in **4b** than the *ortho*-PYA for quasi-isosteric ligands. This conclusion is also supported by the slightly higher field Pd–CH₃ resonance in **4b** compared to **4d** ($\delta_{\text{H}} = -0.64$ vs. -0.58).^{37–39}

Complexes **4a–d** display only limited stability in dry DMSO-*d*₆ and new and sharper resonances appeared over time, presumably due to the hygroscopic nature of DMSO. Indeed, dissolving complex **4a** in D₂O resulted in the immediate appearance of a new species, together with a resonance at 0.2 ppm that is diagnostic for methane formation.⁴⁰ After 90 min, no residual complex **4a** was detectable anymore, and only the new species was present (Fig. S25). Macroscopically, formation of a palladium mirror was observed, and pressure build-up was noted when opening the NMR tube. These results indicate protonolysis of the Pd–CH₃ unit,^{41–43} which is known to occur even with weak acids,⁴⁴ and subsequent ligand rearrangement to form [Pd(bisPYA)₂]Cl₂.¹⁷ The homoleptic complex [Pd(bisPYA)₂]Cl₂ was identified by the symmetrization of the ligand resonances in the NMR spectra, and by HRMS ($m/z = 681.0948$, calcd for [M–Cl]⁺ 681.0957, Fig. S25). Similar reactivity was noted for complexes **4c** and **4d**, though protonolysis was much slower with these complexes and only 5% degradation was observed after 8 h.⁴⁵

Reactivity towards ethylene

In order to probe ethylene conversion, complexes **4a–d** were activated *in situ* with NaBARF, an established additive for enhancing catalytic activity in olefin oligomerization.^{17,46–50} The *in situ* activation furthermore avoids the introduction of an ancillary ligand such as MeCN that may interfere with olefin bonding and conversion.^{16,51} To assess the potential activity of the palladium complexes, a solution of bisPYA complexes **4a–d** and 1.1 eq. NaBARF in CD₂Cl₂ was saturated with ethylene (1 bar, *ca.* 1 M), and olefin conversion was monitored by ¹H NMR spectroscopy (Table 1, Fig. S53–S59). Under these conditions, complex **4a** produced predominantly butenes in the first 45 min, and this composition did not change upon extending the reaction time to 16 h (Table 1, entry 1, Fig. S58). This low activity towards olefin oligomerization may, in part, be attributed to the low solubility of **4a**. In an attempt to improve the solubility, complex **4a'** with *N*-Bu rather than *N*-Me substituents was prepared (Fig. S26). Despite the longer aliphatic substituents, the solubility of **4a'** was not significantly improved and catalytic activity was identical to that of **4a** (entry 2). When the *para*-PYA was sterically rigidified by two methyl

^a Reaction conditions: [Pd] (10 μmol), NaBARF (11 or 25 μmol), durene (50 μmol, internal standard) in dry CD₂Cl₂ (0.5 mL) saturated with ethylene (~1 M). ^b Conversion monitored by ¹H NMR spectroscopy after 45 min and 16 h under constant spinning at 23 °C, incomplete ethylene conversion was determined by ¹H NMR integration of the butene and propylene resonances against the residual ethylene signal and is approximate only. ^c Alkyl/vinyl and linear/branched (l/b) ratios determined by ¹H NMR spectroscopy of the crude reaction mixture (Fig. S53–S55). ^d Decreasing alkyl/vinyl ratio attributed to the precipitation of polymeric products.

substituents as in complex **4b**, the activity increased and oligomers were formed upon extended periods of time, indicated by the 15 : 1 alkyl/vinyl proton ratio after 16 h (entry 3, Fig. S53–S55).

A similar correlation between catalyst structure and activity was observed for the *ortho*-PYA complexes. While the un-substituted *ortho*-PYA complex **4c** was only poorly active and did not reach full ethylene conversion, yielding predominantly butenes (entry 4), the methylated version **4d** promoted the formation of oligomers already within the first 45 min, and these chains further grew upon extending the reaction time to reach a 31 : 1 alkyl/vinyl ratio after 16 h (entry 5). Also, the branching degree of the oligomers increased considerably from 20 : 1 to 20 : 15 during this time, indicating efficient olefin insertion and β-H elimination processes. GC-MS analysis revealed the presence of fragments as large as C₂₄H₄₈ (Fig. S64–S76).

Higher activity was achieved when the quantity of NaBARF was increased to 2.5 eq. While complex **4a** gave only modestly longer oligomers, with butenes remaining the major products (entry 6), **4b** resulted in the formation of oligomers already after 45 min (17 : 1 alkyl/vinyl ratio), and gave polymeric material after 16 h, indicated by a high 190 : 1 alkyl/vinyl ratio (entry 6). Again, branching increased drastically during the process. While initially the formed oligomers were essentially linear with a 99 : 1 linear/branched ratio, this ratio switched to 1 : 4 after 16 h (entry 7). The effect is even more pronounced with the *ortho*-PYA systems **4c** and **4d**. Complex **4c** gave oligomeric products (entry 8), whereas the rigid *ortho*-dimethyl PYA yielded polymeric material already after 45 min with a 340 : 1 alkyl/vinyl ratio (entry 9; Fig. S60 and S61). The preference of the catalyst to initially form linear products is shown also for **4d** with a 5 : 1 linear/branched ratio, though after 16 h, no linear fragments were observed

anymore, suggesting a very high branching degree as required for low-density PE. The high branching is attributed to a very effective chain walking and β-hydrogen elimination processes imparted by the sterically rigid and shielding bisPYA ligand.

Obviously, the mild conditions (1 bar ethylene, room temperature, closed system) used for assessing these preliminary activities introduce a limited availability of ethylene, which also caps the polymer length and the catalyst productivity. Therefore, experiments were carried out by providing a continuous supply of ethylene (1 bar) into the reaction mixture. Under these conditions, only complexes **4b** and **4d** yielded polymeric products. The productivity of **4b** was rather poor and reached 1.4 g PE per g Pd, presumably due to fast catalyst decomposition as indicated by the detection of some signals in the NMR spectrum that suggest a dissociated bis(PYA) ligand. In contrast, complex **4d** produced a waxy polymer that was partially soluble in CD₂-Cl₂. NMR analysis revealed a high branching degree of 111 methyl groups per 1000 methylene units¹¹ with a wide variety of branching structures and topologies (Fig. S62 and S63).^{52–54} Under these ambient conditions, **4d** reached a productivity of 101.5 g PE per g Pd or 10.8 kg PE per mol Pd. These values are at the lower end when comparing with the Pd(acac)₂/BF₃·OEt₂ system,^{55a} or phosphine-sulfonate systems with ferrocene or naphthalene bridges, even though the latter were used at 5–10 bar ethylene pressure.^{55b,c} The productivity is also far from the 4000 kg PE per mol Pd productivity of state-of-the-art Brookhart-type palladium catalysts, though those conversions were obtained under harsher conditions (10 bar ethylene, 60 °C)^{22,56} compared to the 1 bar/25 °C conditions applied here for **4d**. Therefore, the productivity and selectivity of complex **4d** represents a promising improvement towards efficient polymerization catalysts based

on PYA ligands, warranting further tests under (co-) polymerization conditions closer to those of industrial settings in terms of temperature, pressure, and possibly comonomer addition.

Metal sequestration by the bisPYA ligand

The excess of NaBARF required to induce high catalytic activity suggests interactions with the Pd complex beyond simple halide abstraction and formation of the putative active species $[\text{Pd}(\text{Me})(\text{ethylene})(\text{bisPYA})]^+$. Based on scattered observations of alkali metal bonding to PYA units, we hypothesized a direct interaction between the Na^+ cation with the bis(amide) backbone of the bis(PYA) ligand of the complex as established for other 1,2-dicarbonyl ligands.^{57,58} Such a bonding might lower the efficacy of NaBARF in halide abstraction with detrimental consequences for catalytic activity.

To verify this hypothesis, reactions of complexes **4a–d** with different sodium salts (NaBARF , Na_2CO_3) were carried out, though no defined products were detectable. As an alternative route, palladation of ligand precursors **2a** or **2d** in the presence of Na_2CO_3 led to incomplete reactions and the formation of mixtures. However, complexation of these ligands with $[\text{PdMeCl}(\text{cod})]$ in the presence of Ag_2CO_3 resulted in the formation of spectroscopically pure trimetallic complexes **5a** and **5d**, respectively, which were isolated as air-stable dark yellow solids (Scheme 3). The ^1H NMR spectra

were distinct from those of **4a** and **4d**, most evidently by the downfield shift of the Pd–CH₃ resonance, e.g. $\delta_{\text{H}} = +0.29$ for **5a** vs. $+0.13$ for **4a** (both DMSO-*d*₆ solutions). Addition of AgPF_6 to a MeCN solution of **4d** gave a precipitate, which has ^1H NMR data identical to those of **5d**, thus providing an alternative synthetic method. Moreover, similar adduct formation was observed when K_2CO_3 was used instead of Ag_2CO_3 , yielding the corresponding trimetallic $\text{Pd}\cdots\text{K}\cdots\text{Pd}$ complexes **6a** and **6d** as air-stable yellow solids.

Adduct formation was confirmed by single-crystal X-ray diffraction of complex **6d**. The molecular structure shows a potassium ion connecting two Pd complex units *via* dicarbonyl chelation. The potassium coordination sphere is completed by interaction with fluorine atoms from two distinct PF_6^- anions. These interactions suggest cation stabilization by the bis(PYA) ligand backbone similar to *O*- or *N*-polydentate systems such as crown ethers and cryptands.^{59,60} The average K–O distance in **6d** is 2.74 Å, in line with the 2.72 Å reported as the mean value for such interactions.^{57,58,61} The K–F contact distances range from 2.815(16) to 3.05(2) Å, at the longer edge of the typically observed 2.84 Å length.^{62–66}

The Pd centers adopt the typical square planar geometry, and the PYA rings are nearly orthogonal to the coordination plane ($\text{Pd}-\text{N}_{\text{PYA}}-\text{C}_{\text{PYA}}-\text{N}_{\text{PYR}} = 82.6(6)^\circ$), indicative of strongly zwitterionic PYA character. Structural comparisons with the precursor salt **2d** reveal only minimal variation in the

Scheme 3 Synthesis of silver-bridged cationic complexes **5a** and **5d** and potassium-bridged complexes **6a** and **6d**, and a crystallographically determined molecular structure of **6d** (hydrogen atoms and non-coordinating anions omitted for clarity). Selected metrics for **6d**: Pd1–C16 2.060(14) Å, Pd1–N2 1.978(5) Å, Pd1–N3 2.055(4) Å, Pd1–N5 2.006(10) Å, C7–O1 1.238(7) Å; average K–O 2.74 Å, average K–F contact 2.97 Å, C7–N2–C2–N1 72.8(7)°; Pd1–N2–C2–N1 82.6(6)°; N2–Pd1–N3 82.79(17)°.

exocyclic $N_{\text{PYA}}-C_{\text{PYA}}$ bond lengths (1.416(8) Å in **6d** vs. 1.408(2) Å in **2d**), reinforcing the strongly donating nature of the ligand framework. Notably, the unit cell contains both *syn*- and *anti*-isomers as proposed for complex **4d**.³⁷

Elemental analysis of bulk **6d** suggests a slightly higher sequestration of K^+ and returned a 1:1 ratio of KPF_6 per Pd(bisPYA) fragment. Similarly, quantitative $^1H/^{19}F$ NMR integration using 1,2,4,5-tetrafluorobenzene as an internal standard was commensurate with 2 PF_6^- anions per bisPYA ligand (Fig. S1 and S2).^{29,67–69} Although attempts to grow single-crystals for the other adducts were unsuccessful, elemental analysis and quantitative ^{19}F NMR spectroscopy provided good support for similar cation bonding in **5a**, **5d** (1.5 PF_6^- per ligand) and **6a** (1.2–2 PF_6^- per ligand; Fig. S1 and S2).

Detailed characterization of these adducts in solution was hampered by the broadness of the 1H NMR signals. For **5a**, two sets of signals were identified in CD_3CN solution. Increasing the temperature to 40 °C resulted in sharpening of the signals into well-defined doublets, suggesting dynamic behavior (Fig. S40). DOSY NMR analysis revealed that the two sets of signals belong to species with similar diffusion coefficients, pointing to stereoisomers such as *syn*- and *anti*-rotamers rather than silver association/dissociation equilibria (Fig. S41). The molecular weight extracted from the measured diffusion coefficient (930 $g\ mol^{-1}$; $D = 9.3 \times 10^{-6}\ cm^2\ s^{-1}$) is consistent with the 973 $g\ mol^{-1}$ calculated for the Ag-containing trication of **5a**.^{70–72} Similar solution behavior was noted for adducts **5d**, **6a**, and **6d**. Moreover, mass spectrometry revealed fragments corresponding to the Pd complex unit plus an Ag^+ and K^+ cation, respectively (Fig. S42, S45, S49 and S52).

Evaluation of the adducts **5** and **6** in ethylene conversion is convoluted by the presence of the MeCN in the palladium coordination sphere. This ligand has been shown to hinder

butene coordination and the formation of polymeric products.^{16,51} Indeed, only butene formation was observed upon exposure of the adducts to ethylene (Table 2, entries 1–4). While complexes **5d** and **6d** with sterically shielding PYA sites lead to considerable ethylene conversion, the *para*-PYA analogues **5a** and **6a** were less active and residual ethylene was detected after 1 h. Addition of 1.1 eq. NaBARF to adduct **5d** induced some oligomerization, while 2.5 eq. NaBARF as an additive gave longer oligomers as deduced from the high 90:1 ratio of alkyl to vinyl protons in the NMR spectrum (entries 5 and 6). Similar effects were observed with the potassium adduct (entries 7 and 8), suggesting that either the BARF anion itself, or the cation exchange from Ag^+ or K^+ to Na^+ plays a significant role in the butene conversion activity of the palladium complexes.

Conclusions

This work demonstrates for the first time the efficiency of pyridinium amidate (PYA) ligands in promoting palladium-catalyzed ethylene polymerization, thus expanding the family of *N,N*-bidentate ligands for this type of reaction beyond α,α' -diimine and bian-type ligands. Related PYA ligand systems have succeeded in converting ethylene, though they afforded either selectively butenes from dimerization, or low-molecular weight oligomerization products, but never showed activity in polymerization. A critical parameter for entailing polymerization is an orthogonal arrangement of the pyridinium heterocycles with respect to the bis-amidate core of the bisPYA ligands, which was imposed by the introduction of *ortho*-dimethyl substitution of the pyridinium ring. Moreover, electronic tailoring of the ligand by using 2-aminopyridine (*ortho*-PYA) scaffolds and *in situ* catalyst activation with BARF to suppress solvent coordination are key factors for

^a Reaction conditions: [Pd] (10 μmol), NaBARF (0, 11 or 25 μmol), durene (50 μmol , internal standard) in dry CD_2Cl_2 (0.5 mL) saturated with ethylene ($\sim 1\ M$). ^b Conversion monitored by 1H NMR spectroscopy after 45 min and 16 h under constant spinning at 23 °C, incomplete ethylene conversion was determined by 1H NMR integration of the butene and propylene resonances against the residual ethylene signal and is approximate only. ^c Ratios determined by 1H NMR spectroscopy of the crude reaction mixture (Fig. S53–S55). ^d Decreasing alkyl/vinyl ratio attributed to the precipitation of polymeric products.

ensuing polymer growth. The sensitivity to solvent coordination underlines the step-growth mechanism of these systems. Under mild conditions (room temperature, 1 bar ethylene), a remarkable productivity was noted with about 10 kg PE per mol palladium, which bodes well for further polymerization tests under industrially relevant conditions (higher temperature and ethylene pressure) as well as for co-polymerization, *e.g.* with polar co-monomers. Time-dependent analysis of the products indicates the initial formation of linear polymers, yet a high degree of branching after prolonged reaction time, indicative of efficient chain walking and β -hydride elimination processes, an attractive property for the production of low-density polyethylene (LDPE). Mechanistic work furthermore provides support for a dual role of NaBARF as (i) an additive for halide abstraction and (ii) as a templating agent *via* coordination to the 1,2-dicarbonyl core of the bis(PYA) ligand. Such metal sequestration may offer opportunities for tailoring the ligand donor properties through remote coordination, an aspect that is currently under further investigation in our laboratories.

Conflicts of interest

The authors declare no competing financial interest.

Data availability

All data pertaining to this manuscript are available as electronic supporting information (SI): synthetic procedures, full characterization of the ligand precursors, Pd complexes, NMR analysis and GC-MS characterization of the catalytic mixtures, crystallographic data and catalytic experiments (pdf). Supplementary information is available. See DOI: <https://doi.org/10.1039/d5cy01102g>.

CCDC 2440549–2440552 contain the supplementary crystallographic data for this paper.^{73a–d}

Acknowledgements

We thank the Crystallography Service of the DCBP for all X-ray analyses and the Swiss National Science Foundation (grant no 200020_212863) for generous financial support of this work.

- Quantitative ¹⁹F NMR analysis (see ref. 29) revealed the presence of 0.75 eq. PF₆ per ligand in 2a and 0.25 eq. PF₆ for 2c.

- 29 Quantitative ^{19}F NMR analysis was performed by adding a drop of 1,2,4,5-tetrafluorobenzene to a pure solution of the analyte. Subsequent comparison of the standard/analyte ratio in ^1H and ^{19}F NMR spectra indicated the number of PF_6 anions per ligand unit. The method was tested against control samples with known number of fluorine nuclei and gave results within classical NMR integration errors. 16 scans and a relaxation delay of 6 s were used to ensure a reliable signal integration (Fig. S1,S2).
- 30 Upon exposing 2c to 2.5 eq. LiHMDS, a species spectroscopically different from 3c was isolated. The chemical shift for the NCH_3 resonance of this species, $\delta_{\text{H}} = 3.86$ lies between the values observed for 2c ($\delta_{\text{H}} = 4.20$) and 3c ($\delta_{\text{H}} = 3.72$, Fig. S17). Additionally, CHN elemental analysis suggested a composition consistent with 3c + $\text{LiPF}_6 + \text{H}_2\text{O}$, while mass spectrometry detected M+Li signals but showed no signal corresponding to M+H (Fig. S18). Quantitative ^{19}F analysis (see ref. 29) indicated 0.9 eq. PF_6 per ligand. Similar data were obtained from the reaction of 2a and 2d with LiHMDS after washing the product with THF, suggesting formation of a LiPF_6 adduct analogous to that observed for 2c.

- 37 Complex 4d displayed two sets of signals even in the presence of excess chloride, most distinctly revealed by the two sets of two different resonances each for the NCH_3 and $\text{C}_{\text{pyr}}\text{-CH}_3$ groups (Fig. S36). These sets were attributed to syn and anti isomers due to hindered rotation about the exocyclic $\text{N}_{\text{PYA}}\text{-C}_{\text{PYR}}$ bond. Upon heating complex 4d to 55 °C in DMSO, one exchange becomes fast on the NMR time scale (attributed to the solvento/chlorido exchange), and at 75 °C, the two remaining sets of signals attributed to the syn/anti rotamers also coalesced (Fig. S35). The energy barrier for this second process was estimated using the Eyring equation (ref 38,39) at $\Delta G^\ddagger = 17.9 \text{ kcal mol}^{-1}$. Notably, in D_2O , only two sets of signals were distinguishable, which was attributed to the rotamers in approximate 3:1 ratio and the absence of the solvento complex (Fig. S37). In both solvents, only the $\text{C}_{\text{pyr}}\text{-CH}_3$ chemical shifts were sufficiently different, which prevented a full assignment of syn vs anti isomers.
